The research project “Wooden slabs in commercial and industrial buildings” has made huge progress since it was started in 2016 [1]. The goal of the research project is to build skeleton structures with flat slabs in timber. Therefore, a biaxial, point supported cross-laminated timber flat slab was developed. As CLT slabs are limited to approximately 20 m length and 3.4 m width a rigid connection is necessary. This key technology, the butt joint bonding of timber, has proven it’s applicability in the last two years. The research team from BFH Biel, ETH Zurich, Timber Structures 3.0, Timbatec, Henkel & Cie., and Schilliger Holz have increased the knowledge about all parts of a biaxial, point supported CLT flat slab. With microscopic analysis the important parameters of the bonded butt joint were revealed and therefore the reliability could be increased. At the same time the implementation of the bonding process into the construction process was improved. Besides the rigid connection of the CLT slabs, transmitting the forces from the slab into the columns is the second crucial part. In 2012 tests at ETH Zurich showed that beech plywood plates can resist high bending moments and shear forces. To lower the cost of construction the same investigations were made with CLT and reinforced CLT plates. This investigation showed that CLT slabs can also withstand high forces. The combination of the gained knowledge led to interesting projects which were accomplished in the last two years.

2. Evolution of timber structures

To explain the actual innovation of this project and the created possibilities in timber construction, we must take a step back. For centuries trunks and beams have been used to build houses. Trees were cut down, branches removed, debarked and sawn to beams and planks to construct buildings. In the 20th century, trees were sawn into boards, dried, planed and glued to glulam or more recently to CLT. With these products a structural beam can be larger, longer and more homogenous than a tree. This development is illustrated in Figures 1 and 2.

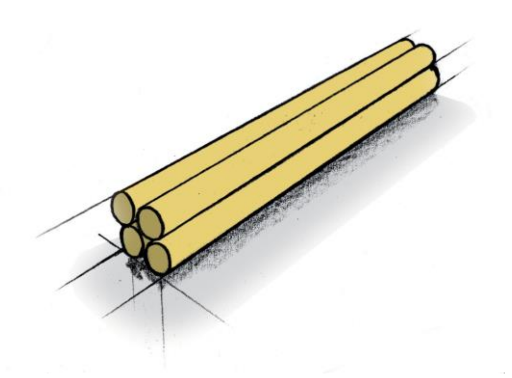

Figure 1. Timber Structures 1.0: Trunks and beams

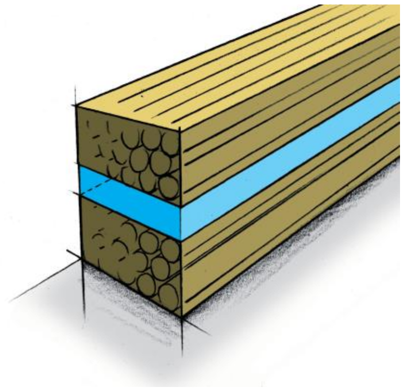

Figure 2. Timber Structures 2.0: Glulam and CLT

The current development illustrated in Figure 3 allows the butt joint bonding of fibres and therefore leads to the 3rd generation in timber construction called Timber Structures 3.0. The rigid connection of several CLT slabs allows new types of timber constructions. Figure 4 shows a multi storey skeleton structure as it is possible to build when several CLT slabs are connected rigidly to a single flat slab.

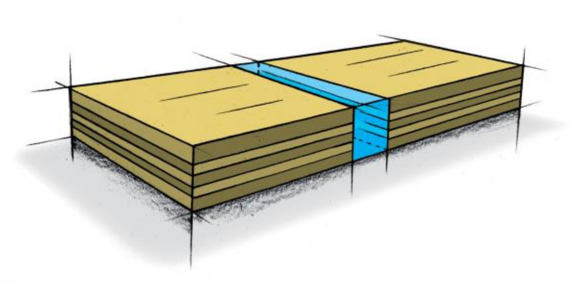

Figure 3. Timber Structures 3.0: Butt joint bonding technology

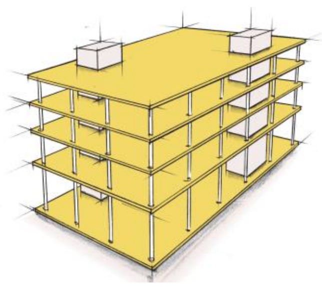

Figure 4. Typical skeleton structure

3. Environmental impact

Replacing building materials with high energy demands for production is a major challenge to achieve a sustainable built environment. Timber constructions have made remarkable progress in the last ten years. In Switzerland, 7.5% of the new built structures were made in timber in 2017. This share almost doubled since 2015. Not only an increased share of buildings is being built in timber, but also the volume of this buildings has increased by 25% over the last 15 years [2]. In the field of residential buildings, timber construction has established itself. In office and business buildings timber construction struggles to provide adequate solutions so far. The here presented technology could increase the current share of only 0.7% of newly built timber office and business buildings per year in Switzerland [2] and replace energy-intensive materials like steel and concrete.

4. Recent research

4.1. Structural system

The structural system shown in Figure 4 is divided into four structural elements. The first element is the rigid connection between the CLT slabs. This connection has to resist bending moments and shear forces. The current status of research is presented in chapter 4.3. The second element is the part of the slab around the column. This element has to lead high shear forces into the column, transfer vertical loads from upper storeys to the next column and at the same time resist high bending moments. The conducted research of this element is presented in the following chapter. The third element is the CLT slab band spanning from column to column. The fourth element is the part of the slab lying between the CLT bands. This element mainly has to resist small biaxial bending moments and therefore does not necessarily have to be a massive timber element such as CLT. Elements three and four are not part of this paper, as they are of lower interest than elements one and two.

4.2. Slab to column connection

Point supported slabs are mostly used for office or industry buildings. For such structures a column grid of 6 - 8 m is required and live loads of 300 - 500 kg/m^2 have to be considered. From this background several scenarios arise with punching loads varying from 380 kN up to 1050 kN. In 2012, Lorenzo Boccadoro tested the punching behaviour of six real scale plates at ETH Zurich [3]. The tested plates had dimensions of 2.5 m by 2.5 m and were 24 cm, 32 cm and 40 cm thick. The plates had a central opening with a diameter of 30 cm. Three of these plates were made of beech plywood and three were made of a combination of beech plywood and spruce boards. The load carrying capacity of all the plates was higher than the required resistance.

To improve the cost efficiency of the flat slab, CLT plates were tested by Marcel Muster in 2017 [4]. CLT plates with dimensions of 2.1 m by 2.1 m, as illustrated in Figure 5, were chosen to be tested. From the elements shown, six specimens were assembled. The basic element was always a six-layered 18 cm thick CLT plate. Two plates consisted of CLT only with opening diameters of 20 cm and 30 cm respectively. On one plate an additional load distribution ring made of beech plywood was placed (Figure 3 bottom left side). Another plate was tested with glued on beech plywood plates on both sides (Figure 3 top right) and finally two plates consisted of both a placed-on load distribution ring and glued on beech plywood plates.

A special feature in the CLT slab is an opening on top of the column as it can be seen in Figure 5. This opening is necessary to lead vertical loads from upper storeys through the slab without subjecting the CLT slab to stresses perpendicular to grain. This necessity on the other hand leads to a great challenge within this research process: at the point where the highest bending moments occur, a part of the slab is missing.

In Figure 6, the load-displacement behaviour of the tested plates is shown. Specimens 1 to 3 did not have any reinforcement plates. Specimen 3 had an additional set on load distribution ring made of beech plywood placed on the hydraulic jack and therefore a higher ultimate load. Specimen 1 with the black dotted line showed early deformations due to the narrow support area which led to a crushing of the timber perpendicular to grain.

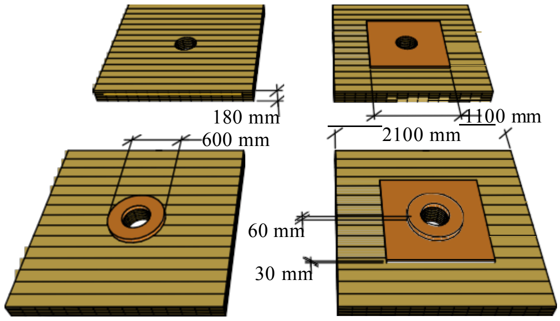

Figure 5. Tested plates

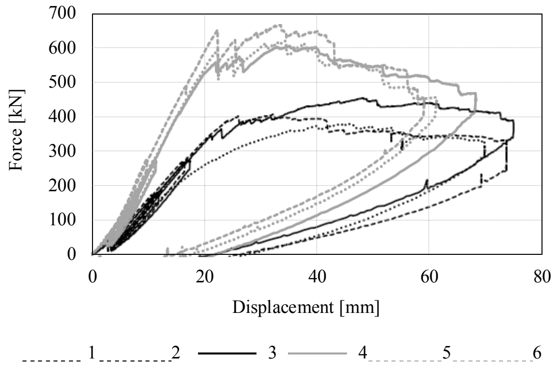

Figure 6. Load-displacement punching tests

The punching tests showed that the chosen slabs are able to transfer high shear forces into the column and can resist high bending moments. With an increase of the thickness of the slab it is also possible to fulfil the requirements defined earlier. In the following table the characteristics of the tested slab, the thickness and the ultimate loads are listed. Specimens F240, F320, F400 were tested by Lorenzo Boccadoro in 2012 [3]. These compositions could be used in situations with higher live loads than 5 kN/m^2.

Table 1. Performed punching tests

Specimen	Ultimate Load	Composition	Opening	Support
1	380 kN	18 cm CLT	D = 30 cm	D = 38 cm
2	408 kN	18 cm CLT	D = 20 cm	D = 40 cm
3	455 kN	18 cm CLT	D = 30 cm	D = 52 cm
4	605 kN	18 cm CLT + 2x3 cm beech plywood	D = 20 cm	D = 40 cm
5	620 kN	18 cm CLT + 2x3 cm beech plywood	D = 30 cm	D = 52 cm
6	666 kN	18 cm CLT + 2x3 cm beech plywood	D = 20 cm	D = 52 cm
F240	1350 kN	24 cm beech plywood	D = 30 cm	D = 55 cm
F320	2257 kN	32 cm beech plywood	D = 30 cm	D = 55 cm
F400	3138 kN	40 cm beech plywood	D = 30 cm	D = 55 cm

4.3. Butt joint bonding

To connect the slab elements rigidly together, various methods were evaluated between 2009 and 2012. Only a bonded butt joint technology can fulfil the broad requirements. So far, no certified adhesive exists on the market for directly bonded butt joints. Purbond AG, part of the Henkel Group, has developed a 2-component polyurethane adhesive which can be used for the required purpose. In the first development stage, various geometries of bonded joints were examined. The simplest geometry to be produced was the butt joint, but also different profiles as v-rabbets and finger joints were examined [5]. In various experimental tests it was studied which thickness of joints could be filled considering different conditions such as different temperatures or joint widths. More than 1’000 tensile tests on lamellas in 24 series have been carried out [[5],[6],[7],[8],[9],[10],[11]]. From these tests, important conditions and requirements for quality assurance were established. Füllemann [6] further examined different influences on building site: minimum joint thickness, temperature, moisture content, soiling with oil or dust, movement and vibrations and different types of pre-treatment of the connecting end-grain faces. Lehmann [11] finally determined by seven series of tests with totally over 250 test specimens statistically reliable strength values for the tensile and bending strength of a bonded butt joint in CLT plates. The tests allowed further a better understanding of the influence of moisture changes and the effects of long-term stresses on the bending strength of the bonded butt joint. The bending strength was determined in four-point bending tests illustrated in Figure 7 with variations of the thickness of CLT, wood moisture and load duration applied with springs as shown in Figure 8.

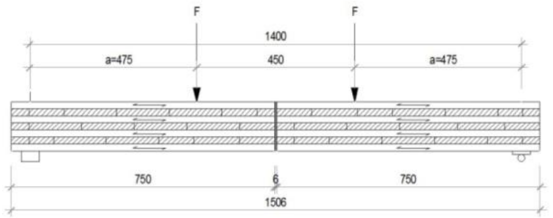

Figure 7. Four-point bending tests on butt joint bonded CLT-beams.

Figure 8. Long-term bending tests on butt joint bonded CLT-beams.

The results of this study showed a consistent good quality of the bonded butt joint. Through this progress, characteristic bending strengths from 15.6 N/mm^2 to 20.7 N/mm^2 were achieved depending on the wood moisture content and the load duration. These values were higher than all strength values reached before.

To reduce the appearance of bubbles in the glue line different techniques were tested most recently [12]. On the one hand, the roughness of the surface seemed to have an influence which was controlled by sanding the surface. On the other hand, different methods to seal the grains were developed and tested. Tensile strength test results showed that there was a considerable increase of mean tensile strength when combining sanding with roughness P 100 and applying a pre-treatment to the of end-grain surface. By sanding the end-grain surface, the intensity of bubbles occurred was reduced to a maximum of 10% of the complete fracture surface area. Latest results of tensile strength tests on butt joint bonded boards with improved adhesive formulation show a characteristic tensile strength higher than 15 N/mm^2. As tensile tests always show lower values than bending tests, an increase in bending strength can be expected. Specimens of this series show partly ripped out wood fibres. To examine that, broken specimens were rejoined with fluorescent PVAC adhesive and examined under the UV-light microscope. This is shown in Figure 9 [12]. The actual rupture line is visible through the fluorescent PVAC adhesive and the numbers indicate ripped out fibres (1), adhesive (2) and wood (3).

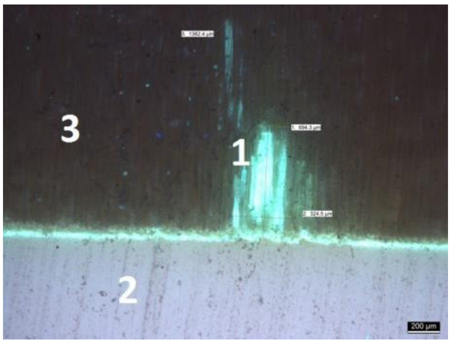

Figure 9. UV-light microscopy picture of broken and rejoined tensile specimen

As research is continuing, even higher strengths of the butt joint bonding are expected. Further research is also done in the process of how to implement the TS3 system the most economical way, meaning e.g. the conservation of the pre-treated surface and on-site construction processes. As in timber structures often serviceability or in other words deformation and vibration are governing a design, the achieved bending strength of the bonded butt joint are already sufficient to build biaxial, point supported flat slabs with a column grid up to 8 m by 8 m.

5. Proof of concept

In the last two years several projects were built with the bonded butt joint technology. In the following, three selected projects are presented.

5.1. Real scale, long term test ETH Zurich

The first real scale structure with a bonded butt joint was built at ETH Zurich in April 2017. Four 26 cm thick and 3 m by 3 m large CLT plates were glued together creating a corner supported 6 m by 6 m slab. The slab was subjected to a distributed load of total 96 kN representing a permanent load in an office building. A roof protected the slab from heavy rain. Since 2017 the slab has been exposed to moisture and temperature changes and also rain, as the roof was leaking several times. Nevertheless the slab showed no signs of weakness. Deformation measurements showed a creep factor of 1.3 after one and a half years. The slab was disassembled in April 2019 and will be reassembled at another place to continue the long-term experiment.

Figure 10. Real scale, long term test at ETH Zurich

5.2. Working platform Wangen b. Duebendorf

In spring 2017 the timber construction company Flueck Holzbau decided to build a new working platform in their factory. The platform was assembled out of three 13 m by 2.5 m large and 36 cm thick CLT slabs glued together along the long side. The slab is line supported on both sides over the 13 m. The slab is designed to withstand distributed loads up to 500 kg/m^2. To reinforce the slab and to avoid large deflections 14 steel bars were inserted into the slab and later post-tensioned. Three load cells were installed to monitor the behaviour of the post-tensioning.

Figure 11. Working plattform in use

Figure 12. Post-tensioned working plat-tform

5.3. Residential buildings Grossaffoltern

Four three storey residential buildings were built close to Biel in the second half of 2018. The floor plans are 12 m by 7 m rectangles with surrounding line supports and three, respectively four (in the left apartment of Figure 14) columns aligned in the centre of the slab. The flat slabs were built out of three and four 16 cm thick and 12 m by 2.5 m large CLT slabs glued together at the long sides.

Figure 13. Residential building

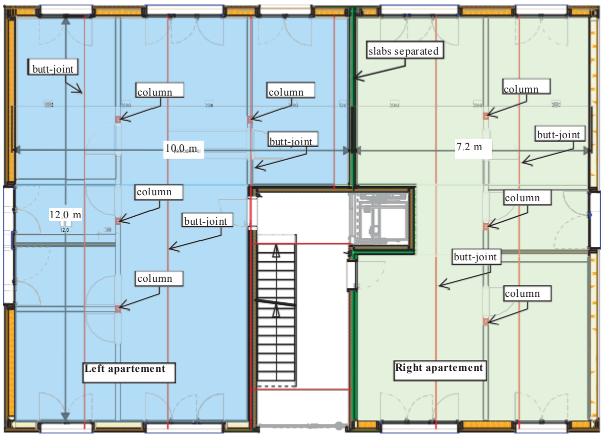

Figure 14. Layout of the CLT slabs

To validate the structural design of the biaxial, point supported slab ETH Zurich performed vibration measurements at different stages of construction. This measurements will help to op- timize future projects.

6. Outlook

The research about the slab to column connection is mostly finished. The next step will be the combination of the design guidelines to provide engineers a reliable and user-friendly design approach. To this design approach a guidance on improving the robustness of the CLT flat slab will be added as soon as the research about this topic is completed. The research about the bonded butt joint is continuing as there is still potential to increase both bending and tensile strength. Besides that, the research team is working on a European Technical Assessment (ETA) for the butt joint bonding.

7. Acknowledgement

The project is a collaboration of Timbatec AG, Timber Structures 3.0 AG, Schilliger Holz AG, Henkel & Cie. AG, ETH Zurich and BFH Biel. Gratefully acknowledged by the authors is the intense cooperation among the partners of this project, as well as Innosuisse, which is funding the ongoing project in large part.

Abstract. The demand for technical and verified documentation of buildings and building materials is growing, along with the increasing focus on sustainability in the built environment. However, despite a common wish to build sustainably, it is still found that EPDs and LCAs are not always similarly interpreted, leading to misunderstandings on how they should be used to quantify and verify sustainability along with being a competitive parameter when choosing materials.
To overcome this barrier this project seeks to discover:

1. How can EPDs be used as a competitive parameter within the sustainable built environment?
2. How can product specific EPDs, used as an input to building-level LCAs, help to quantify the concept of 'circular economy'?
3. How do some countries seem to succeed in introducing EPDs to industry while others only succeed to a lesser extent?

By involving the Danish building-industry's value-chain through qualitative interviews, workshops and reference groups, as well as by contacting EPD programme operators throughout Europe and USA, a mapping has been performed on the tendencies of how and to what extend EPDs are used to quantify and support material decision-making in buildings. Further, the drivers as to why EPDs are used in some countries is investigated along with suggestions on how to boost the development, use and integration of EPDs with the aim of quantifying and documenting sustainability in the built environment.

1. Introduction

Due to an increasing demand for sustainability in the built environment a natural need for documentation and transparency has evolved – both globally and locally in Denmark [1,2]. In Denmark, while the construction industry is actively seeking a development towards increased sustainability, authorities and the regulatory system are lagging behind and fail to provide a structured, holistic approach to this transition. Therefore, a part of the industry is starting to come up with various individual initiatives and strategies on how to move forward [3,4].

A Danish report from 2017: "Roadmap 2030 – Bygningers rolle I den grønne omstilling" [3] (which roughly translates into: Roadmap 2030 – The role of buildings in the green transition) touches on several matters and suggestions for actions to be taken within e.g. energy consumption, indoor climate and environmental aspects. Being managed by a Danish innovation network for sustainable construction, InnoBYG, the project included a broad variety of stakeholders within the built environment, covering NGOs, universities, consultants, engineers, architects etc.
One of the recommendations made within the environmental considerations was to improve and strengthen the documentation of materials and their impact on building environmental sustainability by performing Life Cycle Assessments (LCAs) that are based on the principles for Environmental Product Declarations (EPDs), and thus measuring embodied energy and environmental impacts. Additionally, they suggest an implementation of a voluntary sustainability classification system within the building regulations of Denmark.

However, despite a common wish to build sustainable, it is still found that EPDs and the underlying LCAs are not always similarly interpreted, leading to misunderstandings on how they should be used to quantify and verify sustainability along with being a competitive parameter when choosing materials.

In Denmark, while the interest in EPDs is rapidly increasing, as well as the number of new EPDs published every year, the total number of EPDs developed and verified so far at the Danish EPD Programme Operator (EPD Danmark) is still clearly in the low end, compared to other European and American EPD Programme Operators. Considering the infographic by Jane Anderson [5], see Figure 1, it is seen that the 'dominating' EPD programmes can be found in Germany, USA, France, Sweden and Norway, i.e. many of the neighbouring countries of Denmark. It is uncertain why this difference occurs.

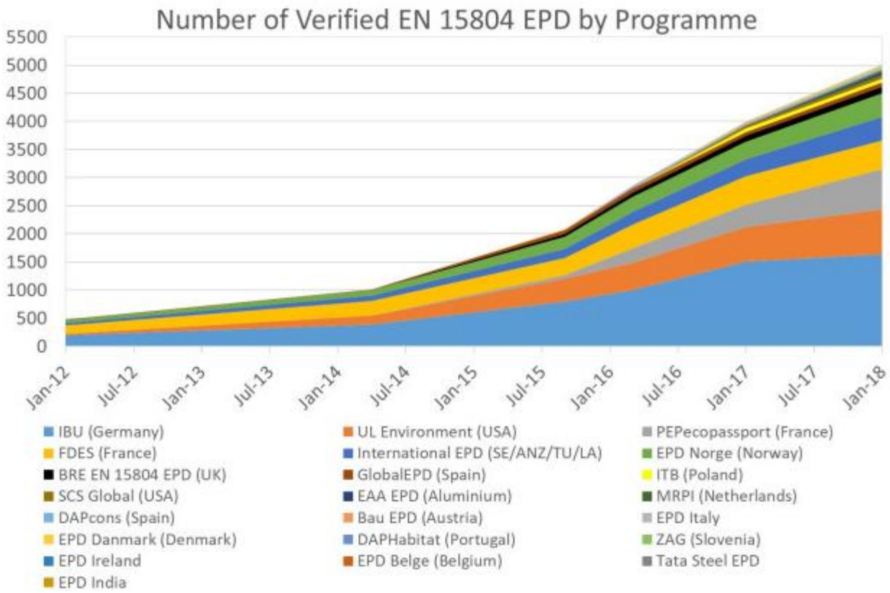

Figure 1. Infographic, showing the numbers of verified EPDs for construction products which align to EN15804 from 2012-2018. Reprinted by permission of Jane Anderson, ConstructionLCA Ltd.

This project aims at defining a consensus for the use and usability of EPDs and their underlying LCAs by gathering knowledge from the industry and provide real-life and practical examples of Danish value-chain stakeholders of the construction industry. Additionally, it is investigated why EPDs seem to be used to a greater extend in some countries and how this has occurred.
The three main questions worked with are thus:
1. How can EPDs be used as a competitive parameter within the sustainable built environment?

2. How can product specific EPDs, used as an input to building level LCAs, help to quantify the concept of ‘circular economy’?
3. How do some countries seem to succeed in introducing EPDs to industry while others only succeed to a lesser extent?

1.1. Literature

The main focus of the project was to investigate how EPDs are used by the Danish construction industry and value chain, through inclusion of stakeholders. However, to define a starting point of the study, a preliminary literature study was performed. The results are shown below.

A study considering some of the aspects in question was done by the Green Building Council in Iceland (IGBC) and a Nordic project group, consisting of Norway, Sweden, Iceland and Finland [6]. The project conducted two surveys, representing stakeholder groups of respectively building owners/consultants/contractors and producers/providers of building products, in the summer of 2015. The report points at the lack of market demand as one of the main obstacles for the use of EPDs. The study found that the first group of respondents (building owners, consultants and contractors) did want fairly more information on environmental impacts of building materials. Other obstacles, beside lack of market demands, were pointed out, such as lack of knowledge about the documentation, high costs and lack of synchronisation of EPDs. This is agreed upon, when considering the second group of respondents in the study by IGBC (material manufacturers).

Ibáñez-Forés et al. (2016) [7] who investigated the barriers towards use and implementation of EPDs in the construction industry, confirmed the findings of the above study by IGBC. Identified barriers included a general lack of knowledge about EPD programs and content of EPDs, the cost of developing the LCA (i.e. the basis for the EPD), lack of international standardisation, and the fact that the content of EPDs can be hard to read for non-specialists [7]. Among the advantages mentioned by Ibáñez-Forés et al. (2016) are the possibility for manufacturers to communicate verified environmental information objectively, thereby also proving their interest in transparency, improve their corporate image, and achieving better knowledge of production processes [7,8]. The latter was additionally observed through the fact that 90% of the manufacturers having an EPD of their product were also enrolled in a voluntary environmental management system [7].

Similar incentives were identified by Passer et al. (2015) [9]. The main advantage identified by the authors was that EPDs are recognised as a feasible format for communication of environmental claims, requirements and demands, facilitating their export market development [9].

In general, main drivers for EPDs have in several studies/mappings been mentioned to be building certification schemes [6,8–11], e.g. HQE, Green Star, LEED, BREEAM and DGNB, being some of the most well-known and applied schemes – some of them having national editions to allow for country-specific aspects to be taken into account.
Many of these certification systems have included either direct (EPD) or indirect (building-LCA) requirements in their guidelines and criteria [8], for example:

- LEED has criteria within their ‘Materials & Resources’ category, that assign credits when applying LCA to prove building life-cycle impact reductions and when using materials which hold an EPD [12].
- BREEAM also allocates credits for criteria about life cycle impacts through the use of LCA and EPDs in the materials section. However, the weighting differs across national editions of the certification scheme, e.g. considering the international, UK and Norwegian editions [13–15].
- DGNB has national editions in some countries, thus the specific criteria may differ from country to country. The Danish version of DGNB contains criteria for both inclusion of EPDs and LCA, weighting respectively 1,5% and 13,5% (considering LCA for both environmental impact

categories and primary energy, representing respectively 7,9% and 5,6%) of the total score [16]. Considering the German DGNB, 'only' LCAs are credited, weighting 9,5% of the total score [17].

Other incentives to develop EPDs mentioned by the literature are Green Public Procurement (GPPs) plans, which are voluntary tools that aim at stimulating the market demand for 'greener decisions' [18]. The voluntary EU-GPP for '*Office Building Design, Construction and* Management' [19], prescribes mandatory LCA-based criteria [18] which can be based on EPDs of main building elements. However, as mentioned in Ibáñez-Forés et al. (2016), the incentives from governmental instances are quite low [7].

A study performed in 2015 by Passer et al. [9] reviewed and discussed the experiences with EPDs in European countries in the past 5-10 years. The review was based on an EPD workshop which was held prior to SB13 Graz conference and reviews the European status of the use and application of EPDs. Alongside a list of current (as per 2015) EPD programmes, authors looked into what is done specifically in five European countries (Austria, Belgium, Germany, France and Switzerland – however the latter not having an official EPD programme) and how EPDs are used, developed and applied. While all five countries follow the European standard for EPDs EN15804 as well as ISO14025, some of them have additional requirements and legislations, incentivising the use of EPDs. An example is Belgium, where the Royal Decree on Environmental Messages [20] imposes modules A4, C and D as obligatory as of 2017 [9], in addition to those already prescribed by EN15804 (A1-A3). In France, the EPD programme (INIES) combines Environmental and Health product declaration (EHPD, in French FDES) [9]. Additionally, the French national appendix for EN15804 set up requirements to include toxicity and ecotoxicity along with sanitary and comfort requirements, in order to conform with existing national requirements/standards. As of 2014 a further decree prescribes that manufacturers wishing to make environmental claims about their product need to support their claims through a cradle-to-grave EPD [9].

According to Sariola and Ilomäki (2016) [21], the Finnish EPD programme (RTS EPD) has set out additional requirements to the included LCA modules for an EPD, namely that modules A4, C1-C4 and D need to be included [21].

1.2. EPDs in Denmark

The programme operator for EPDs in Denmark is EPD Danmark. Currently there are more than 30 EPDs registered, covering 80+ products.

While the largest incentive for EPDs in Denmark is building certification, and specifically the Danish version of the German building certification scheme, DGNB, other incentives are actions from public instances, such as municipalities (e.g. Aalborg [22] and Copenhagen [23]) or partnerships where various public instances commits to follow a Green Public Procurement having outlined a Green purchasing method.

While Denmark does not have any direct requirements or legislation about the use of LCA and EPDs, the construction sector is willing to improve and drive sustainability further. One of the initiatives is a voluntary add-on to the Danish building code, to classify buildings according to their overall sustainability level [4]. The system, which has been proposed and recommended by the construction industry itself, does not have a clearly defined format yet. However, one of the suggested parameters is the development of building LCAs, which should preferably be based on EPDs.

2. Method

Apart from the preliminary literature study, the project aimed to seek answers through stakeholders and implementation of real-life practice. This has been done through qualitative interviews, workshops and meetings with a reference group. Furthermore, the aspect of discovering as to why other programme operators seem to meet a greater demand for EPDs than experienced in Denmark, the project group has interviewed EPD programme operators throughout Europe and USA, certification bodies and Danish consultancy companies working internationally.

2.1. Qualitative interviews

The qualitative interviews where performed by setting up a list of questions specific for each interviewed group along the value-chain: consultants (architects and engineers), contractors, builders, manufacturers, public authorities and technical organisations (i.e. programme operators and certification bodies).

Due to the natural focus of the project on the building materials and competitivity effects as a consequence of the use of EPDs, the main group of interviewees were found within the manufacturers of building materials, as illustrated in Figure 2.

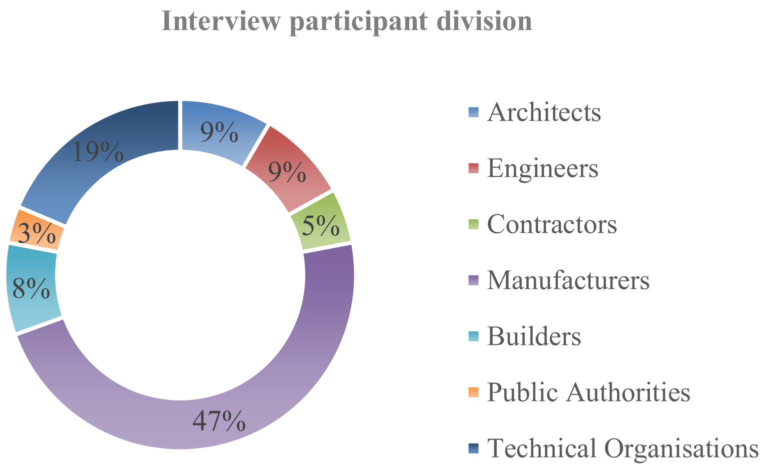

Figure 2. Interview participant division

The method was not strictly scientific, due to a limited number of participants (~60), however it does give an indication of the obstacles and opinions about EPDs and constitute a valuable starting point for further discussion at workshops.

2.2. Workshops

Throughout the project period, two workshops were held, where the building industry was invited across the value-chain. The topics of the workshops were respectively:

- EPDs as a competitive parameter
- Circularity in the built environment and documentation (with a focus on whether and how EPDs might be used)

As the invitation for the workshops were public, a broad spectre of participants showed up to discuss the given topic – some of them had previous experience with EPDs and some were new to the topic, wanting to expand their knowledge.

The workshops were used to discuss and analyse the qualitative interviews, extrapolate common tendencies, and investigate the underlying hypotheses. Additionally, guest-speakers provided their perspectives to the questions asked and gave input for further discussion to qualify the output.

2.3. Reference groups
Reference groups were used to provide opinions and guidelines to the questions asked in the project, along with supporting development of, and discussing, preliminary results before their publication.

2.4. Format of results
The main project outcome was a booklet of real-life examples (published in spring 2019 by EPD Danmark) referring to the Danish construction sector, explaining how and why EPDs should be used.

The results in this project cannot be divided into results found from one of the individual investigation methods, as the discussions were iterative and summed up all thoughts and angles found throughout. The results (which correspond to the content of the booklet) are presented in the following section, including the identified tendencies and a discussion on how to improve the understanding and increase the use of EPDs as a documentation for environmental sustainability in the built environment.

3. Results & Discussion

As the project put up three main questions to be investigated, the results are presented coherently. However, as mentioned earlier, the answers and conclusions mix, which is why the discussions will overlap in between the project questions.

3.1. EPDs as a competitive parameter
An initially observed tendency showed that many stakeholders throughout the value-chain of the Danish construction industry did not find EPDs to be a competitive parameter. However, when putting up a hypothesis on this initial finding, arguments against this were made, summing up the value of getting an EPD depends on the definitions of value.

When added value and increase in competitiveness was defined as a 10% increase in the producers' customers portfolio, it was a common conclusion that EPDs could not be considered to have *direct* value. However, several stakeholders recognised the value of having EPDs when considering:

- The knowledge obtained by the manufacturer about a product, when utilising the LCA lying behind an EPD.
- The willingness from the manufacturer's side to be transparent about their products and processes, and their impacts on the environment.

Other mentioned that the value and ability to use an EPD as a competitive factor was dependent on the type of customer for the specific product. There was broad agreement about the fact that EPDs are not highly rated by general customers as much as other parameters, such as price, aesthetics and durability. However, if aiming to sell and distribute materials and products for larger construction projects (e.g. tenders from public authorities and large investment companies), there was a clear increase in the demand for documentation – especially for sustainability claims.

This again supports the perception that EPDs themselves are not the 'value', however the knowledge obtained about the product, through an LCA, and the willingness to be transparent about the product were. The EPD is thus 'only' the document that sums up the facts.
Thus, an EPD cannot provide value to the 'unknowing' and 'unenlightened' customers, as they do not have the tools to utilise the potential behind the EPD.

However, even though arguments in favour of EPDs and their possibilities appeared, there is still a cold fact that only front-runners have, and use, the EPDs. Recurring reasons for this were identified as the cost of developing an EPD, lack of a requesting market when looking at tenders and a general lack of knowledge.

While the cost of getting an EPD might not be easy to reduce, due to the elaborate work going into developing the LCA at its basis (even though recent development within digitalisation and automation might shift this), issues about lack of demand and knowledge can be offset – and this might in the end also affect the cost of developing EPDs.

At current, the main, and virtually the only, driver for EPDs is building certification schemes. This lack of demand often leads to the industry pointing fingers at each other. The manufacturers keep repeating that they do not see a reason for getting EPDs for their products if the builders do not request them in e.g. tenders. On the other hand, builders say they cannot see a reason for demanding them, as there are not enough EPDs to accommodate this demand in tenders. Thus, there is a need for all stakeholders in the building industry to move simultaneously, as they all demand sustainability, but no-one appears to really move. Some stakeholders also point to the authorities when discussing who needs to make the move. This can be either authorities themselves, who put out requirements in their own tenders (as they often own large projects), or to legislate on the industry, e.g. the previously mentioned sustainability classification that the Danish construction industry suggested to be introduced in the Danish construction code, similar to the existing (and successful) operational energy classification regulations. Future implementation of the 7th basic requirement (BRCW7) of the Construction Products Regulation (CPR) regarding sustainable use of resources and related to the CE marking and Declaration of Performance (DoP) may increase the demand for LCA data on building products substantially.

Considering the lack of knowledge about EPDs and implied also the view on cost of EPDs, there is a clear need for more and better information about the groundwork, e.g. guidance on how to read an EPD or a general informative campaign on the added value gained through the LCA, which is the backbone of the ‘bought’ EPD.

3.2. EPDs as input to quantifying ‘Circular economy’

The increasing focus on resources and ‘circular economy’ in Denmark [24] has led to initiating a discussion on how to quantify these concepts and the potential of using EPDs for this purpose.

While there was a general consensus about that fact that EPDs do not provide any specific information about circular economy, several participants throughout the project mentioned that EPDs might be used in building-level LCAs. This could have a significant effect with respect to circular economy, if the EPDs include the LCA phases about End of Life (EoL, C1-C4) and potential for Recycling (D). These phases may enable a verified and quantified knowledge about EoL and resource management.

A recurring issue was however how to define the LCA phases C and D. While the intentions (increased documentation and transparent quantification) are seen as positive, several stakeholders, throughout the project, questioned the assumptions for EoL and recycling potential scenarios and the accuracy of the relevant data.

Well aware that this issue is part of a broader discussion throughout the industry and also the LCA communities (researchers, practitioners), the project group and the stakeholders recognised that we have at the current state little or no knowledge at all on how we will handle building demolition in 50-100 years (if not even longer) and how materials will be treated. It is therefore only possible to base the LCA phases C and D on today’s know-how and practice, which is a significant limitation. It is difficult to say whether this will hold true, however we reasonably expect that today’s ‘standards’ will be conservative compared to what will be possible in the future. In general, there was common agreement, that documenting something and making necessary assumptions, although uncertain is better than ignoring these phases. In the coming revised version of EN 15804 (expected to come into force this summer, 2019) the inclusion of the phases C and D is mandatory (due to adaption to the EC PEF scheme, i.e. EU Single Market for Green Products).

The discussion focused also on the current practice for modelling EoL and regulatory challenges regarding waste handling were pointed out, calling out for authorities to take actions and lead the industry. Considering clear differences in e.g. cost of landfilling vs. recycling/reuse, regional waste management fees and the fact that manpower for selective demolition and proper dismantling for recycling is more expensive than new materials, the incentives to 'choose circular' are not necessarily supported, according to the Danish construction industry.

3.3. Use and demand of EPDs outside Danish borders

One of the research questions driving the project was why the amount of EPDs registered and used in Denmark was significantly lower than in neighbouring countries. An important consideration, which represents part of the answer, was made by several manufacturers. While they acknowledged that not many EPDs are registered by EPD Danmark, the Danish EPD Programme operator, compared to other countries, more EPDs exist from Danish manufacturers. For various reason these may just not be registered at EPD Danmark – some argue due to a large export market for which reason they've placed their EPDs where their buyers are, other already worked with environmental documentation even before EPD Danmark was established in 2014, for which reason their EPD is placed with other programme operators.

The lack of registered EPDs by EPD Danmark might thus support the argument discussed earlier, about a lack of incentive driven by a demand in the Danish construction industry, whereas countries like Germany, Norway and the UK have had better success in creating incentive – e.g. public procurement, regulation, building certification schemes and knowledge and requirements of documentation about environmental claims.

4. Conclusion and recommendations

The current project investigated the conditions for and the use of EPDs within the Danish construction industry. The project results confirm that most conditions and obstacles found in studies conducted between 2015 and 2018 still account as barriers. The most dominating ones include lack of demand from the authorities and builders, expenses for the LCA/EPD and lack of knowledge about how to document sustainability in the built environment. These barriers need to be addressed in order to strengthen the competitive power of EPDs within the Danish building sector.

Funding

This project has been supported by two Danish foundations: Grundejernes Investeringsfond and Bolig-fonden Kuben.

Acknowledgements

The project has been helped by contributors throughout the Danish construction industry and EPD programme operators throughout Europe and the US, by allocating time for interviews, workshops and conferences.

Roles of the reference service life (RSL) of buildings and the RSL of building components in the environmental impacts of buildings

Abstract. The Life Cycle Assessment of a building is a complex analysis that also involves the use of the predicted Reference Service Life (RSL) of the building components and materials, as well as the predicted RSL of the whole building. The RSL values of individual materials and building components can be obtained from different sources and are not exactly comparable. In the present study, the influence of selected RLS values on an LCA assessment was evaluated. Three different RSL databases were used as the sources of the data to estimate the environmental impacts of selected building components (internal wooden door and external finishing coat). Two scenarios were presented. In the first scenario a building component can be reused in another building, while in the second scenario the reuse of the building component is not possible. The study showed that dependent on the selected RSL database, the results can differ by up to a factor of five. Therefore, it is very important to describe clearly the maintenance scenarios for a building in order to have a reliable comparison of the results of LCA assessments.

1. Introduction

It is estimated that buildings account for 30–40% of energy use and greenhouse-gas emissions [1,2]. The EU has been focusing on reducing energy use and, consequently, the environmental impact of the use phase of buildings. As a result of these measures, the ratio between energy use and the embodied energy of a building and its components has drastically changed: the embodied energy of the building has become more significant [3]. Therefore, it is important to assess the environmental impacts during the whole life cycle of a building, including the phases of producing the materials and components, the process of constructing the building, the operation and the decomposition. A Life Cycle Assessment (LCA) is a method used to evaluate the potential environmental impacts during the whole life cycle of a product and this method is also increasingly being used to evaluate the environmental impacts of complex products, such as buildings. The methodology is outlined in the ISO 14040 series of standards [4].

LCA studies consider the service life of the building and its components; therefore, their lifetimes need to be known as a reference service life (RSL). The building's RSL is defined as the period during which a building is in use. The building itself, however, has a very long RSL, usually longer than the individual components. In addition, the RSL of the component can vary greatly from one component to another. But the most important point is that the RSL values for the same buildings or components can vary depending on the database they originate from [5].

The RSL of a building component is influenced by many parameters, among them the indoor and outdoor environments, the predicted maintenance, the design of the product, etc. [6–8]. Different approaches can be used to estimate the RSL of a building's component and the building itself. In the study of Grant et al. [7] three main approaches to predict the RSL of a component were identified.

- First, the principles of structural engineering can be used to estimate the structural integrity and the fatigue of materials in accordance with the physical loading, the ongoing chemical reactions, and the degradation over time.
- Secondly, the factor method offers different factors that are used to modify the reference service life of a component (RSLC) to calculate an estimated service life of the component (ESLC). The method is declared in ISO Standard 15686-1 and includes factors for the quality of components (factor A), the design level (factor B), the work-execution level (factor C), the indoor environment (factor D), the outdoor environment (factor E), the in-use conditions (factor F), and the maintenance level (factor G):
-

  ESLC = RSLC × Factor A × Factor B × Factor C × Factor D × Factor E × Factor F × Factor G

- The third option is the use of empirical data. This method is seen as very accurate, but at the same time the acquisition of empirical data is very costly and time consuming.

The RSL of a component that is determined using one of the above-described methods can be acquired from different sources [9]:

- individual EPDs (cradle to gate, or cradle to grave);
- client requirements and current practices;
- product and component manufacturers' information;
- existing applicable standards such as ISO 15686-1, -2, -7 and -8;
- conventional service life in a national context or within an LCA software package for buildings.

There are also other sources that can be used to determine the RSL of building components and products:

- publicly available, national or commercial databases;
- research-group publications and initiatives;
- scientific publications.

The Eeb Guide states that in an LCA analysis the RSL of the component has an influence on several aspects of the life cycle of the building [9]. The RSL of the building influences the length of the use phase and thereby the impacts connected with the operational energy and water use as well as the maintenance. A lot of LCA studies are not paying enough attention to the maintenance scenarios of building components, although according to EN 15978, which divides the life cycle of the building into different stages (Fig. 1), various maintenance scenarios should be included in the life cycle of the building, i.e., B2 - maintenance; B3 - repair; B4 - refurbishment and B5 - replacement. According to EN 15978 the module B2- maintenance applies to planned actions and should include preventive and regular maintenance operations as well as cleaning operations. Maintenance scenarios should be provided along with a product's RSL according to EN 15804. The scenario B3 - repair encompasses all the actions, including corrective, responsive or reactive treatments of a construction product and the replacement of a broken component or part because of damage (replacement of a whole element should be assigned to B4 - replacement). B4 - replacement covers the replacement of a complete construction element [EN 15804], including the impacts on the production and installation of a new (and identical) construction element. The B5 - refurbishment module is applied when the connected actions of modules B2, B3 and B4, for a significant part of the building or a whole section of the building, are carried out.

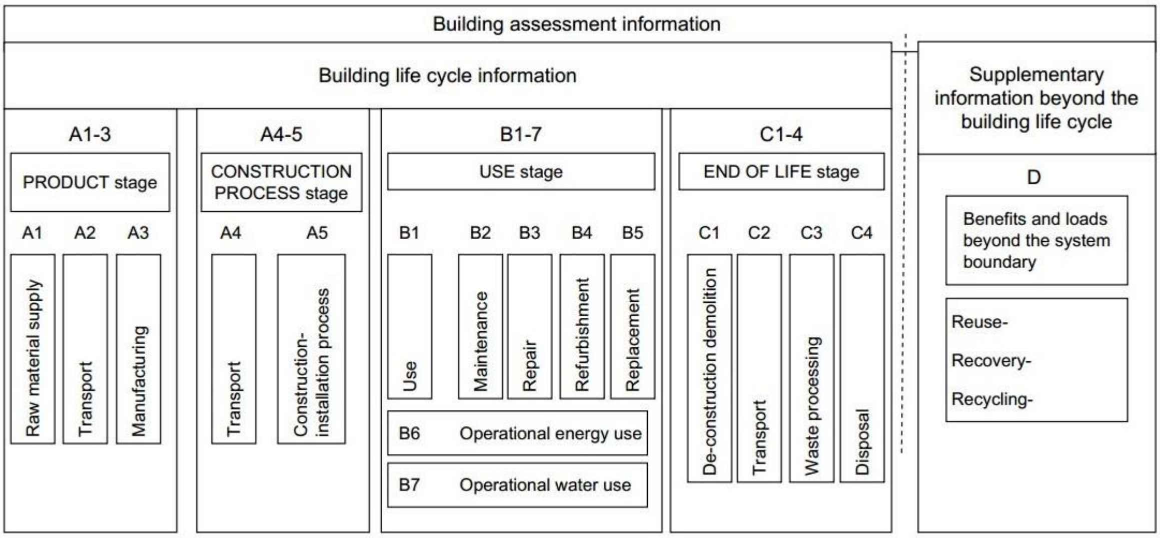

Figure 1. Building's LCA stages according to EN 15978.

A building's RSL has a significant influence on the LCA results related to the use stage of the building. Firstly, the RSL of the whole building influences the energy use of the building. In the case of a long RSL for a building, the amount of energy needed to operate the building can be much higher than in the case of a shorter RSL (modules B6 and B7). Secondly, the RSL of a building influences the results for the energy needed to maintain the building, since it affects the maintenance and the number of replacements of individual components (modules B2, B3, B4 and B5). And vice versa, the lengths of the RSLs of the components affect the number of their replacements over the entire lifetime of the building. However, it often happens that the end of the RSL of a building and the end of the RSL of the last replacement of the component under consideration do not coincide. If the RSL of the component exceeds the RSL of the building and if the component is still intact, it can be reused in another building (Figure 2). In this case the environmental impact of this last replacement can be divided between the life cycle of the first and the second buildings.

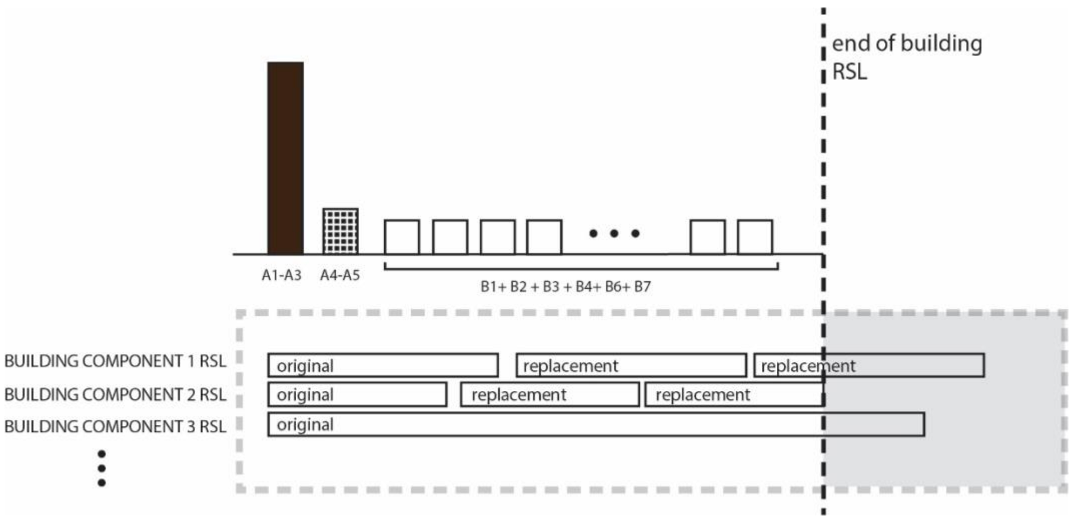

Figure 2. Residual RSLs of individual building components after the end of the building's RSL (marked grey)

Grant et al. [6,7] showed that LCA studies are not using uniform RSL values for the calculation of environmental impacts. They demonstrated that different predictions for the RSLs of building components and maintenance scenarios directly influence the environmental impacts of a building with an RSL of 50 years. In their study they compared the impact of the replacement phase for different building components in five RSL databases that are mainly present in the US market. The results can vary from 4 % to 25 % depending on the impact category. For an easier comparison of LCA studies it is very important that appropriate data about the use stage of the building's components and materials is provided, including information about their service lives and the maintenance scenarios. The RSL values of the building's components should be provided along with a maintenance scenario, as required by EN 15804. The LCA analysis should also take into account the decline in the performance of the building's products and components because this also has an influence on other aspects of the use stage (e.g., a lower performance of the heating system could result in a higher energy consumption), but this is almost never performed in practice.

The aim of the presented study is to show the role and importance of the length of the RSL of a building and its individual components in the calculation of the environmental impacts of the building. In the first part of the study the sources of the RSL values from different EU countries are described and compared. The study shows whether the RSL data is acquired from a standard or from legislation or is determined by the national method for LCA. In the second part of the study a comparison between the RSLs taken from three databases for buildings and building components is made, with the aim to clarify to what extent different RSL values in two scenarios of a possible product's reuse can influence the results of an LCA study.

2. RSLs of buildings and building components

2.1 RSL regulations in European countries

In order to carry out LCA studies, EU countries use data sources of various origins for determining the RSLs for buildings and their components. In general, the countries have developed their own databases, which are often based on the current standards, such as ISO 15686 or SIA 2032. The RSL values in Austria, for instance, are obtained from a document that is issued by the government; in Switzerland there is a standard, while the RSL in Slovenia is determined by legislation. In the case of Belgium and the Czech Republic the RSL database is included in the national LCA method.

Table 1 presents the sources of the RSLs for building materials and components in some European countries. The listed databases are mainly used for LCA calculations; although some can also be helpful for other analytical procedures (e.g., life cycle cost analysis).

Table 1. RSL regulation in European countries

Country	RSL Source for building components	Standard, legislation or part of the national assessment method	RSL of the building defined in relation to the main structural material	RSL of the building defined in relation to the building's use
Austria	Nutzungsdauerkatalog baulicher Anlagen und Anlagenteile 2012 [10]	Legislation	no	no
Belgium	Durées de vie dans MMG2017/TOTEM [11]	National assessment method	yes	no

Czech	SBToolCZE [12]	National assessment method	yes	no
Germany	Nutzungsdauern von Bauteilen für Lebenszyklusanalysen nach Bewertungssystem Nachhaltiges Bauen (BNB) [13]	National assessment method	no	no
Slovenia	Pravilnik o standardih vzdrževanja stanovanjskih stavb in stanovanj [14]	Legislation	yes	no
Spain	Documento Básico SE Seguridad structural [15]	Legislation	no	no
Switzerland	SIA 2032 [16]	Standard	no	no

Table 1 also provides information about whether there is a link between the RSL of a building according to its main construction material (fourth column) and between the RSL of a building and the use of the building (the last column). To illustrate this, the RSL value of wooden buildings in Slovenia is for 50 years, while this data for masonry buildings is for 90 years. It is clear that in the above-listed databases there is no distinction whatsoever between the RSLs of buildings according to their use (last column). Nevertheless, there are certain building-certification schemes, for instance DGNB, where the RSLs of buildings depend on the building type (e.g., office building, residential building) [10].

When calculating the environmental impacts, it is essential to differentiate between the building components that can be further reused in the same form either in the renovation of the same building or can be used in a second building and the building components that cannot be further used, although they have not reached their full RSL at the time of the building's demolition (Fig.2). For example, if a roof tile is still functional, it can easily be reused on a second building. On the other hand, it is impossible to reuse external wall finishes, even if they have not reached the full RSL at the time of the building's demolition. In the first case the environmental impacts can be divided between the two buildings, and in the second case the whole burden is assigned to only one building.

Table 2, below, shows the RSL data for building components from Slovenian's legislation, the Austrian catalogue (Nutzungsdaurekatalog) and the European Organisation for Technical Assessment (EOTA) technical guidelines.

Table 2. RSL for the building components of Slovenia, Austria and the EOTA

Building elements	**Slovenia**	**Austria**	**EOTA**
Foundations	90	60	100
External walls (above ground)	80	100	100
External door	50	30	25
Windows	50	30	25
Internal wall construction (supporting)	80	100	50
Partition wall (non-supporting)	50	30	25
Internal door	**50**	**30**	**25**
Floors (structural)	80	50	50
Ceilings	80	80	100
Roof structural construction	70	60	50

Stairs and ramps (structural)	50	70	50
Water system	40	N/D	25
Sewage system	40	N/D	50
Electrical system	40	N/D	25
Heating system (heat producer)	20	N/D	25
Heating system (heat distribution)	25	N/D	25
Ventilation system	20	N/D	25
External finishing coat	**40**	**30**	**25**
External thermal insulation (compact facade)	30	N/D	25
Roof cladding - inclined roof	30	N/D	25
Internal finishes (walls, floors)	30	30	10

2.2 Comparison of the environmental impacts of building components calculated with different RSL databases

In the continuation of this study a comparison of the environmental impacts determined based on different RSLs is presented. The environmental impacts were calculated for two building components with specific scenarios, an external finishing coat and an internal door. Each calculation was performed for three databases (Slovenia, Austria and the EOTA) in which the RSL for the building and the components under consideration differ considerably. The RSL data for both components, the finishing coat and internal door, are shown in Table 2 (marked bold). The environmental impacts were calculated with the data for the GWP impact category, taken from the Oekobaudat database [11] (Table 3).

Table 3. Oekobaudat data for the GWP impact category, used in this study

Internal wooden door (1pcs)

Indicator	Unit	Provision of raw materials A1	Transport A2	Production A3	Transport C2	Waste treatment C3	Elimination C4	Recycling potential D
GWP	kgCO(2)-Eq	-43,8	1,19	28	0,0792	101	2,6	-40,1

External finishing coat (1 kg)

Indicator	Unit	Production A1-A3	Transport A4	Installation A5	Elimination C4	Recycling potential D
GWP	kgCO(2)-Eq	1,22	0,199	0,0289	0,0112	-0,0193

For the purpose of the comparison, the study included two scenarios. The first scenario is related to the building component, the internal wooden door, which can be reused in a second building. The calculated environmental impacts of the replaced door can therefore be divided between the life cycles of both buildings. At the end of the second scenario (decomposition of the building) the building component, the external finishing coat, is destroyed. Consequently, it cannot be reused in the same form in another building, so the whole environmental burden of the finishing coat falls on the first building. The RSL of the whole building in our case study was 90 years for Slovenia, 100 years for Austria and 100 years for the EOTA database.

The internal wooden door

Within the RSL of the building the internal wooden door must be replaced several times, since the RSL of the door is much shorter than that of the building. The RSLs for the internal wooden door considered were 50 years for Slovenia, 30 years for Austria and 25 years, as proposed by the EOTA (Table 2). The needed replacements are as follows: one time according to the data for Slovenia, and three times according to the data for Austria and the EOTA.

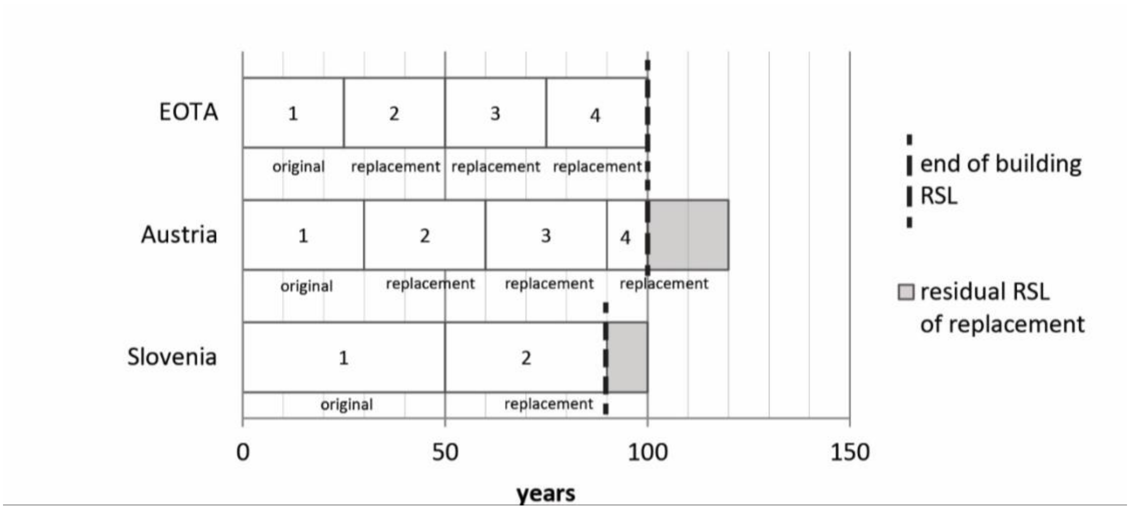

Figure 3. Internal door replacements in the RSL of the building according to the selected RSL databases

In the case of Austria and Slovenia the RSL of the last replaced internal wooden door exceeds the RSL of the building. So only the part of the production phase (A phase according to EN 15978) is assigned to the life cycle of the first building, while the rest (C3, C4 and D phases according to EN 15978) should be assigned to the LCA of the new building where the material will be subsequently used.

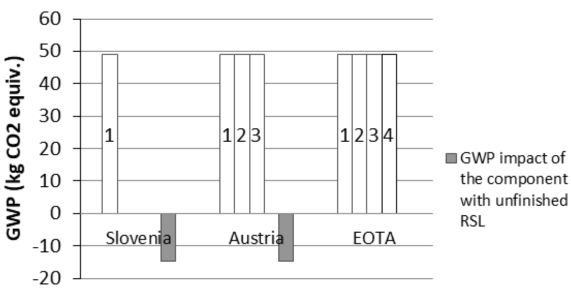

Figure 4. GWP emissions of each internal door (original + replacements) during the RSL of the building

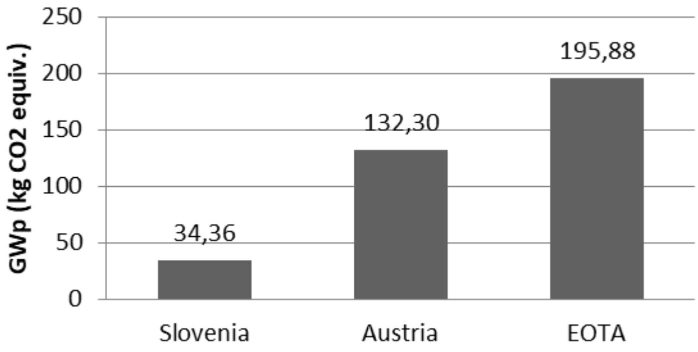

Figure 5. Total GWP emissions for an internal door (original + replacements) during the RSL of the building according the selected RSL databases

The production phase for the internal door has an impact of -14,61 kgCO2equiv., the end-of-life phase 103,6 kgCO2equiv and the D phase has an impact of -40,1 kgCO2equiv. In the case of Slovenia, the impact of the original door (the sum of all the phases) and the production phase of the replacement door are summed together. According to Austria's RSL database the impact of the original door, the impact of the first two replacements (all life cycle phases) and the production phase of the third replacement are summed. For the EOTA the total impact of the original and the total impact of all three replacements are summed.

The calculation shows that the results can differ by up to a factor of five (Fig. 4 and Fig. 5). The gap between the results is further emphasized by the fact that the internal door is made of wood, which is considered as a carbon sink. This means that the benefits of the carbon sequestration are attributed to the first building, as a positive impact on the environment (Fig. 4), while the environmental burden of wood disposal is assigned to the second building.

External finishing coat

An external finishing coat is a type of product that is virtually impossible to disassemble in such a way that it can be reused. Therefore, it is anticipated that although this product has not reached its full RSL it has to be disposed of at the end of the RSL of the building. The entire burden of the external finishing coat, even if it is still functional, needs to be ascribed to the first building.

Again, the RSL of the building in our case study was 90 years for Slovenia, 100 years for Austria and 100 year for the EOTA database. The RSL for the external finishing coat was 40 years in Slovenia, 30 years in Austria and 25 years as proposed in the EOTA (Table 2).

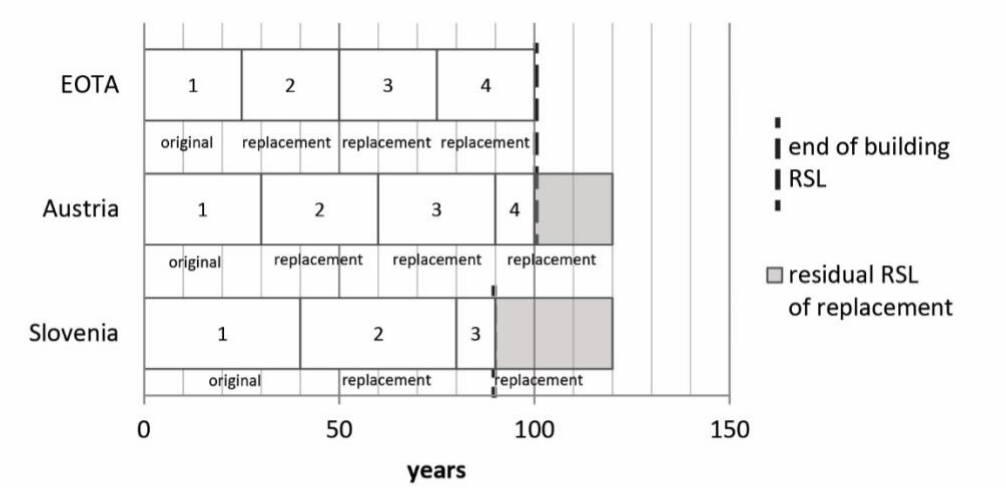

Figure 6 Finishing-coat replacements in the RSL of the building according to the selected RSL databases

Also, the external finishing coat must be replaced several times within the RSL of the building: two times according to the Slovenian data and three times according to the data from Austria and the EOTA. It is clear (Figure 6) that in the case of Austria and Slovenia the RSL of the external finishing coat exceeds the RSL of the building. Nevertheless, the whole environmental burden of the last replacement of the component must be assigned to the building.

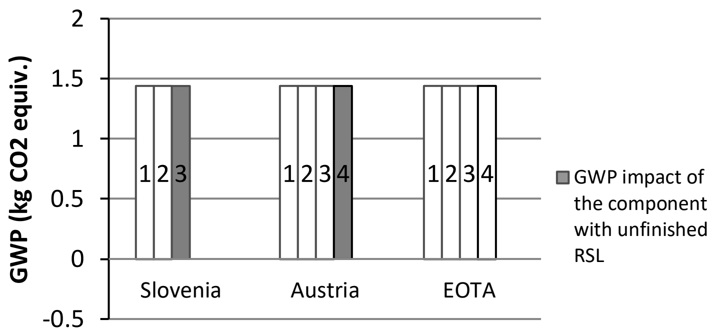

Figure 7. GWP emissions of each kg of finishing coat (original + replacements) during the RSL of the building

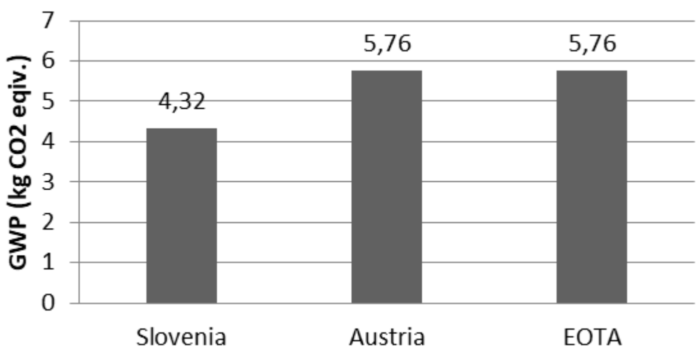

Figure 8. Total GWP emissions for 1 kg of finishing coat (original + replacements) during the RSL of the building according to the selected RSL databases

The production phase for 1 kg of finishing coat has an impact of 1.448 kgCO2equiv., the end-of-life phase 0.011 kgCO2equiv and the D phase has an impact of -0.019 kgCO2equiv. According to the Slovenian RSL database two replacements are needed (the environmental impact of all the life cycle phases is calculated). In the case of Austria and the EOTA the environmental impact of the whole life cycle of 1 kg of finishing coat is calculated four times (original + three replacements).

The GWP emissions caused by 1 kg of external finishing coat are the same when calculated with the Austrian or the EOTA RSL data, despite the fact that the RSLs of the finishing coats are 30 and 25 years. In both cases three replacements of the coating in the RSL of the building are required (Fig 7). In Slovenia the RSL of the external finishing coat is longer and only two replacements of the external finishing coat are needed; consequently, the GWP emissions of the latter are lower (Fig 7).

3. Conclusions

This study confirms that the reference service life (RSL) of a building and its components can have a significant influence on the results of the LCA analysis of a building. Therefore, for ensuring a reliable comparison between analyses it is extremely important that the RSL data in European databases are reasonably harmonized and clearly presented.

The results of the analysis showed that the calculation scenario at the end of the RSL of a building must be consistent with the actual handling of the components when the building is decomposed. In an ideal scenario, multiple RSLs of building components and the RSL of a building would end simultaneously. In reality this is very rare: the environmental impacts of the component strongly depend on the reuse scenario in terms of whether they should be attributed only to the life cycle of the first building or the next one, in which it is reused as well. This case study confirms that the scenarios for the reuse of individual components must also be methodologically consistent.

The influence of building components' RSLs was analysed with just two examples. It was shown that due to the selected European RSL databases and the predicted scenarios the results of the environmental impacts in a life cycle of a building can differ by up to a factor of five. In real buildings there are hundreds of components, so the influence of various reuse scenarios on the overall LCA analysis results can be even more significant.

RSL values of the individual materials, building components and buildings can be selected from many sources and are not completely comparable. It was found that the RSL sources in the European context are usually linked to different kinds of national legislation, but the background for their definition is not exactly known. Some countries have a uniform RSL for all the buildings, while others (including Slovenia) have RSL values that are mainly related to the type of building material (brick, concrete, wood, steel). There are some cases where the RSL values primarily depend on the use of the buildings. It is obvious that further research based on European data and subsequent comparisons of the results are needed to define reliable RSL values for specific individual materials and building components as well as for buildings.

Abstract. The aim of this paper is to identify existing methods for economic valuation or monetisation of life cycle environmental impacts and to assess its applicability in the broad European context. Although environmental awareness is more and more important in several industrial sectors, including the construction sector, easy to understand data are still missing for professionals to assess and manage impacts related to the whole life cycle of a building. Life Cycle Assessment (LCA) is one of the most commonly accepted methodologies to calculate potential life cycle environmental impacts of a product or service. However, the results of such method, even when published in an Environmental Product Declaration, meant for business to business communication, are not always comparable or easily understandable by non-practitioners. Economic valuation or monetisation of LCA results is a weighting step that can make it easier for non-practitioners to use LCA results to support decision-making. From the several monetisation methods analysed, it is discussed the one that is most suitable for use when LCA results already exist. It is concluded that further work is needed to improve such weighting methods or develop a common one that can be representative at a broader geographical level (for instance, Europe-wide).

1. Introduction

Environmental degradation, such as climate change or resource scarcity, are increasing due to human activity. Population concentration in urban areas and fast urbanization are also aspects with the potential to impact society. Despite its importance in economic and social aspects (namely, accounting for 6% of the global Gross Domestic Product (GDP), providing millions of jobs, and the social service of providing housing), the construction sector is the largest global consumer of raw materials, and responsible for 25-40% of the world's total carbon emissions [1].

To enable Architecture, Engineering and Construction (AEC) professionals, decision-makers and investors throughout the EU to consider impacts related to the whole life-cycle of a building, empirical-based, reliable, transparent and comparable data are needed, based on clear indicators of the building performance [2]. Life Cycle Assessment (LCA) is a commonly accepted and well-established methodological tool. It applies life cycle thinking, quantitatively, to the environmental analysis of activities related to processes or products [3]. However, to apply the Sustainability concept to buildings based on its three pillars (environmental, social and economic), other tools must also be used. Currently, several European standards, developed by the Technical Committee (TC) 350 of the European Committee for Standardization (CEN) (TC350/CEN), are published concerning the evaluation of construction works performance in all these three pillars [4–7]. Both TC350/CEN and ISO have also developed standards concerning the communication of environmental impacts through Environmental Product Declarations (EPD), that aim at providing AEC professionals with LCA information on construction materials [8, 9].

In what concerns LCA application within the building sector, as a strategy to reduce environmental impacts, it is often identified as complicated and time-consuming. Moreover, most of the impact assessment methods commonly used result in a set of environmental categories that are not easily understandable or interpretable [10]. This conclusion can be obtained from the analysis of the list of parameters and environmental information specified for a Type III Environmental label - EPD [9]:

- Parameters describing environmental impacts (7 impact categories);
- Parameters describing resource use (17 parameters);
- Environmental information describing output flows (4 parameters);
- Environmental information describing waste categories (3 parameters);
- Parameters describing pollutants emission from materials (3 parameters);

Taking this into account, for AEC professionals to use LCA more efficiently as a decision support tool, this information needs to be simplified, and monetisation is a solution for that. Currently, opinions diverge on the monetisation of environmental impacts, with a discussion on whether and how to value them [11]. This paper intends to identify existing monetisation approaches and methods for environmental impacts and their main pros and cons when applied to LCA results. More specifically, it intends to assess their application in the case that LCA results are available in the form of an EPD.

2. Material and Methods

The main method used for the development of this work was through a literature review.

Methods reviewed for this work include LCA and monetisation methods already developed, used and accepted by the scientific community.

3. The Life Cycle Assessment method

LCA is a structured, comprehensive and internationally standardised method (ISO 14040 series [12]). It allows the quantification of all relevant emissions, resources consumed and the related potential environmental and health impacts and resource depletion issues that are associated with any goods or services (“products”) (ISO, 2006). This is a complex and data-intensive methodology that considers the potential impacts of the whole life cycle of a product, from the extraction of resources, through production, use, and recycling, up to the disposal of remaining waste [13]. This method is an important tool applied to [12]:

- Identify “critical points” and respective opportunities to improve the environmental performance of products at several stages of their life cycle;
- Inform decision-makers in industry, government or non-governmental organizations in the search for more sustainable consumption and production (e.g. for the purpose of strategic planning, priority setting, product or process design or redesign);
- Select relevant indicators of environmental performance, including measurement techniques;
- Marketing activities (e.g. implementing an eco-labelling scheme, making an environmental claim, or producing an environmental product declaration).

LCA methodology is standardized namely by ISO 14040 concerning Environmental management - Life cycle assessment - Principles and framework [12] and by ISO 14044 concerning Environmental management - Life cycle assessment - Requirements and Guidelines [14].

ISO 14040 describes the principles and framework for LCA, including its four main stages: the goal and scope definition of the LCA study, the life cycle inventory analysis (LCI) phase, the life cycle impact assessment (LCIA) phase, and the life cycle interpretation phase.

There are cases in which the aim of an LCA can be achieved by performing only the first two phases - it corresponds to an LCI study [15]. However, a complete LCA includes the evaluation of the environmental impacts associated with these inputs and outputs of the system (LCIA) and the interpretation of the results of the inventory and evaluation phases, taking into account the objectives of the study [14, 15]. Life cycle impact assessment is the stage of an LCA that allows understanding and evaluating the magnitude and significance of the potential environmental impacts of a product system. ISO 14040/44 refers to several steps in the LCIA [12, 14], as described in the following paragraphs.

- Mandatory elements:
  - Selection of impact categories, category indicators and characterization models;
  - Classification: assignment of LCI results to the selected impact categories - each elementary flow from the inventory is assigned to the impact categories according to the substances' potential to contribute to different environmental problems (e.g., eutrophication, climate change); these impact categories may be endpoint (human health, resource depletion, later in the cause-effect order) or midpoint (climate change, land use; earlier in the cause-effect order);
  - Characterization: calculation of category indicator results - for each impact category several substances contribute with specific magnitudes.

To reduce all substances to a common equivalent unit, normalisation, equivalence factors or characterisation factors may be applied during this step (optional).

- Optional elements:
  - Normalization: calculating the magnitude of category indicator results relative to reference information, for instance, in reference to the average level of pollution produced by an average European citizen;
  - Grouping: sorting and possibly ranking of the impact categories;
  - Weighting: converting and possibly aggregating indicator results across impact categories using numerical factors based on value-choices;
  - Data quality analysis: better understanding the reliability of the collection of indicator results/the LCIA profile.

Thus, weighting is an optional element with two possible procedures, either to convert the indicator results or normalized results with selected weighting factors or to aggregate these converted indicator results or normalized results across impact categories. Weighting steps are based on value-choices and are not always objective [14]. This is the step that allows the monetisation of environmental impacts by attributing an economic value to the equivalent unit of the characterisation result of each impact category.

4. Monetisation approaches and existing methods

Monetisation expresses the relative importance of an impact category in monetary value. This value can be based on the costs associated with preventing or repairing damage (e.g. damage costs using market prices). Another example to monetise an impact category is to measure how people are willing to pay to prevent a given impact. These include expressed willingness (through interviews) or estimated willingness to pay through value attribution by the users or measurement of welfare losses, as well as political willingness to pay [16, 17]. These are applicable to both use and non-use values, i.e. the value that people derive from goods independently of any use, present or future, that they might make of those goods, in contrast with use values, which people derive from direct use of the good [16]. A summary of monetisation approaches is presented in Table 1.

Based on these approaches, several monetisation methods/weighting sets have been developed and are widely used for the weighting of environmental impacts resulting from LCA studies. The most relevant are listed in Table 2.

5. Discussion

The **Eco-costs** approach is a prevention-based monetisation method [18]. It translates the environmental impact into economic cost by measuring the cost of preventing a given amount of environmental burden [19]. Eco-costs provides monetary values for the following impact categories: acidification (from the LCIA method International Reference Life Cycle Data - ILCD): eutrophication and summer smog (from the LCIA method Recipe); ecotoxicity and human toxicity (from the LCIA method UseTox 2); fine dust (from the LCIA method RiskPol); and global warming (from the LCIA method of Integrated Pollution

Prevention and Control - IPPC). In addition, there is a set of eco-costs to characterize the 'midpoints' of resource depletion [18]:

- Eco-costs of abiotic depletion (metals, including rare earth, and fossil fuels);
- Eco-costs of land-use change (based on loss of biodiversity);
- Eco-costs of water (based on the midpoint Water Stress Indicator - WSI);
- Eco-costs of landfill.

Table 1. Monetary valuation approaches (adapted from [20]).

Approach	Description
Revealed willingness to pay	Market prices (damage costs: loss of production, loss of capital or added value)
	Revealed preference methods (productivity method and travel cost method)
	Hedonic pricing (combining market places of a good and the influence of environmental aspects on the user's willingness to pay)
Expressed willingness to pay	Stated preference methods (contingent valuation and choice modelling)
Imputed willingness to pay	Damage cost avoided method (e.g. restoration costs, remediation costs, defensive expenditures)
	Replacement cost method uses the cost of replacing an ecosystem or its services
	Substitute cost method uses the cost of providing substitutes for an ecosystem or its services
Political willingness to pay	Costs-to-reach-target
	Taxes
Avoidance costs	Estimation of the cost to limit some emissions or impacts to a chosen limit, based on a hypothetical situation and not on willingness to pay

Table 2. Identified monetisation methods and respective approach.

Method	Approach
Eco-costs	Revealed willingness to pay - Market prices (prevention prices)
Ecotax 2002	Political willingness to pay - Taxes
Ecovalue 08	Revealed willingness to pay - Market prices (added value) and imputed willingness to pay - Damage cost avoided method (defensive expenditures)
Environmental Prices	Revealed willingness to pay - Market prices (prevention prices)
Environmental Priorities Strategies in product design (EPS)	Imputed willingness to pay - Damage cost avoided method (defensive expenditures)
External costs of energy (ExternE)	Revealed willingness to pay - Market prices (added value)
LIME	Expressed willingness to pay - Stated preference methods
Social Cost of Carbon	Revealed willingness to pay - Market prices (damage costs: loss of welfare)
Stepwise 2006	Imputed willingness to pay - Damage cost avoided method (defensive expenditures)

Eco-costs refers to the environmental categories most often used in the environmental assessment of building materials and assemblies, which are compatible with the environmental information provided in EPDs [21, 22]. The marginal prevention costs at a midpoint level can be combined and expressed as "endpoints" in three groups, plus global warming as a separate group [18]:

- Eco-costs of human health = the sum of carcinogens, summer smog, and fine dust;
- Eco-costs of ecosystems = the sum of acidification, eutrophication, and ecotoxicity;
- Eco-costs of resource depletion = the sum of abiotic depletion, land-use, water, and landfill;
- Eco-costs of global warming = the sum of CO_2 and other greenhouse gases (GWP 100 table);
- Total eco-costs = the sum of human health, ecosystems, resource depletion and global warming.

Ecotax 2002 is a monetization approach based on the Swedish eco-taxes and fees on emissions and resource use. It assumes that political decisions reflect societal values of environmental impacts. This method also uses CML Baseline midpoint impact categories, which are compatible with the use of EPDs. In some cases, a tax or fee can be used directly as a weighting factor, for example, the taxation on CO_2 for global warming (CO_2 eq.). In other cases, weighting values are calculated based on existing taxes, for instance, taxes on nitrogen fertilizers are adapted to provide a weighting factor for eutrophication [23–25].

Ecovalue 08 builds on weighting factors that aggregate midpoints on a monetized endpoint impact. It is based on market valuations of resource depletion and individual Willingness To Pay (WTP) estimates for environmental quality. The characterisation method used for the midpoint impact categories is CML (Centre for Environmental Sciences - Leiden University) baseline [26]. This method is compatible with the use of EPDs as information sources for the environmental LCA results.

Environmental Prices expresses the willingness-to-pay for less environmental pollution in Euros per kilogram of pollutant [27], similarly to Eco-costs. It indicates the loss of economic welfare derived from each additional kilogram of the pollutant entering the environment and often coincides with external costs. Environmental prices distinguish on the environmental categories it values. Environmental Prices Handbook defines five endpoints [27]:

- Human health (morbidity, i.e. sickness and disease, and premature mortality);
- Ecosystem services (including agriculture);
- Buildings and materials (man-made capital);
- Resource availability;
- Wellbeing (aesthetic and ethical values).

Regarding midpoint categories, environmental prices closely follow the categories used in the ReCiPe method, add a nuisance-related category, and are not consistent with the information provided by EPDs. However, environmental prices are presented also at the pollutant level, allowing for the application of the method based on the inventory of the product/process assessed.

Environmental Priorities Strategies in product design (EPS) system [28] is one of the eldest (1991-1992) monetary valuation models developed to facilitate comparison of environmental impacts (mostly for product development). It calculates environmental costs using inventory data, characterization factors, and weighting factors (monetisation), reaching an endpoint result. The impact categories in the EPS method are identified within four areas of protection: human health, ecosystem production capacity, abiotic stock resources, and biodiversity. Damages to these safeguard subjects are monetised according to the willingness to pay (WTP) to avoid changes from the present state of the environment. Environmental aspects such as emissions of substances (e.g. CO_2, CO, NO_x, SO_x, etc.) or resources extraction (e.g. fossil fuels, minerals) are classified in each of the mentioned areas of protection. Weighting factors are defined for 15 impact categories, grouped in 4 main damage categories, as defined in the EPS 2000 method used for life cycle impact assessment, not consistent with the information provided by EPDs.

External costs of energy (ExternE) is a project funded by the European Commission, which started in 1995, intending to monetise socio-environmental damages caused by distinct energy carriers. ExternE makes a detailed and systematic assessment of the full cause-to-effect chain from burdens or emissions to environmental impacts and damages. The three safeguard subjects considered are public health, built environment, and ecosystem production capacity. Impacts are valued based on market prices or 'willingness to pay'. The two follow-up projects of ExternE are the New Element for the Assessment of

External Costs from Energy Technologies (NewExt) and the New Energy Externalities Developments for Sustainability (NEEDS). The aim of the former was to improve the assessment of externalities and that of the latter was to evaluate costs and benefits of energy policies and of future energy systems [25]. This method is also not compatible with the use of products' EPDs as input for the monetisation.

LIME, Life-cycle Impact Assessment Method based on Endpoint Modelling, is a Japanese project that aims at developing a database to assist industries in implementing reliable LCA studies in the characterization step. LIME considers 11 impact categories: urban air pollution, hazardous chemicals, eutrophication, global warming, ecotoxicity, acidification, ozone layer depletion, photochemical oxidant creation, land use, waste, and resource consumption. The monetisation is based on a survey conducted in 2004 (in Tokyo) and in 2012 (throughout Japan) to assess the WTP of the Japanese society to avoid damage on certain safeguard subjects (for example, human health or biodiversity). With the use of logit modelling, the weighting factors to aggregate midpoint categories were calculated estimating the environmental attitudes and preferences of the Japanese public. Based on the logit model, LIME provides two types of weighting factors: a dimensionless index; and an economic valuation. Both can be used on the results of different impact assessment methods for estimating monetary values [24, 25].

Stepwise 2006 [29] is a monetization method built on the results of LCIA method Ecoindicator99 [30], which provides results as physical scores for each of the three safeguard subjects: humans, ecosystems, and resources. These damage categories are redefined [29] so that they can be measured in: Quality Adjusted Life Years (QALYs - the amount an average person is willing to pay for an additional life year) for impacts on human well-being; in Biodiversity Adjusted Hectare Years (BAHYs) for impacts on ecosystems; and in monetary units for impacts on resource productivity. To aggregate these results, a monetary value is attributed to QALY and to BAHY and an exchange rate between BAHY's and QALY's is set, measuring impacts on resource productivity. Both valuations allow environmental impacts to be expressed in monetary values [29]. Considering that the LCIA method Ecoindicator99 is an endpoint method based on panel approach, there is already a high subjectivity of the results even before the monetisation step. However, currently, the STEPWISE method uses characterisation models from IMPACT2002+ v. 2.1 and the EDIP2003 methods, that are second-generation methods, building on previous work (Ecoindicator1999 and EDIP1997, respectively) [31]. Still, the format of environmental information provided by EPDs is not compatible with this method.

The Social Cost of Carbon (SCC) is a commonly employed metric of the expected economic damages from carbon dioxide (CO_2) emissions [32, 33]. SCC represents the economic cost associated with climate damage derived from the emission of an additional tonne of carbon dioxide (tCO_2). Considering that global warming potential, measured in $CO_{2eq.}$, is one of the indicators provided in EPDs, this valuation method may also be compatible with this source of information. It neglects, however, other important environmental impact categories declared in these declarations.

Table 3 presents some examples of the application of the identified monetisation methods. The examples chosen were those from the most recent years and, when available, including the application of the valuation methods to the construction sector.

6. Conclusions

Taking into account the economic and environmental relevance of the construction sector, there is a growing need to provide the AEC professionals with tools that support the improvement of its sustainability, namely in the environmental dimension. LCA is an important methodology for that. However, considering the complexity, and the information and time demand, of this methodology, it is understandable that it is not the focus of these professionals. Even the results of an LCA study as presented on EPDs (most common sources of LCA results for these professionals) are usually difficult to interpret and use. The weighting of these results in the form of monetisation of environmental impacts has the advantage of providing a single indicator in an objective unit, allowing professionals to evaluate and easily compare options while being aware of the magnitude of environmental impacts in each life cycle stage (in relation to market costs of a project).

Table 3. Examples of application of the identified methods.

Method	Reference and additional methods	Objective of the use of monetisation
Eco-costs	Scheepens *et al*, 2018 [34]	A combined analysis of cost, (market) value, and eco-burden was used to compare strategies of passive (insulation focused) and active (behaviour focused) end-users, by applying the methods of eco-costs/value ratio (EVR) and eco-efficient value creation. The analyses identified the economic and environmental payback and the likelihood for potential rebound effects.
	Mano *et al*, 2017 [35]	Incorporation of costs of the environmental impacts caused by energy generation and equipment construction in the heat exchanger networks (HEN) using the eco-costs methodology. The inclusion of indirect costs (externalities) in the optimization procedure was found to significantly affect the characteristics of the minimum cost design, the operational conditions and HEN topology.
	Carreras *et al*, 2016 [36]	Eco-costs method was used to translate the environmental impact of the building envelope into monetary units. This was incorporated into the economic performance assessment, to optimise the thermal insulation of a building envelope in different climate zones.
Ecotax 2002	Du *et al*, 2018 [37] (also Ecovalue 08)	Comparison of the environmental performance of two bridge types through the whole life cycle, based on eight selected cases in Sweden, applying Ecovalue08 and Ecotax02 methods to evaluate the environmental costs of each design option.
	Nguyen *et al*, 2016 [25] (also EPS and Stepwise 2006)	Calculation of the environmental externalities of electricity from renewable (e.g. biomass) and from non-renewable sources (e.g. coal, oil, and gas), comparing three monetization methods, the EPS 2000, the Stepwise 2006, and the Ecotax.
Ecovalue 08 (also Stepwise 2006)	Huysegoms *et al*, 2018 [24]	Application of different monetization methods of LCA study results to the assessment of the site remediation of a former gas plant. Implementing monetized LCA results in social cost-benefit analysis (CBA) allowed for a more detailed overview and valuation of the secondary environmental effects.
Environmental Prices	Huysegoms *et al*, 2019 [38]	Application of the environmental prices method to incorporate LCA in Social CBA in the comparison of remediation alternatives for a dry-cleaning facility.
ExternE	Entler *et al*, 2018 [39]	Ex-ante economic analysis of a fusion power plant in terms of the cost of electricity. It includes the external costs of energy based on the OECD statistical data and on the EU ExternE project results.
	Jochem *et al*, 2016 [40]	Comparison of the main external cost components for electric vehicles and internal combustion engine vehicles, based on the ExternE method.
LIME	Yamasaki *et al*, 2019 [41]	Incorporation of life cycle impact assessment (LCIA) into the calculation of environmental loads for administrative divisions applying monetisation method LIME-3.
Social Cost of Carbon		Investigation of the cost-effectiveness and environmental impacts of a green roof in an educational building of the University of Florida. Environmental costs were integrated using Global Warming Potential (GWP) measure to determine the social cost of carbon.

In this work, it was possible to identify several monetisation methods. However, taking into account standards for the development of EPDs, Eco-costs, Ecovalue 2008, Ecotax 2002 and Social Cost of Carbon are the most suitable ones, because they are based on CML baseline midpoint impact categories, declared in EPDs. Moreover, the first two were the methods for which case studies were found related to the construction sector. However, they do not show broad geographic representability, since they are both strongly influenced by the Swedish framework (in terms of existing taxes and of the valuation of environmental impacts).

From this work, it is possible to conclude there is a need for further development/improvement of monetisation sets or methods, in order to obtain larger consensus and representability. Considering the efforts for the democratisation of the use of LCA and the communication of its results, it would be important to develop a monetisation method that can be Europe-wide representative as well as easily applicable to the available information, for instance, EPDs or other standardised sources of LCA information. Moreover, standards and guidelines related to these communication tools could also include the option of weighting the LCA results through monetisation, providing the common user with an easier to interpret and more tangible information in what relates to the potential life cycle environmental impact of a product.

Abstract. In building & construction (B&C), polymeric materials are being used for roofing and waterproofing membranes, coated fabrics ("textile architecture"), window profiles, electrical installation, flooring, pipes, etc. The most widely used plastic for such long-life applications in B&C is Vinyl (PVC). VinylPlus is the value chain's commitment for sustainable development. The voluntary commitment has a track record with publicly available progress reports, based on third party auditing and monitoring since 2001. More recently: After having substituted certain additives such as lead compounds, that had previously been used as stabilizers, and after abandoning mercury cell technology, VinylPlus is addressing further needs of the sustainability communities, e.g. by zooming in on additives and complementing standard LCA requirements. The VinylPlus voluntary commitment for sustainable development has been developing an additives sustainability footprint (ASF) and a set of criteria for its product label.
The scope and the current status of those tools will be presented and examples be given in order to document the relevance of those efforts. The information given is intended to fuel the discussion on how can / to which extent should those value chain commitments be integrated into existing sustainability.

1. Sustainability principles and assessment methodologies

The contemporary concept of sustainable development evolved progressively from growing awareness of the interdependence of social and economic progress with the supporting environment. Development of the concept culminated in 1987 with the UN's report Our Common Future (World Commission on Environment and Development, 1987), also known as the 'Brundtland Report'[1], which introduced the most widely recognised definition: "…development that meets the needs of the present without compromising the ability of future generations to meet their own needs". New or amended definitions of sustainable development have continued to proliferate, and regulatory instruments and management tools have increasingly sought to integrate the concept into operational norms.

The UN's consensual 17 Sustainable Development Goals (SDGs[2], United Nations, 2016) make a welcome addition to considering the limitations in the sustainable development narrative. The SDGs succeed in re-focusing attention on a linked set of human needs aimed at "Meeting citizens' aspirations for peace, prosperity, and wellbeing, and to preserve our planet"[3]. The SDGs have to be understood in a systemic context, addressing all goals as an inherently interconnected set. The SDGs also provide a framework for assessment of progress towards a more sustainable future. Such a framework avoids a company, value chain or other institution to fall into the trap of selecting just a few goals in a given sector[4].

A comprehensive review of sustainability assessment schemes is obviously impossible within the limited size of the present paper. We will therefore briefly mention a few particularly relevant for the construction industry and/or the VinylPlus sustainability programme.

1.1. Sustainability assessment methodologies relevant for VinylPlus

In view of the wide use of vinyl products in construction applications, it is worthwhile mentioning the most widely used building rating systems in Europe such as the Leadership in Energy and Environmental Design (LEED) developed by the U.S. Green Building Council (USGBC)[5], BREEAM (the Building Research Establishment Environmental Assessment Method)[6] and the rating system developed by the German Sustainable Building Council (DGNB)[7].

Those methodologies focus essentially on the sustainability of entire buildings—but not to the same extent on the sustainable production of individual building elements. Unless there are established sustainability labels, e.g. FSC for timber, on the elements and materials level the predominant schemes build on the ecological characterization of products.

The analysis of upcoming and/or commercially less relevant sustainability rating systems is not within the scope of this paper.

The Cradle to Cradle methodology[8] (C2C) has its own set of aspirational principles and terminology, which is sometimes presented as an alternative model to sustainability and a foundation for the circular economy. Its essential reliance on chemical hazard of substances, embodied in its Banned List of Chemicals, does not however consider impacts during product use, nor the contribution of chemicals to product functionality.

Transitioning to a sustainable society is obviously a complex endeavour, requiring, e.g., extensive coordinated collaboration across disciplines and sectors. How can humanity hope to succeed with this without having a unifying and operational definition of sustainability, and a systematic approach to planning and acting for the fulfilment of it? In response to this problem, a consensus process aiming at developing such a definition and approach began in Sweden in the early 1990s and the result is now widely known as the Framework for Strategic Sustainable Development (FSSD). This scrutiny also involves a kind of modelling where scientists study contemporary sustainability issues and test whether they are all covered, and can be clustered under the different sustainability principles. Forecasting and backcasting represent two major approaches to support planning and decision making. Forecasting is often used in attempts to predict and solve problems but is not appropriate when planning for long term and novel goals in complex systems and when the dominating trends are themselves a main part of the problem[9]. For such planning endeavours, backcasting is a more appropriate approach[10]. Backcasting begins by defining the vision, and then asks: what shall we do today and subsequently to get there?

This was one of the main reasons why the European PVC industry called on the expertise of The Natural Step (TNS). TNS approach[11] relies on the backcasting approach and is based on four basic rules defining success (sustainability principles). According to these principles, in a sustainability society, nature is not subject to systematically increasing concentrations of substances from the earth's crust, concentrations of substances produced by society, and degradation of physical means. In that society, there are no structural obstacles to people's health, influence, competence, impartiality and meaning.

2. VinylPlus's approach to sustainable development

"The sustainable use of (sustainable) chemicals aims at providing socially necessary products while minimizing resource consumption, reducing substance losses and controlling exposures by corporate, design oriented, organizational and technical means and at the same time enhancing healthy workplaces and fair social conditions."[12]

Already in 2000 the entire European PVC industry value chain—resin manufacturers, converters and additive producers —launched the voluntary commitment Vinyl 2010. This 10-year programme marked a leap in the PVC industry's journey towards sustainability. Despite a financial crisis and a much-enlarged target area due to the addition of EU member states, all goals were met and in some instances even exceeded.

Building on the achievements of Vinyl 2010, the partners decided to launch a new 10-year voluntary commitment, VinylPlus, undersigned in June 2011[13]. First, a fundamental assessment of the sustainability aspects of PVC was conducted and it became logical to involve The Natural Step since the NGO also has a clear vision of a sustainable society and a history of working with PVC-related issues. As a ‘critical friend’ of the industry, TNS became involved in laying out the basic principles. The VinylPlus programme builds on The Natural Step’s well-recognized science-based framework System Conditions for a Sustainable Society. For PVC, five challenges were identified that form the core of VinylPlus:

- #1 Controlled loop management, with an ambitious target of recycling 800,000 tons of PVC waste per year by 2020.
- #2 Organo-Chlorine Emissions, addressing concerns about to the undesired release of chlorinated organic substances from the whole life cycle of PVC to avoid any systematic increase of any concentrations in nature.
- #3 Sustainable Use of Additives: An essential component of PVC products, additives should also be used in sustainable way in order to secure alignment with the TNS sustainability principles.
- #4 Sustainable Energy & Climate Stability, which entails minimising climate impacts through the reduction of energy and raw material consumption.
- #5 Sustainability Awareness by which VinylPlus commits to building sustainability awareness across the value chain, including stakeholders inside and outside the industry. Its targets include, but are not limited to, developing a VinylPlus Product Label, and promoting VinylPlus’ sustainability principles to the audiences outside EU28.

In addition, the VinylPlus programme took over from the earlier Vinyl 2010 operational features ensuring transparency and accountability:

- An independent monitoring committee with representatives of the European Parliament and Commission, trade unions, retailers and consumer organisations oversees its progress[14].
- VinylPlus publishes every year a progress report which is independently audited and verified[15].

The VinylPlus programme plays a role in the overall progress towards sustainability by contributing to many of the 17 goals identified by the UN Sustainable Development Goals, in particular by minimizing impacts, while contributing to economic growth with suitable products for infrastructure and smarter cities (SDGs 7, 8, 9, 11, 12, 13, 17)[16]. It is also worth mentioning that VinylPlus has been a member of the Green Industry Platform since 2013, a global partnership led by the United Nations Industrial Development Organization (UNIDO) and the UN Environment Platform Programme (UNEP).

3. The VinylPlus Product Label

The development of a VinylPlus Product Label was one of the key targets of VinylPlus Challenge #5. The VinylPlus Product Label is a multi-criteria, third-party sustainability certification scheme. As other schemes[17], it has been created with the intent to shift the market preference towards the supply and demand of products with superior sustainability performance. Manufacturers of certified products can communicate these certifications to the downstream actors via a product label. For the buyers of such products, such label provides a simple way to convey information helping to select the products with best sustainability performance.

Voluntary certification schemes can be described and analysed using the tripartite standard regime framework developed by Busch[18,19]. In this framework, a scheme is characterized in three dimensions by Governance, Standard and Certification.

Governance tells how the scheme is owned and managed, how the auditors are accredited, how the engagement with stakeholders is organized, and how the scheme's activities and performance are communicated. All these elements drive the scheme's **legitimacy**.

The VinylPlus Product Label scheme is owned by VinylPlus but is operated and developed together with the Building Research Establishment (BRE) and TNS. As both organizations are independent from the vinyl industry, the scheme can be considered as a multi stakeholder initiative. As an important part of requirements are taken from the BES 6001 standard created by BRE, the third party audits have been run so far by BRE. With the recent recognition of the scheme by Accredia, the Italian accreditation body, and the expected recognition of the scheme by the 35 other members of the European cooperation for accreditation (EA), the audits will be run in a near future by properly trained auditors from ISO 17065 certification bodies specifically accredited for the scheme by government bodies. Auditors for many of the other environmental or sustainability schemes are certified by the scheme owner[20]. Criteria revisions and developments of the VinylPlus label are open to all relevant stakeholders through a procedure available on the website of the scheme[21]. All activities related to the scheme can be consulted at any time and any one on this website.

The second dimension of the framework is **Standard**, which describes the set of requirements and criteria that are set in the scheme. These elements directly impact the **effectiveness** of the scheme.

The VinylPlus Product Label scheme includes 18 requirements. 11 requirements are based on the VinylPlus challenges defined by TNS, based on a science-based definition of sustainability. They cover topics like recycling and building controlled loops, using the PVC resin and additives sustainably, committing to energy efficiency and internally and externally communicating to raise sustainability awareness. The other requirements are taken from BES 6001, the Framework Standard Responsible Sourcing developed by BRE[22].

Responsible sourcing of construction products offers a way to improve the implementation and traceability of sustainability objectives throughout the project supply-chain[23]. BES 6001 scheme is more comprehensive than chains of custody schemes such as Forest Stewardship Council or managerial systems such as ISO 14001[24]. BES 6001 includes a series of organisational management, supply chain management and environmental and social requirements; it covers legal compliance, management systems, traceability and more specific aspects such as waste management, transport impacts and life-cycle assessment. For each of the 18 requirements, a set of specific criteria is defined against which achievement can be scored; there is each time a threshold level of achievement which acts as a barrier to entry.

The third dimension of the framework is **Certification,** which describes the audit and certification processes and procedures. These elements impact the **efficiency** of the scheme.

By making use of the documents available on the website, any manufacturer of a PVC construction product can first determine if its product could be appropriate for certification. If this self-test reveals that threshold levels have been achieved for all requirements, the applying organisation sends its application online. VinylPlus then does a first conformity check and acknowledges reception of the application.

The audit is then prepared together with the auditor selected by the applicant among trained and accredited auditors. Once all the requested information has been gathered by the applicant, the auditor undertakes a pre-assessment. If this pre-assessment is positive, an on-site audit is performed by the auditor to collect additional pieces of evidence of conformity.

A detailed performance report is then prepared by the auditor. If required evidence is missing, the applicant has one year to fill any conformity gap. After all evidence has been gathered, the performance report is verified by BRE and additional inputs from the applicant may be requested. Once verified, the report is transmitted to VinylPlus. If the audit process is successful, VinylPlus grants a label certificate valid for 2 years. After this period, the certification needs to be renewed following the same process.

As of end of February 2019, 33 PVC window profiles manufactured in 11 manufacturing sites in 10 European countries have been certified[25]. The scheme is now being open to all PVC building and constructions products as defined in the EU Construction Products Regulation[26].

Figure 1. The visual design of the VinylPlus Product Label is protected as an internationally registered trademark of VinylPlus®. The mark consists of the stylized blue word "VINYL" in the middle of a green outlined teardrop-shaped leaf design and the stylized white wording "VERIFIED" in the middle of a green banner design.

4. The Additives Sustainability Footprint

The VinylPlus Challenge #3 recognises the sustainable use of additives as a key challenge. Sustainable use should not only account for the intrinsic properties of additive substances but also considers the risks and positive benefits within the full societal life cycle context of the PVC articles into which they are incorporated, based on the TNS science-based definition of sustainability.

Existing schemes for assessment of chemical sustainability differ significantly in definitions of objective, interpretation and scope. Many such schemes concentrate on intrinsic chemical properties and particularly potential hazard[27]. Regulatory mechanisms and management tools such as the REACH Regulation predominantly focus on hazard reduction or elimination. Risk assessment integrates hazard with potential exposure[28].

Both approaches—hazard and risk—fail to account for wider sustainability issues related to sourcing, production and application of chemicals, their interaction with products within which they may be used and their fate at or beyond end-of-life. Life Cycle Assessment (LCA) measures some of these aspects, using well-established environmental impact categories such as global warming potential, eutrophication, different aspects of ecotoxicity and ozone-forming potential[29]. Yet, models used to assess life cycle impact differ from each other in basic principles, scope and outcomes, potentially omitting impacts of chemical emissions and making different approaches hard to reconcile[30]. Lack of social considerations in conventional LCA has been acknowledged as a deficiency, and the SETAC/UNEP Social Life Cycle Assessment model is working to include social impacts as a more useful tool in progress towards sustainable development[31].

The European Commission is developing a Product Environmental Footprint (PEF) methodology for potential application to all products on the European market[32]. It remains unclear when or if this methodology will be used or be applied to any important PVC construction products (e.g. window profiles).

The Additive Sustainability Footprint (ASF) tool has been developed by VinylPlus since none of the REACH, LCAs, and PEFs initiatives, taken alone, can account for the roles and behaviours of the additives as functional constituents of complex products. None of these initiatives accounts for the wider context of sustainability as articulated by the TNS System Conditions. None accounts for positive benefits arising from the functional contributions of additives, enabling articles to address the meeting of human needs on a potentially sustainable basis.

The ASF uses the Sustainability Life Cycle Assessment (SLCA) approach developed by TNS (Lundholm et al., 2008[33] and 2011[34]). This life cycle assessment methodology implements the TNS FSSD within the ISO 1404X-compliant LCA methods[35]. SLCA addresses strategic pathways towards full sustainability based on the FSSD, rather than focusing on specific known problems[36]. SLCA has been applied in various operational contexts, including for example to paints[37].

The ASF development follows the ten-step SLCA approach consistent with established LCA protocols:

1. **Setting goal and scope** establishes vision and meaning about the sustainable use of additives. The agreed vision statement wording based on TNS criteria was:
    - Additives are sustainably produced using materials that are responsibly sourced.
    - Additives support the sustainable management of PVC products (e.g. safe and recyclable).
    - The functional benefits of additives enable PVC products to support sustainable development (e.g. meeting the UN Sustainable Goals)

2. **Creating a shared definition of the sustainable product system** entails agreement on success criteria for sustainable use of additives across each of the life cycle stages based on TNS sustainability principles;
3. **Setting system boundaries** establishes de minimis additive concentrations and other aspects of the life cycle such as aligning with assumptions in the published EPD and other protocols used by the industry, as well as agreement on guiding principles;
4. **Inventory analysis** collects information relevant to addressing the social and environmental criteria covered by questions in Step 6;
5. **Sustainability assessment** uses TNS System Conditions to assess sustainability strengths and weaknesses;
6. **Identify key impact areas** entails answering sustainability-relevant questions for each combination of TNS System Condition and life cycle stage;
7. **Brainstorm possible solutions** considers options to address 'sustainability hotspots' highlighted in Step 6;
8. **Prioritise solutions** prioritises optimal solutions to address 'sustainability hotspots';
9. **Create an innovation roadmap** entails taking innovations through to measurable actions; and
10. **Measure and report progress** includes as a useful output a summary 'Snapshot report' comprising a description that an ASF has been performed, an explanation of the process of the study, a link to further contact and other information, verification by those behind the study, and the insights and recommendations that arose from the process.

A pilot implementation of the method to the additives of a generic PVC window profile has demonstrated that the ASF method is workable, robustly founded on science-based sustainability principles, makes use of pre-existing assessments in addition to novel social and environmental criteria comprising a broader picture of necessary conditions of sustainability, and takes account of multiple dimensions associated with the sustainable use of additives throughout the full societal life cycle of the articles into which they are incorporated.

Development is ongoing to develop an online version of the ASF tool now the basic protocols are tested, with auto-filling of generic information for some implementations of ASF, making assessment easier, quicker and cheaper. The online tool can also serve as a vehicle for publishing outcomes whilst protecting commercially sensitive inputs.

5. Conclusion, outlook and vision

The unique value chain approach of VinylPlus, its wide range of targets to enhance the sustainability of PVC, and the concrete tools it has developed, such as its product label and additives sustainability footprint, are mentioned by policy makers as a kind of role model. For example, an EU Commission director stated that "VinylPlus can be considered as a frontrunner for the circular economy"[38].

It is particularly this toolbox, that positions VinylPlus as a valuable partner for stakeholders developing and implementing policies aiming at a more sustainable European industry, especially the construction industry.

In a nutshell, the VinylPlus Product Label is a document of responsible sourcing of feedstock—e.g. no mercury cell technology used; it is a proof of the absence/substitution of certain additives—such as lead compounds that had previously been used as stabilizers; and last but not least the Vinyl Plus Product Label stands for controlled loop and traceability—in order to guarantee the highest possible recycling level after decades of a product's useful service life.

The instruments of product label and additives sustainability footprint AFS allow for an easy discrimination between material grades and consequently of product sustainability levels. The label should thus be considered for direct integration into existing and future building sustainability schemes.

info@polystyreneloop.eu

Abstract. For decades polystyrene (PS) foam is known as an efficient insulation material in the building and construction environment. At the end of its very long useful life, the waste remains a valuable material source for a variety of products. However, the flame retardant HBCD, which has been used since the 1960s until 2017, is considered a pollutant and millions of tons of PS foam waste can no longer be regularly recycled.
PolyStyreneLoop is developing a solution with a physico-chemical recycling process, based on the CreaSolv® Technology. The applied technology turns PS foam waste into new high-quality raw material. During the recycling process, impurities, such as cement or other construction residues, as well as the imbedded flame retardant HBCD are safely removed. The HBCD is destroyed, while the valuable bromine component and polystyrene are recovered.
In 2019 an industrial scale demonstration plant (with the capability to handle 3.3 kt of PS insulation foam waste per year) will be built in the Netherlands. The plant is aimed at starting up by the end of 2019. Subsequently the technical, economic and environmental viability of this new recycling process will be assessed. When proven to be successful, the process will be further rolled out with additional commercial plants in other countries throughout Europe.

1. Introduction

Polystyrene (PS) foam is one of the most widely used insulation materials ensuring climate control and energy efficiency of buildings. Over the lifetime, the energy savings achieved during heating save a multiple of the fossil resources required for its production. However, in the sense of a modern, low-carbon, resource and energy-efficient economy every effort must be made to use all resources sparingly. That's exactly where PolyStyreneLoop starts. It is a new recycling process for polystyrene (PS) foam that can be used for both expanded polystyrene (EPS) and extruded polystyrene (XPS). For this purpose, a demonstration plant will be built in the Netherlands. The primary aim is to recycle insulation materials that contain the imbedded flame retardant HBCD (which is no longer used). As PolyStyreneLoop will start with the recycling of EPS, the focus will be placed on this material in the remainder of this article.

EPS is a lightweight, rigid, plastic foam insulation material consisting of 98 % air and 2 % polystyrene. It is typically used in External Thermal Insulation Composite Systems (ETICS) and for flat roof, perimeter or impact sound insulation. Builders often choose EPS, because it is cost-effective, durable and easy to install.

1.1. Global and European Regulations for HBCD

To meet national fire regulations Hexabromocyclododecane (HBCD) has been used in many European countries since the 1960s until 2017 as a flame retardant in insulation materials made of expanded polystyrene (EPS) and extruded polystyrene (XPS). In 2013 HBCD was brought under the Stockholm Convention regime due to its persistent, bioaccumulative and toxic properties as well as its potential for long-range transport and has been listed as a Persistent Organic Pollutant (POP) [1].

In Europe the provisions of the Stockholm Convention were implemented in Regulation (EC) No 850/2004 [2]. The concentration limits for HBCD in articles and waste were set in amendments to this regulation. HBCD in articles is allowed in concentrations equal to or below 100 mg/kg [3]. HBCD in waste is allowed in concentrations below 1,000 mg/kg [4].

The REACH regulation listed HBCD already in 2011 as a persistent, bioaccumulative and toxic substance [5] and prohibited it to be placed on the market or used after 21 August 2015. After this date HBCD could still be used for EPS until 21 August 2017 by companies granted with an authorisation under REACH. Since 1 January 2015, producers in e.g. Austria, Germany and Switzerland have converted to the new polymeric flame retardant pFR.

Table 1. Allowed HBCD concentrations.

HBCD concentration	Concentration limit for HBCD in products and waste	Legislation
≤ 100 ppm	Products placed on the market (unintentional trace contamination)	EC 2016/293
< 1,000 ppm	Recovery or disposal	EC 2016/460
≥ 1,000 ppm	Physico-chemical treatment (i.e. PolyStyreneLoop) or incineration	Basel Convention

1.2. Disposal of Construction EPS Waste today

One option of disposal is mechanical recycling, where EPS waste is ground into granulate. It might be added to thermal insulation panels for instance, but also serves as an aggregate for lightweight concrete, bound EPS ballastings [6] and insulating plaster, and acts as a pore inducer in the brick industry. This recycling process is possible for packaging EPS without HBCD and construction EPS with pFR, but not for old construction EPS with HBCD, as the concentration limit of 100 ppm for HBCD in the recycled product would be exceeded.

Another option is to use the calorific value of EPS in incineration plants and cement factories: 1 kg of waste saves 1.3 litres of valuable heating oil. The advantage of this process is that the requirements regarding cleanliness of the EPS waste are low. In a large-scale test in the Würzburg waste incineration plant [7] in 2013 it was proven that burning PS foam containing HBCD has no negative effects on the environment. The flame retardant HBCD is totally destroyed [8]. Even a proportion up to 30 percent by volume (or 2 wt%) of PS foam containing HBCD at the waste incineration changes nothing in terms of the composition of the end products such as slag, dust and filtration residues, owing to the high temperature applied. This means that old construction EPS waste containing HBCD can be burned in any state of the art municipal incineration plant [9].

In many European countries landfilling is not an option, because there are restrictions for waste with a high content of organic carbon (TOC). In this respect, EPS waste is no different from other insulation material waste of organic origin such as cork, wood fibre or hemp.

In 2017 the total EPS foam waste stream in Europe amounts to 527,000 tons. Of this, 98,600 tons come from the demolition of buildings [10]. This construction EPS waste stream will increase in the next decades and secures enough input for the future physico-chemical recycling.

1.3. EU Plastics Strategy

In December 2015, the Commission adopted an EU Action Plan for a “Circular Economy”. There, it identified plastics as a key priority and committed itself to ‘prepare a strategy addressing the challenges posed by plastics throughout the value chain and taking into account their entire life-cycle'. In 2017, the Commission confirmed it would focus on plastics production and use, and work towards the goal of ensuring that all plastic packaging is recyclable by 2030 [11].

1.4. EUMEPS EU Voluntary Pledge

The association "European Manufacturers of EPS" (EUMEPS) has submitted a voluntary pledge [12] on behalf of its members, as requested in Annex III of the EU Plastics Strategy, to indicate their recycling targets by 2025. Many companies in the value chain are already working to ensure that the EUMEPS pledge can be realised.

Table 2. Recycling targets of the EUMEPS EU Voluntary Pledge.

Object	Polymer	Baseline	Pledge	Quantities 2025 (estimates)		Quality	New Technologies involved
				Market	Recycle		
Insulated Packaging (e.g. fish boxes)	EPS	Conversio Study 2017	50 %	140,000	70,000	High quality EPS	Food grade quality potential (EPS SURE)
Protective Packaging (e.g. appliances)	EPS	Conversio Study 2017	50 %	230,000	115,000	Standard EPS	
Building Deconstruction	FR-EPS EPS	Estimated 2025 market	27 %	150,000	40,000	High quality EPS	PolyStreneLoop – HBCD removal and recycling of bromine. Chemical recycling.
New build and renovation	FR-EPS EPS	Conversio Study 2017	80 %	40,000	32,000	Standard EPS	
Civil Engineering New build and Deconstruction	EPS		90 %				
TOTAL			**46 %**	**560,000**	**257,000**		

FR = Flame Retarded

2. PolyStyreneLoop – Physico-chemical Recycling

A demonstration plant in Terneuzen, Netherlands, shall demonstrate the technical, economic and environmental feasibility of a physico-chemical recycling process. It is seen as an opportunity to roll out a system where PS foams containing HBCD can be handled as part of the circular economy.

2.1. Cooperative and its Members

PolyStyreneLoop is a cooperative, currently counting 66 members from 14 European countries from the whole polystyrene value chain. The cooperative was inaugurated on 6th of November 2017. Members and supporters include flame retardant producers, styrene and polystyrene producers, EPS and XPS producers, EPS converters, waste collectors, industry associations, recyclers and machinery manufacturers.

2.2. Financing – Funding Cooperative, LIFE Grant and Bank Loan

The total investment of the project is € 10.4 million. Of this, € 2.4 million were provided by membership fees and supporter contributions. Furthermore, PolyStyreneLoop received an EU initiated LIFE Subsidy program of € 2.7 million. The project is known under LIFE-PSLOOP (LIFE 16 ENV/NL/000271) and runs from 2017 till 2021 with the option of an extension, if requested by PolyStyreneLoop. For XPS recycling a regional additional funding of € 1 million has been received from the Province of Zeeland in the Netherlands. The remaining financing needs are covered by a bank loan.

2.3. CreaSolv® Technology and Bromine Recovery Unit (BRU)

The CreaSolv® Technology is a development of Fraunhofer Institute for Process Engineering and Packaging IVV in corporation with CreaCycle GmbH (CreaSolv® is a registered trademark of CreaCycle GmbH). Plastic wastes are selectively dissolved with a specific proprietary solvent formulation. The components of the CreaSolv® Formulation are fully REACH registered and not considered as hazardous according to the Globally Harmonized System (GHS). This dissolution is a physico-chemical separation process. It is a pre-treatment technology, which has the potential to recover plastic molecules and separate them from legislated additives (like HBCD) or other impurities.

The process consists of three steps [13]. Steps 1 and 2 are pre-treatment for step 3.

1. PS foam waste is dissolved in tanks containing a PS-specific liquid. The solid impurities (dirt, cement and the like) are separated through filtration and then incinerated.
2. Another liquid is added, which transforms the PS into a gel, while the additive (HBCD) stays in the remaining liquid. The PS gel is then separated from the process liquids. Once cleaned, this gel is transferred into granulated polymer and the liquid, together with the additive, is distilled and re-used in a closed loop; the additives remain as sludge.
3. Finally the HBCD additive within the sludge is destructed in a high temperature waste incineration. During the last step the elemental bromine is recovered and can be reused to produce new products (e.g. modern flame retardants), thereby closing the loop.

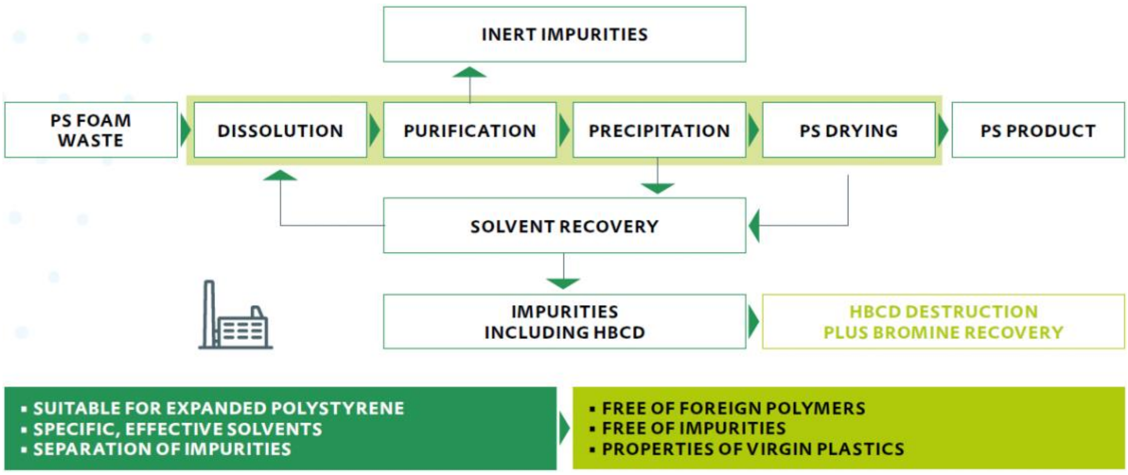

Figure 1. PolyStyreneLoop – CreaSolv® Technology and bromine recovery unit (BRU).

2.4. Technical Feasibility

The CreaSolv® Technology has been tested on laboratory scale and with PolyStyreneLoop it will be applied on demonstration scale for PS foams containing HBCD. The findings so far are that the characteristics of the recycled PS coming from PolyStyreneLoop are similar to virgin general purpose polystyrene (GPPS). The main difference is that PolyStyreneLoop GPPS recyclate is often dark, while virgin GPPS is clear. The dark colour of the recyclate comes from the carbon (graphite) that is present in part of the input material coming from new generation EPS insulation boards. As the PolyStyreneLoop project aims at closing the loop for EPS in the construction industry and the remaining graphite improves the insulating properties, less needs to be added to the raw material.

In order to utilise a CreaSolv® Plant, it is required that such a new technology be incorporated in the Basel Convention Technical Guidelines as an end-of-life (EOL) option alongside incineration. In May 2016 PolyStyreneLoop presented the CreaSolv® Technology at the Headquarters of the United Nations Environmental Programme (UNEP) in Nairobi, Kenya and got support from most global parties including many NGOs. At the 13th Meeting of the Basel Convention in Geneva in May 2017 it was finally agreed to include the individual process steps of the CreaSolv® Technology for the separation of polystyrene and HBCD as Best Available Technique (BAT) to treat PS foam waste with HBCD concentrations ≥ 1,000 ppm [14]. The guidelines are to be finalised and approved in May 2019.

2.5. Economic Feasibility

In the standard scenario, no costs for EPS waste have been set for the period 2020-2026. This stands in contrast to regulations in some countries, where it is already required to pay for the disposal of EPS waste (potential revenue upside). The forecasted sales prices have been set between the 2016-2018 sales prices of GPPS and styrene monomer. An input material conversion factor of 1.112 was taken into account. The cooperative expects that debt capital will be fully repaid in 2025.

In the worst case scenario, unlike the standard scenario, costs for the input materials occur. Although this is highly unlikely, the payback time for debt capital remains more or less unchanged.

2.6. Environmental Feasibility

TÜV Rheinland in cooperation with BASF performed a Life Cycle Assessment (LCA) [15] for the end of life treatment of EPS coming from deconstruction of External Thermal Insulation Composite Systems (ETICS). Two different end of life options for 1 ton of EPS were quantified and compared: incineration with energy recovery and the PolyStyreneLoop process. The data show that recovered polystyrene from the PolyStyreneLoop process has a 47 % lower global warming potential (GWP).

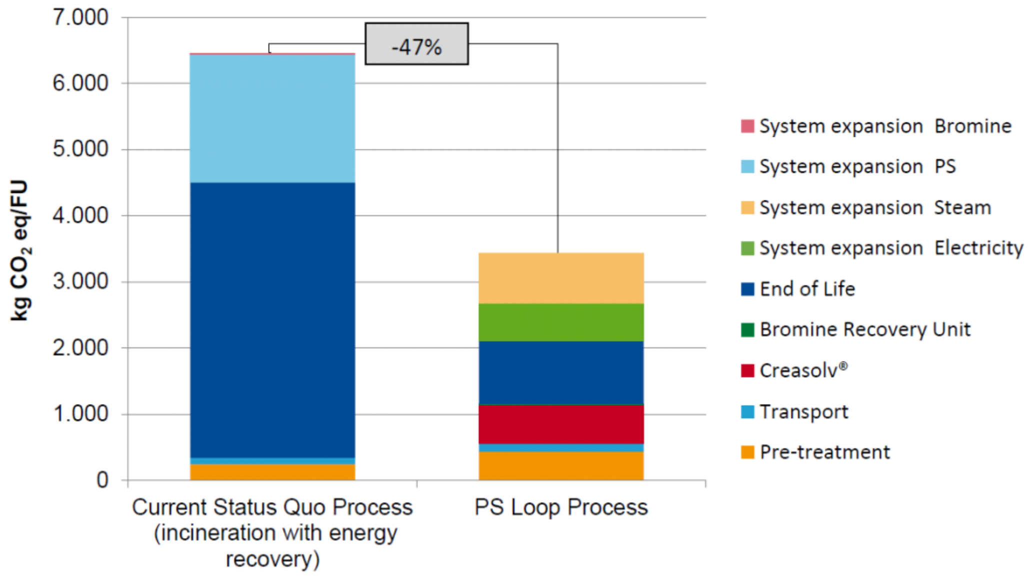

Figure 2. Climate Change in kg CO_2 eq/FU.

3. Waste Stream of Construction EPS Waste from Demolition Sites

Special attention has to be devoted to the waste stream to the PolyStyreneLoop demonstration plant, because the quality of the input material has an immediate effect on the quality of the output material. In addition, it is a crucial cost factor.

3.1. Collection and Pre-treatment

The material coming from demolition sites is collected and pre-treated by decentralized collection points, so-called HUBs. Most of the HUBs are managed by demolishers or recyclers with the necessary experience and network in the market. PolyStyreneLoop sources material only from certified HUBs. Making use of the cooperative model, only members of the cooperative can operate such a HUB.

PolyStyreneLoop requires certain input specifications regarding impurities of the material: HBCD content < 1.5 wt.%, water content ≤ 3 % and all other impurities ≤ 7 wt.% (PUR, mineral wool, cement, nails/iron and glue). Bituminous impurities are not allowed. As there are different applications for PS insulation such as ETICS or flat roofs with bituminous sheeting, the processes for deconstruction and waste treatment differ as well. A guideline for the collection and pre-treatment of PS foam waste is under preparation as part of the LIFE Grant requirements.

ETICS are widely used applications for the insulation of buildings. In Germany alone, it is estimated that between 1960 and 2012, 900 million m² of ETICS were installed of which, 80 % used EPS as insulation material. The complexity of the recycling of the EPS in ETICS lies in the fact that it is a composite of different materials such as adhesives, coating with reinforcing mesh and plaster. While the majority volume of ETICS is EPS, the insulation material itself only accounts for 10 % in terms of weight. Currently, Münster University of Applied Sciences and RWTH Aachen University are researching the necessary pre-treatment for ETICS for different utilisation processes such as PolyStyreneLoop. Through the crushing of ETICS with different stress loads, a selective pure EPS stream can be obtained. The universities are working on further optimizing the output through improved crushing. In a subsequent step, density-based sorting such as wind shifting can further concentrate the EPS fraction [16].

EPS Powerbrush [17] is a technology developed for cleaning EPS flat roof boards bond with bitumen sheets. At the demolition site the bitumen is removed by hand from the EPS boards. The bitumen is collected and follows a special recycling route. Then the EPS boards are stacked and transported to the pre-treatment plant. There the boards are sorted – to speed up the cleaning process – and fed to the EPS Powerbrush (maximum contamination 15 %). The outcome is clean EPS boards, free of bitumen, which can then be used for further recycling. The extracted impurities are finally burned. In 2014, the machine was already tested on a 6000 m² EPS flat roof.

Figure 3. EPS flat roof boards with bitumen leftovers before and after treatment [18].

3.2. Compaction

EPS is a lightweight material, because it consists of 98 % air, with a density of 11-30 kg/m³. This makes it easy to handle on a construction site, however to optimize transportation the material needs to be compacted after the pre-treatment. By compaction of the material to a density of 100-450 kg/m³ the volume is reduced by a factor 5-25.

The technology to compact EPS from demolition sites is already available and a number of manufacturers sell the necessary machinery. With mobile compactors HUBs can additionally offer the service to smaller recyclers or demolishers, which do not have the necessary machinery themselves. The temperature inside a screw compactor is a critical issue for EPS compaction, because the temperature of EPS rises during compacting. If the temperature of the material exceeds 90 °C, EPS can start to degrade. This is undesired for the quality of the polystyrene product and might lead to clogging in the screw mechanism.

XPS has a slightly higher density of 30-50 kg/m³, but may not be compacted (or even broken) without a deep cool unit, if it contains (H)CFCs, as these would otherwise be emitted.

3.3. Storage and Transportation to PolyStyreneLoop Demonstration Plant

EPS needs to be compacted into briquettes with a weight between 15 to 50 kg for better handling. The compacted briquettes are then either stored in Big Bags or stocked on pallets, wrapped in PE shrink foil. The wrapping prevents the material to become wet, if storage takes place outside, and avoids any loose material spread in the environment.

Once HUBs have collected, pre-treated, compacted and stored sufficient material, full truck loads are transported to the storage location in Terneuzen. In order to have enough feed-stock once the demonstration plant is operational, PolyStyreneLoop is already storing material from its certified HUBs.

3.4. Notification and Permits

The European Waste Shipment Regulation (EC) No 1013/2006 [19] establishes procedures and control regimes for the shipment of waste. If waste is transported across borders, a notification needs to be submitted to the authority of the place of origin by the transporting company. This requires notification (annex IA) and movement documents (annex IB). Each waste transporter is required to follow this notification procedure.

4. Future Developments

The PolyStyreneLoop demonstration plant is expected to run a test phase until 2021. In the meantime the technical, economic and environmental viability will be assessed. After successful results the concept is set to be gradually rolled-out to other locations throughout Europe coping with the upcoming volumes of PS foam waste in the following 10 years.

For XPS recycling a deep cool unit has to be installed for collecting the (H)CFC's under the Montreal Protocol.

5. Conclusions

The goal of PolyStyreneLoop is to build a plant for recycling polystyrene (PS) foam in Terneuzen, Netherlands. It shall demonstrate the safe destruction of HBCD while recycling the valuable resources polystyrene and bromine and thus closing two loops and contributing to a circular economy.

PolyStyreneLoop is a physico-chemical recycling process based on the CreaSolv® Technology. PS foam waste is dissolved and the polystyrene recovered. Subsequently, the remaining impurities including HBCD are destroyed and the bromine is recovered. This process has already been included in the UNEP Basel Convention Technical Guidelines as a best available recycling technology to handle HBCD waste. The financial plan of PolyStyreneLoop predicts a repayment of the debt capital within a few years. A Life Cycle Assessment by TÜV Rheinland certifies the environmental benefits of the PolyStyreneLoop process versus incineration.

Decisive for the success of the project will be the availability of the input material in sufficient quantity and quality. A guideline for the collection and pre-treatment of PS foam waste is under preparation. Corresponding demolition and pre-treatment techniques are already in place, further innovations are expected in the near future. In order to facilitate economic transportation, compaction of the foam waste is essential. Certified decentralized collection points (HUBs) will make sure that certain input specification will be fulfilled to ensure a smooth operation. For the transportation of waste containing HBCD across borders, a permit is required.

In 2019 the PolyStyreneLoop demonstration plant will be built. It is funded by companies from the entire PS foam value chain, and has also attracted the support of a European LIFE Grant. The plant shall be operational by the end of 2019. If the technical, economic and environmental viability will be as expected, the concept is set to be gradually rolled-out to other locations throughout Europe.

Building Physics as a Tool for Development of New Components: Roof Window

Tywoniak J[1], Calta V[1], Staněk K[1], Novák J[1], Maierová L[1]

[1]Czech Technical University in Prague, University Centre for Energy Efficient Buildings, Třinecká 1024, CZ 273 43 Buštěhrad, Czech Republic

jan.tywoniak@fsv.cvut.cz

Abstract. Knowledge and instruments of building physics (calculation methods and measuring procedures) can be used as key tools and perspectives to develop new components for building envelopes. This paper illustrates this fact by presenting the successful development of a roof window fulfilling higher requirements on reduction of overall heat losses and avoiding the risk of water vapor condensation on surfaces at very low external temperatures (thermal transmittance below 0.7 W/m^{2}K in the first generation, close to 0.5 W/m^{2}K in the second one) and better daylight distribution for the interior. This is the result of a publicly supported project with an industrial partner: from a general idea through detailed analysis of thermal performance in geometrical and material alternatives up to construction, prototyping, and verification by measurements and certification. Building physics tools applied in the project are discussed here together with lessons learned which are important for technical design. An effective shading system equipped with PV elements for energy smart harvesting is mentioned in the conclusion.

1. Introduction

Roof windows are traditionally known as the weakest part of the building envelope concerning thermal transmittance. For this reason, they are not commonly accepted by designers of energy optimized buildings (passive house level etc.). Nevertheless, they should be used in some cases and the consequence due to increased heat transmission must be compensated in order to achieve the passive house criteria [1]. On the component level, there is a usual requirement for cold moderate climate not to exceed thermal transmittance of 0.8 W/(m^{2}K) by keeping the linear thermal transmittance due to connection to building envelope negligible. These values should be critically analyzed with respect to specific situations of roof windows in order to derive correct targets for new developments.

2. Comparison to vertical windows in the wall

By comparing roof windows with vertical windows in walls, the following significant differences can be found (see Fig.1, Fig.2):

- Heat transfer in the air cavities between glazing panes is larger due to increased heat convection caused by air movement (the more inclined the more significant.) Result: U value increased in the range of 0.1 – 0.2 W/(m^{2}K), relative to the whole window.

- Heat transfer in the connection of the window to the opaque part: In roof windows a very important problem arises from the geometrical situation (Fig.2). The external perimeter of the window is situated in the cold area of the roof. So, it is not possible to achieve the so called thermal-bridge free solution (see Fig.3). The result is expressed as linear thermal transmittance ψ [W/(m.K)] in the range of 0.05 – 0.03 W/(m.K) by optimized solution.
- Surface heat transfer coefficient h [W/(m^{2}K)] describing the heat transfer between internal surface of the window and surroundings varies. In the case of larger vertical windows one can expect the standard values across the area [2]. In smaller, inclined roof windows, additionally often influenced by heaters close by, the situation can be dramatically different: To be on the safe side from the energy perspective, the h-Value can be up to twice as high as the standard value. This is the preliminary result of our own in-situ experiments.
- The radiation heat exchange between the external surface and the (clear) sky [3] is higher for roof windows (e.g. multiplied by factor 1.5 for 45° sloped windows). This fact leads to an increase of the total external surface heat transfer coefficient.
- Passive solar gains in the rooms and risk of their overheating is primarily influenced by the orientation of the façade/roof, by the shading from external obstacles, by shading devices, and by the coefficient of the permeability of total solar radiation (solar factor) g [-] of glazing unit. The overall effect cannot be related to window quality itself. It depends on several other parameters of the (occupied) room, including thermal inertia, ventilation strategy and actual climatic data. Generally, there is a higher passive solar gain due to the inclination of roof windows. Moreover, efficient external shading such as venetian blinds are not applicable for roof windows.
- Specific effects can be observed in roof windows in summer conditions: The external air can be significantly warmer close to the roof surface (heated by the roof covering) compared to climatic data. This further increases the risk of the room overheating.

From the list above can be concluded that the actual desired U-value of roof windows for passive house quality must be lower compared to vertical windows. It should be 0.7 W/(m^{2}K) or less, ideally approaching 0.5 W/(m^{2}K). Simple parametric studies (Fig.3) have shown that the unavoidable heat transfer due to the thermal coupling of the window to the roof plays an important role, especially in energy optimized windows. Corresponding compensation must be found in other components of the building envelope.

For this reason it is recommendable to integrate the additional heat transfer due to thermal coupling in the (extended) thermal transmittance $U_{w,inst}$ to have a „full picture" in one value [4]:

$$U_{w,inst} = \frac{A_g . U_g + A_f . U_f + \Sigma(\psi_g . l_g) + \Sigma(\psi_w . l_w)}{A_g + A_f}$$

where the $\Sigma(\psi_w . l_w)$ describes the influence of installation. It is illustrated in Fig.2 for a hypothetical window of excellent quality: Assumed thermal transmittance of the glazing unit U_g 0.60 W/(m^{2}K), frame U_f 0.60 W/(m^{2}K), thermal bridges of glazing edge expressed by linear thermal transmittance ψ_g 0,03 W/(m.K), thermal bridge due to installation in the roof (ψ_w 0.05 W/(m.K), considering the reference window size 1.14 m x 1.40 m. It can be seen that for improvements of roof windows all parts are of a high importance: glazing, frame, installation method and overall geometry.

Summer situation should be analyzed carefully as well and new ways of effective sun-protection should be found.

- Requirements on U-value of the roof construction result in overall thickness approx. 400 mm and more. This can negatively influence the daylight quality due to very deep side lining. Therefore, the daylight distribution in rooms as the primary function of each window should be studied very carefully as well.

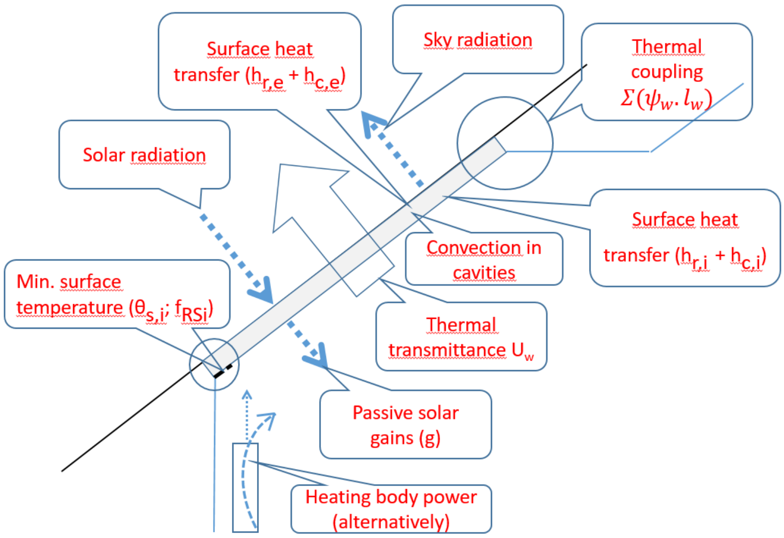

Figure 1. Significant thermal phenomena related to roof windows.

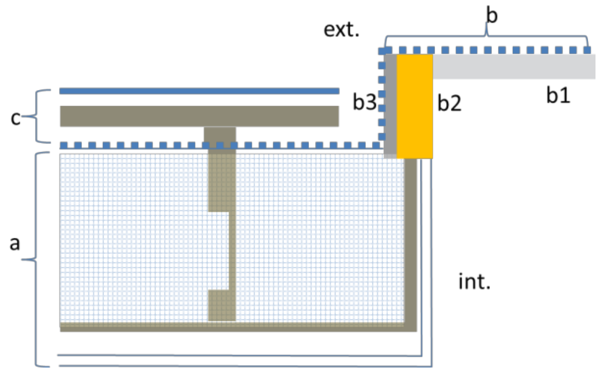

Figure 2. Schematic horizontal cross section of a typical position of roof window in a pitched roof. Dotted line represents the surfaces exposed to the exterior temperatures. (a typical pitched roof assembly (from interior): indoor gypsum board lining, OSB boards, thermal insulation, protective membrane open to water vapor diffusion), b roof window (simplified): b1 glazing unit, b2 frame and sash, b3 possible additional thermal insulating shield), c roof covering)

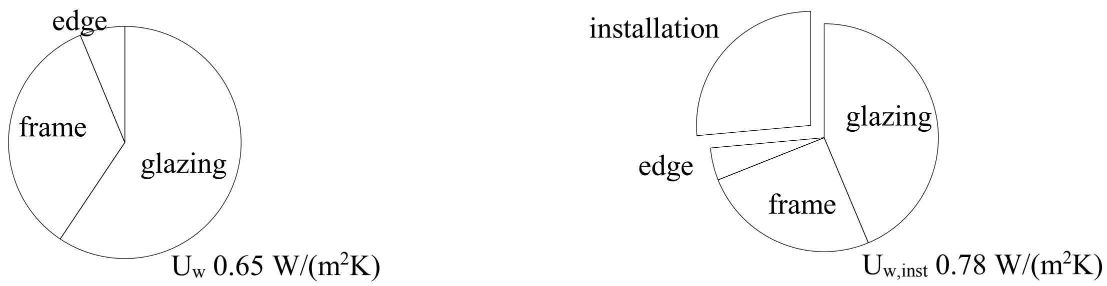

Figure 3. Result of a parametric study for (hypothetical) excellent roof window. Heat transfer (left), heat transfer including the effect of installation into roof (right) based on 2D calculations for all relevant cross sections.

3. Other technical and non-technical facts

Of course, not only building physics related phenomena should be studied before starting any development works. From the discussions with the experts (including unpublished results of questionnaire campaign) one can conclude following: a. total weight of the window should not increase, b. installation work on roof should not be more complicated, c. acceptable price increase of new, high performing product is approximately 10-20 %.

4. Methodology

Several steps were performed in order to support the development activities in close cooperation with our industrial partner:

a. Introductory parametric studies based on repeated 2D-heat conduction calculation [5,6]. Search for general relation among geometry of frames, position of glazing, material and construction. The quality of glazing unit and methods of installation in the roof were set as fixed.
b. The construction team selected a solution from parameters found in a), and a 2D-heat conduction calculation was used to check its plausibility, respecting the technological limitations. Some prototypes were built accordingly after.
c. Measurements in climatic double-chamber. Prototype installed in a fragment of roofing structure for studying surface temperatures on window and lining.
d. Detailed 2D-heat conduction calculation supporting fine-tuning in detailing of selected prototypes.
e. Declarative heat transfer calculations. Estimation of thermal transmittance (U-value) for standardized reference window size, estimation of temperature factor for evaluation of surface temperatures. Performed for promising alternatives and for two types of glazing units.
f. Simulation of daylighting in the room [7]. Study of influence of side lining geometry (perpendicular and slanted, "open" to the room).
g. Measurement of daylight distribution on a model of under roof space in the scale 1:4 under artificial sky. Alternatives for different side lining geometry were analyzed.
h. Catalogue of overall solution in interactive form. It serves for the selection of proper alternative including detailed solution of roof construction and joints window-roof considering type of construction, roofing and geometry.

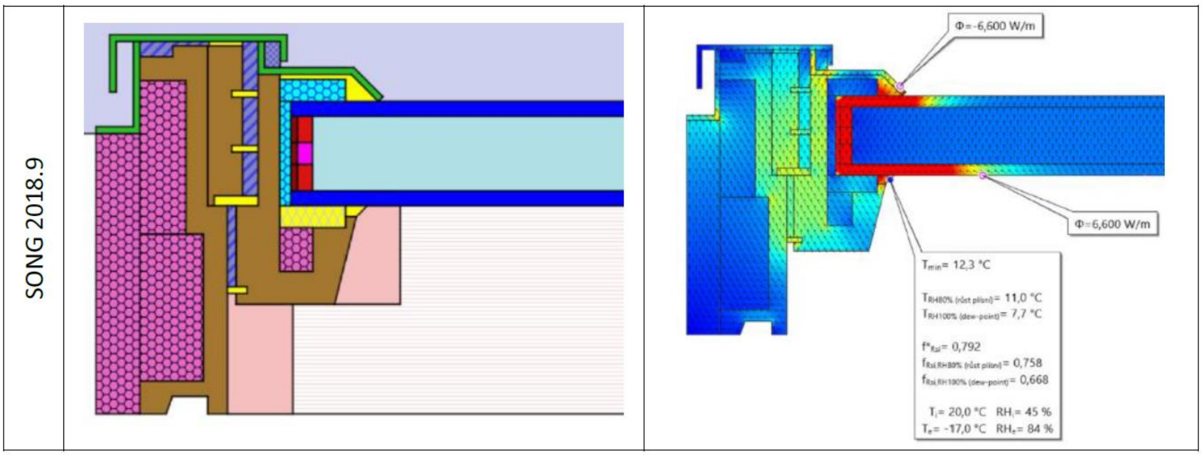

Figure 4. Example of analysis. Left: simplified geometry of a cross section. (Violet color corresponds to hardened polystyrene placed in the window frame, brown for wood, turquoise for aerogel stripes.). Glazing unit with two transparent foils. Right: Results of 2D-heat conduction calculation in HT-flux software.

5. Results

For the real technical solution, the following principles were applied:

a. Profiles made of hardened polystyrene (thermal conductivity 0.039 W/(m.K) are used here in combination with wood for increasing of thermal resistance of the frames in both directions, perpendicular and parallel to roof layer (Fig.4).

b. Glazing unit: Triple glazing with thermal transmittance 0.5 W/(m^{2}K) or special glazing having two transparent foils between glazed panes (glazing pane – air gap – foil – air gap – foil – air gap – glazing pane) with thermal transmittance 0.3 W/(m^{2}K) are applied alternatively.
c. No additional insulated mounted frames in the roof are used.
d. Surface temperature is safe: high enough to prevent the risk of condensation of water vapor, including all critical areas.
e. Smart detailing can be applied for even higher surface temperatures at the edges (use of aerogel stripes).
f. Slanted side linings are recommended in most cases in order to support better daylight distribution in rooms. Additional slightly increased heat transfer due to limited space for placing of the thermal insulation is neglectable.
g. Low emissivity coating at external surface of external glazing can be advantageous additionally.

Based on the results of standard calculations (reference size of window, vertical position, standard value of surface heat transfer) it can be concluded that U-value of 0.7 W/(m^{2}K) is feasible with our newly developed frame for usual triple glazing and near to 0.5 W/(m^{2}K) for glazing with two foils (with extra bonus of lower weight).

Figure 8. Figure shows the prototype presented at a building fair in September 2018.

6. Conclusion and outlook

In general, roof windows cover only a small area of the overall building envelope of each house. But their influence can be significant. During the project with the industrial partner a new generation of roof window was developed, including sub-variants. Technical information and construction detail can be found in an interactive catalogue [8], adjusted for different roof construction. Analyses using building physics tools played a key role in overall process. One prototype was tested on all obligatory parameters according to EN 14351-1 [9] in independent certification institution with very good results (thermal transmittance, airtightness, resistance against wind driven rain). The first product is ready to be placed on the market, but the development can continue.

We tested the possibility of further reduction of thermal transmittance to 0.4 W/(m^{2}K) level which seems to be possible through significant change of the frame construction using identical materials. On the other hand, we should keep in mind the additional heat transfer caused by thermal coupling to roof construction: In such case it will be in the same range as the window itself. Therefore, a future development should be focused on other phenomena, especially on reduction of overheating risk by keeping the daylight quality in interior.

Exterior shading system with integrated function for roof windows was designed (patent pending). Such system consists of a set of movable lamellae, partly covered by photovoltaics elements. The small amount of harvested energy is used preferably for fans supporting the air movement in the air cavity between shading and external surface of glazing and it is used for movement of lamellae as well. Such system can operate partly in autonomous mode or according to information from local control unit or superordinate control unit of the house.

Abstract. Hospitals produce high amounts of emissions due to their continuous operation, high flow of people, and intensive HVAC requirements. In order to reduce the environmental footprint of hospitals, it is crucial to improve energy performance while still maintaining a comfortable indoor environment for the occupants. Also to avoid high environmental burdens, it is important to understand the impact of building material selection from the full life cycle perspective. Window systems influence the energy loads and comfort in buildings and provide access to daylight and views. Therefore, windows contribute significantly to the energy consumption and indoor environmental quality of buildings and impact the well-being of occupants. The aim of this study is to determine the influence of various window system design configurations on the environmental performance of patient rooms in Belgium through life cycle assessment (LCA). The method is innovative as it combines dynamic energy simulations and daylight analysis and integrates these in the LCA study of the window systems. The influence of several components is investigated, such as the choice of glazing and shading system. The results are analysed and compared in terms of energy cost for heating, cooling, and lighting, daylighting performance and life cycle environmental impacts. A typical patient room from a hospital design in Belgium is used as a case study. Based on comparative analysis, the paper discusses potential window system design configurations that allow for energy efficient, daylit and environmentally-friendly patient rooms.

1. Introduction

Hospitals are large consumers of natural resources and energy due to their continuous operation, high flow of people, intensive HVAC demand and artificial lighting requirement. In order to reduce the environmental footprint of hospitals, it is crucial to moderate operational energy use through enhanced energy efficiency while still maintaining a comfortable indoor environment that supports the health and well-being of the occupants. So as to avoid high environmental burdens, it is important to understand the impact of building material choices from a full life cycle perspective. Window systems influence energy consumption and thermal/visual comfort in buildings and profoundly affect the indoor environmental quality by providing access to daylight and external view. Therefore, in order to reduce energy demands, emissions from energy use and the environmental burden associated with the choice of building materials, selecting the appropriate window system configuration is a fundamental part of the early design stage decisions and are difficult to change later on.

Literature review shows that only a limited number of studies address the environmental performance of window systems [1,2,3] and there appears to be no study focusing on combining dynamic energy simulations and daylight analysis and integrating these aspects in the LCA study of the window systems. There is hence a need for integrated performance analysis of window systems in patient rooms and this paper provides the first step towards this approach.

This paper presents an integrated approach for the LCA study of the window systems where the link between various window design parameters, and their combined effect on energy consumption, daylighting and environmental impacts are considered. The aim is to determine the influence of various window system configuration on the energy cost, life cycle environmental impact and daylighting in patient rooms. The effect of several components, including glazing type and shading device configuration is investigated. The various window system design alternatives are explored through parametric modelling. The key objective of this study is to identify window system configurations which balance the objectives of a daylit, comfortable and energy efficient patient room with the least environmental impact. The methodology combines dynamic energy simulations, daylight analysis and integrates these in the LCA study of the window systems. The methodology was applied to a typical patient room from a hospital design in Belgium.

2. Methodology

This paper investigates the effect of window system design on the life cycle environmental impact of the patient rooms. The alternative design options are evaluated in three steps. In a first step, the environmental impact study, the energy cost for heating, cooling, and daylight-linked artificial lighting and the daylighting performance of different window systems without any shading device are carried out. In the next step, various shading device configurations are added to the windows and the different design alternatives are evaluated based on environmental cost, energy cost and daylighting. After analysing and comparing the data for each glazing type, the design options with the least environmental and energy cost and higher access to daylight are identified. The final step provides a side-by-side comparison of the benchmark design (without shading) with the best performing selected design options with shading for each glazing type.

The patient room is modelled in Grasshopper [4], which is a plugin for Rhinoceros (3D modelling tool) [5]. Ladybug & Honeybee [6] components for Grasshopper are used to assign detailed patient room simulation parameters including construction types, materials and schedules to the model. Parametric simulations are performed using the Grasshopper plugin Colibri [7] and for the energy and daylighting analysis Ladybug & Honeybee are used to interface with the simulation engines EnergyPlus, Radiance and Daysim. The LCA was performed using the "MMG+_KU Leuven" tool which is an Excel-based tool developed at the research division of Architectural Engineering at KU Leuven in collaboration with VITO (Vlaamse Instelling Voor Technologisch Onderzoek) and BBRI (Belgian Building Research Institute).

2.1. Simulation model description

The patient room dimensions are 4.0 m x 6.0 m x 3.0 m (length x width x height) with 40% WWR (Window-to-Wall Ratio). The simulations only take into account the floor area occupied by the patient, the service area is excluded from the model (see Figure 1). In order to investigate the impact of glazing characteristics on the performance, six glazing types are considered. The double/triple glazing consists of 4 and/or 6 mm glass panes with 15 or 16 mm cavity (90% argon). The Berkeley lab WINDOW 7.6 software is used to determine the thermal and optical characteristics of the glazing. Table 1 lists the key properties of the glazing and Figure 2 shows the position of the coating within the glazing. The uncoated glazing acts as a benchmark for understanding the impact of the coating. Coated aluminium is the choice of material for shading devices. The patient room has one external wall (U-value = 0.22 W/m^{2}K) with a single window facing south; all other surfaces are assumed adiabatic. The patient room is located on the second floor and no external obstruction is taken into account. The simulation is performed with the EnergyPlus weather data for Brussels (latitude 50.90° N and longitude 4.53° E).

2.2. Energy analysis

EnergyPlus is used to calculate the annual energy use for heating, cooling and artificial lighting; taking into account the solar and thermal properties of the glazing with detailed layer by layer modelling of the glazing system. Daylight-linked lighting control is employed which incorporates a lighting schedule generated by Daysim software using Honeybee component for annual daylight simulation. The illumination threshold for activating lighting is 300 lux, as this value represents the illuminance necessary for simple examination and reading. The lighting sensor is placed at the patient's position to ensure sufficient light at this location.

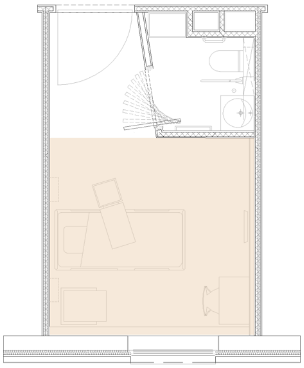

Figure 1. The patient room area taken into account for parametric model dimension

Table 1. Glazing characteristics

GLZ [Tvis/g-value]	Configuration	Coating features	U-value (W/m^{2}K)
GLZ1 [0.82/0.80]	4-16-4	No coating	2.50
GLZ2 [0.73/0.41]	4-16-4	Solar control + Thermal insulation	1.10

Dotted line: position of coating(s)

Space heating and cooling setpoint temperatures are assumed to be 21°C and 24°C respectively. Mechanical ventilation and infiltration are set to 2.00 (ac/h) and 0.20 (ac/h) respectively. These assumptions are in line with standards provided for patient rooms in Belgium. Mechanical ventilation is modelled with heating and cooling using the EnergyPlus Ideal loads system; the effects of heat recovery and economiser are included. In order to calculate the energy cost for heating a global system efficiency of 0.85 and for cooling a CoP (Coefficient of Performance) of 1.80 are considered. Natural gas (heating) and electricity (cooling and artificial lighting) prices (€/kWh) are based on the Belgian market prices of 2017; the price of electricity for one kWh is approximately four times the price per kWh of natural gas.

2.3. Daylight analysis

This study used climate-based daylight modelling which provides hourly daylight predictions for an average year derived from weather data. Honeybee is used to interface with the Radiance based daylighting analysis tool Daysim. The output from Daysim is a data file containing the annual illuminance/luminance values for the analysis points in the room.

UDI (Useful Daylight Illuminance) and sDA (spatial Daylight Autonomy) are used to assess the daylighting performance. The metric $sDA_{300/50\%}$ describes the percentage of an analysed area that meets the target illuminance of 300 lux for at least 50% of the annual occupied hours. This threshold also represents the "minimum" daylight provision value required by CEN daylighting standard (EN 17037: 2018) on the task plane during more than 50% of the daylight hours [8]. $UDI_{100\text{-}2000lux}$ determines when daylighting levels are within the range defined as useful for the occupants and $UDI_{>2000lux}$ presents the times when excessive levels of daylight could lead to visual discomfort [9]; This metric could also act as a proxy for detecting the likely appearance of glare. UDI metric describes the hourly varying daylight illuminances for the entire year at each of the calculation points [9].

The daylighting simulation is performed from 6 AM to 9 PM, as during this period of the day the patients need daylight/lighting. The task plane level is located 0.9 m above the ground (bed surface) with a grid of sensor points with a 0.3 m spacing, the reference point (sensor) location is selected based on the patients position in the room (see Figure 1). The walls, ceiling, floor and shading device reflectance are assumed to be 50%, 80%, 20% and 60% respectively.

2.4. LCA study

The "MMG+_KU Leuven" tool is based on the MMG method: the national method in Belgium to quantify the environmental performance of building elements. The LCIA (Life Cycle Impact Assessment) method applied in the MMG method combines the environmental impact indicators CEN and CEN+ [10]. The CEN indicators consist of seven environmental impact categories in line with the European standard and the CEN+ indicators include ten additional impact categories considered in Belgian legislation. For each impact category, the results are expressed as characterised results (equivalents) and as external environmental costs (monetary values, €). The environmental life cycle costs are calculated by multiplying the characterization values by a monetisation factor. This value represents the costs required to avoid, repair or compensate the damage caused by the environmental impacts [11]. Further details regarding this method can be found in De Nocker and De Backer [12].

The environmental impacts associated with each glazing type are assembled based on the data obtained from the AGC (Asahi Glass Co., Ltd) Glass Europe. The aluminium shading material is modelled via SimaPro and the environmental impacts are calculated. These inventory data are then further processed in MMG+_KU Leuven tool. In order to calculate and study the life cycle environmental impact of the patient rooms, the selected design options are modelled in the MMG+_KU Leuven tool (with and without shading device). In this study energy consumption data estimated via EnergyPlus is the basic input for the MMG+_KU Leuven tool.

3. Result and discussion

3.1. Step 1

In this step, for each glazing type the environmental impact, annual energy cost, $UDI_{100\text{-}2000lux}$, $UDI_{>2000lux}$ and $sDA_{300/50\%}$ are calculated without a shading device. The data obtained from this step acts as a benchmark for analysing the impact of shading devices on environmental performance. It should be noted that the criteria taken into account for evaluating the performance of the design options are environmental cost, energy cost, $sDA_{300/50\%}$>50% and UDI.

As can be seen in Figure 3, uncoated double and triple pane glazing (GLZ1 and GLZ4) show the highest energy and environmental cost due to higher heating and cooling loads. Moreover, triple pane GLZ6 which has a g-value of 0.38 and the lowest U-value among the glazing types shows the least energy and environmental cost; this is due to the lower heating and cooling loads. As for daylighting performance GLZ6 still maintains a sufficient level (58% sDA). The results show that there is ca. 18% difference between the sDA value for the highest (GLZ1) and lowest (GLZ3) light transmission glazing. However, GLZ3 has the highest $UDI_{100\text{-}2000lux}$ and lowest $UDI_{>2000lux}$ compared to the other glazing types which indicates higher access to useful daylighting levels and visual comfort.

3.2. Step 2

The second step consists of analysing different overhang and fixed horizontal louvres configurations for each glazing type. The parameters of the parametric analysis are shown in table 2. The shading device depth range is in accordance with the suns position for this latitude (peak sun angle is ca. 63°) and the height of the window. The shading devices are modelled without mounts and/or anchors. The performance criteria taken into account for evaluating the performance of the design alternatives are similar to the previous step. After adding the shading devices to the benchmark design and running the simulations it is evident that for some coated glazing a higher WWR (50%) is required due to the fact that the sDA$_{300/50\%}$>50% criterion is not met. However, for each glazing the design option without shading device still acts as a benchmark for that type of glazing.

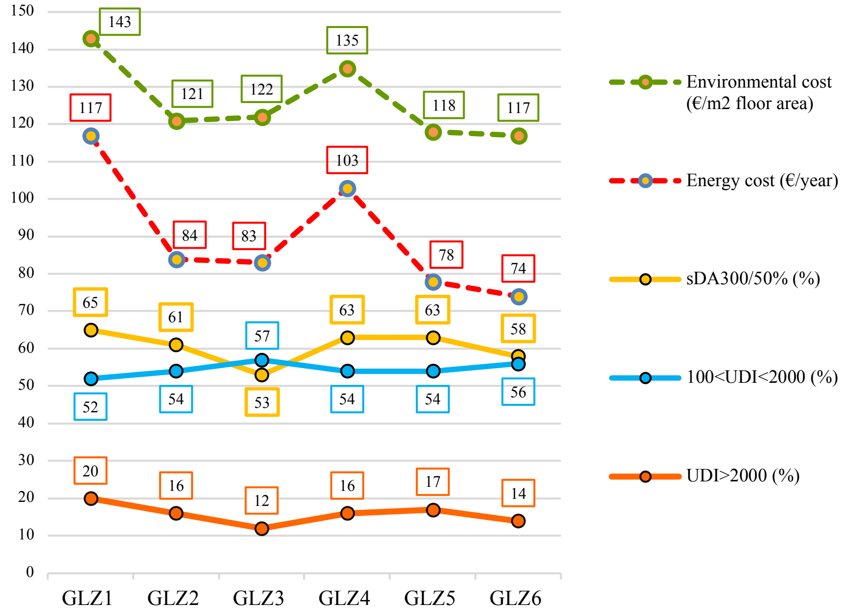

Figure 3. Benchmark designs performance without shading device (40% WWR – South orientation)

Table 2. Value of parametric variables

Variables	Minimum	Maximum	Step
Overhang depth	0.5 m	1.0 m	0.10 m
Slat depth	0.1 m	0.3 m	0.05 m
Number of slats	5	10	1

3.2.1. Overhang. In this stage for each glazing type, the design option with the least energy cost and sufficient daylight (sDA$_{300/50\%}$>50%) are selected; shown as highlighted grey cells in Figure 4. The results show that overhangs decrease sDA levels but still increase the useful daylighting levels and visual comfort (lower UDI$_{>2000lux}$) for all glazing types compared to the benchmark design even for coated glazing with higher WWR (50%). Moreover, the increase in window size for coated glazing designs results in slightly higher energy costs. In the next phase, the environmental cost of the selected design option for each glazing is calculated. As can be seen in Figure 5, the options with uncoated glazing (GLZ1 and GLZ4) and GLZ6 have the highest and lowest environmental costs respectively, similar to the previous step. The results show that the selected designs with coated glazing have higher environmental costs compared to the benchmark design, this is due to the increase in window size (50% WWR) which leads to higher quantities of overhang material and energy loads.

3.2.2. Fixed horizontal louvres. In the first phase after running energy and daylighting simulations for all glazing types the design options that meet sDA$_{300/50\%}$>50% criterion are identified and highlighted in a light grey tone as shown in Figure 6. The darker grey cells represent the slat depth which shows better energy and daylighting performance for the specified number of slats for each glazing type. The results show that the selected design options (darker grey cells) for each glazing type have fairly similar energy costs and the main difference between the options are the daylighting levels. In the second phase, the environmental performance of the selected design options for each glazing type are calculated and analysed, see Figure 7. The findings show the environmental impact of each design option is directly linked to the quantity of material used for the shading system. However, for designs with coated glazing the difference between the best and worst case scenario is ca. 2.5%. As for uncoated glazing design options the difference is less than 2%; this is due to lower operational energy use for cooling. The results indicate that the optimal shading device configuration differs based on the project goal i.e. in this study the goal is to have the least environmental and energy cost with sufficient daylighting levels and visual comfort. The black cells in Figure 6 show the best performing design option for each glazing type that fulfils this goal.

3.3. Step 3: Side-by-side comparison

Figure 8 and 9 show the side-by-side comparison of the benchmark design (without shading) and the optimal design options for each glazing type with shading devices. Figure 8 shows that the design options with fixed horizontal louvres have better performance in most analysed criteria compared to the other designs, except for higher environmental costs in some design options. This is due to the quantity of the material used for the shading system, which in some cases is slightly higher. Moreover, some design options with horizontal shades show lower sDA values (ca. 10% less in the most extreme case) compared to the benchmark design but still maintain a sufficient level ($sDA_{300/50\%}$>50%). The comparison also shows that fixed horizontal louvres reduce UDI>2000 lux values which could reduce the likely appearance of glare and increase visual comfort. The results, as can be seen in Figure 9, reveal that GLZ5 and GLZ6 design options show the least environmental impacts compared to the other glazing. This is mainly due to lower operational energy use for heating and cooling. As for GLZ5 design option with louvres this is also the result of smaller window size and less quantity of shading material.

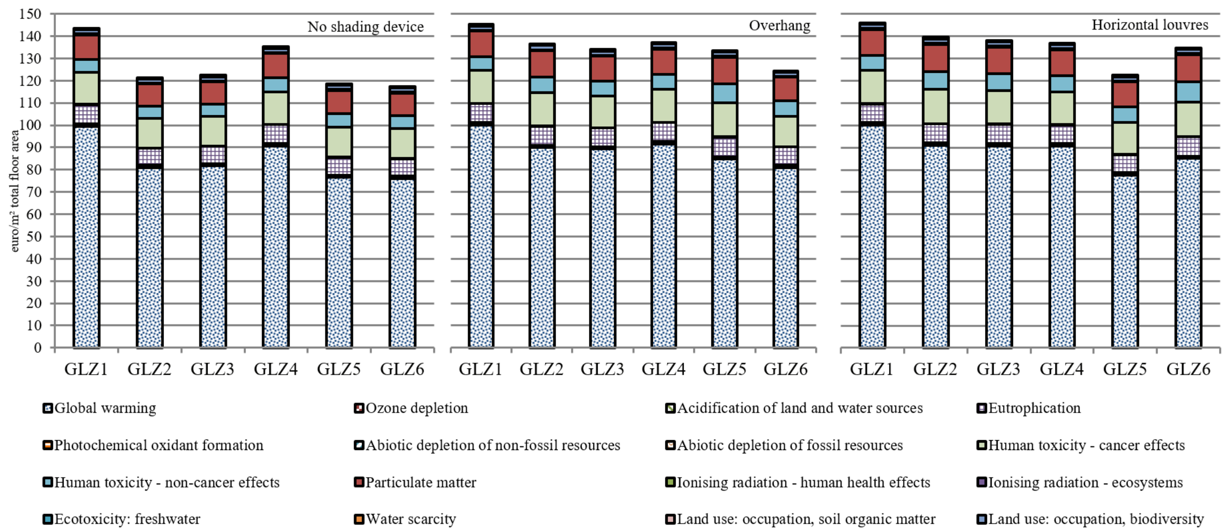

Figure 9. Side-by-side environmental performance comparison of the benchmark designs (without shading) with the selected best performing design options with shading device

4. Conclusion

The findings show that the glazing characteristics and the shading device configuration impact the design performance significantly and hence the selection and configuration of the window system design should be considered carefully during the early design process. The results highlight the fact that the window size and shading device configuration have a major impact on daylighting levels and visual comfort. This is especially important for patient rooms where adequate daylighting level is necessary and the patients have limited movement and generally are unable to adapt by moving around in the space. It is observed from the results that in the design options with shading, the main contributors to the environmental impacts are the window size and the quantity of material used for the shading system. The results show that design options with coated glazing have lower life cycle environmental impacts compared to options using non-coated glazing with similar conditions due to the reduction in energy use. The results also indicate that the most significant environmental impact indicators in all the design options are associated with global warming, particulate matter formation and human toxicity (cancer effects). This study shows that a comprehensive and integrated performance analysis approach is required to have a correct insight into the window system design performance. It can be concluded that a parametric study which considers the impact of window system design options (WWR, glazing characteristic, shading device, etc.) on various performance criteria (energy cost, environmental cost, sDA, UDI, etc.) can assist architects in understanding the cross effects. Thus, this approach can support the selection process of the most preferred window system design configuration based on the project objectives.

Abstract. To reach the environmental goals set by EU, Energy Performance of Buildings Directive (EPBD) and national building regulations will demand reductions in building's energy consumption. Energy consumption goals for buildings are pursued through high thermal performance building components (HTPBC). Paradoxically, building regulations have no requirements regarding the embodied energy of buildings and components. To meet the requirements set by governments, HTPBCs in most cases require an increasing embodied energy (from insulation), assumed to be paid back during the service-life of HTPBCs. Accounting for decarbonization of the future energy supply, the expected payback might not be feasible in terms of total environmental footprint, since the future energy supplies are expected to be greener than the building's embodied energy. Using roof windows as a case study, we assess if strict demands for building's energy consumption, will lead to more sustainable buildings if all temporal variations in terms of global warming impacts across the service-life are taken into account. A comparison of double and tripple glazed windows reveals that the expected net energy savings obtained during the use phase are compromised by relatively higher impacts induced in the production stage. The case study indicates requirements of building's energy performance might compromise the overall sustainability of building component solutions, as the additional embodied energy required to produce triple glazed windows most likely will not be compensated for by saved operational energy, when taking into account the forecasted decarbonatization of the building energy future supply.

1. Introduction

Life Cycle Assessment (LCA) of building components can be used to select environmentally favourable building components. Many building components have service-lives in the order of decades and sometimes half centuries [1]. LCAs of such components are most often conducted in a formalised manner relying on standardized and traditional product system modelling principles assuming that the foreground and background systems of building components remain unaltered across the entire service-life of the building components, even in the case when the service-lives amount to 5-6 decades. For some building components serving solely ornamental purposes, lasting the entire service-life of the building and not demanding any replacement nor maintenance across the service-life of the entire building, the changes in the background and foreground systems of the product system will most likely only have moderate to low influence on the overall environmental performance of the component. The limited influence of the temporally dependent system changes on the environmental performance of such building components, stems from fact that the changes in the foreground and background systems only will affect processes taking place after installation which for the such "passive" building components is limited to disposal or rather End-of-Life (EoL) processes. On the other hand will the environmental performance of building components serving functional purposes (i.e. structural, thermal, light transmission etc. purposes), needing replacement(s), needing energy supply, demanding maintenance during the service-life of the building in which they are installed, to a much larger extent be influenced by temporal changes in the foreground and background systems. The reason for the much larger influence of temporal changes in foreground and background system on the last group of "active" components is caused by the fact the systems supplying these component e.g. energy supply systems, systems producing replacement components etc. will inevitably change over time most often becoming more resource and often (not always) also environmentally efficient meaning that the overall environmental performance of the building components most often improves if temporal changes are accounted for in LCAs of components. The fact that the LCA framework from early on was not envisioned to account for temporal system changes, makes accounting for temporal changes (obviously) quite tricky, since the most elementary parts on an LCA i.e. inventory data and product system modelling both are designed not to be able to account for temporal changes.

Irrespective of the obstacles encountered by life cycle assessors when attempting to conduct temporally dependent LCAs, a recent review introducing a much-needed terminology for temporally dependent LCAs (see Sohn et al., 2019), reveal that approximately a dozen temporally dependent LCAs have been conducted and published so far. The concept introducing review by Sohn et al. [2] further reveals that time dependency in LCA is not a single concept, but rather a concept that can be applied to all of the four ISO defined phases of an LCA, meaning that a fully dynamic (i.e. dynamic in all 4 LCA phases) LCA (a so-called DLCA – which is yet to be seen) will have to include a fully dynamic goal and scope definition, fully dynamic inventory, fully dynamic impact assessment and a fully dynamic interpretation phase. If not all stages of an LCA are made dynamic the outcome is what is referred to as "a partially Dynamic LCA" or rather pDLCA.

The term *dynamic* is a word that most often causes a lot of confusion, but which basically can be boiled down to one single modelling issue – time dependency. However, time dependency can as illustrated by Sohn and co-workers be introduced in LCAs using off-the-shelf software and data sources. Basically there are two types of time dependent LCAs: prospective and dynamic LCAs. Two fundamental points in time are needed in order to distinguish between the two types of time dependent LCAs: t_0 (the time the first activity in a product system takes place) and $t_{terminal}$ (the time where all activities in a product system ends). Depending on the number of (time) steps between t_0 and $t_{terminal}$ the difference between prospective and dynamic LCAs is revealed. If the number of time steps accounted for between t_0 and $t_{terminal}$ equals 1 then the assessment is referred to as a prospective LCA. On the other hand, if the number of time steps between t_0 and $t_{terminal}$ is larger than one 1 then the assessment is considered a (fully/partially) dynamic LCA.

In the study at hand we present comparative LCAs and pDLCAs (i.e. a novel form of LCA) of double and triple layered windows assessed as a building component both disregarding (i.e. LCA) and taking into account (i.e. pDLCA) carefully selected time dependent changes in the energy systems providing the necessary energy to heat the building in which the windows are installed and the systems that provides the energy needed to produce and dispose of the windows during the service-life of the building in which the windows are installed. The functional unit applied is hence "Allow daylight into a building, through a window with an area of 1.6m2 with a light transmittance of at least 0.7, placed in the roof of a residential building, at an angle of 45◦ for 40 years".

The purpose of conducting such an assessment is to illustrate how time dependent inventory changes in a building LCA may affect the results. Here we are merely illustrating how installation of a window (i.e. double or triple glazed Velux (2019a) [3] and Velux (2019b) [4] affects the environmental performance across the entire service-life of a single family when assessed in a conventional and dynamic LCA manner and hence a non-standardized form of LCA.

2. Method

For the assessment the attributional LCI modelling framework was be applied, in accordance with the ILCD recommendations for decision context C1 [5]. This study applies cut-off allocation, meaning that recycled materials are considered "burden-free", and only the impacts related to the recycling process and associated transportation are attributed to subsequent cycles of the service-life cycle of a product. However, the primary user does not benefit from producing the recyclable materials either [6].

Figure 1 presents the product system assessed along with the system boundaries of our study. In accordance with Figure 1, the analysis includes all life cycle stages from cradle to grave. The product systems compared include all processes which are required to provide the functions/service of the windows, including upstream stages (i.e. extraction and production of raw materials and manufacturing), the use stage and downstream stages (i.e. disposal and end-of-life).

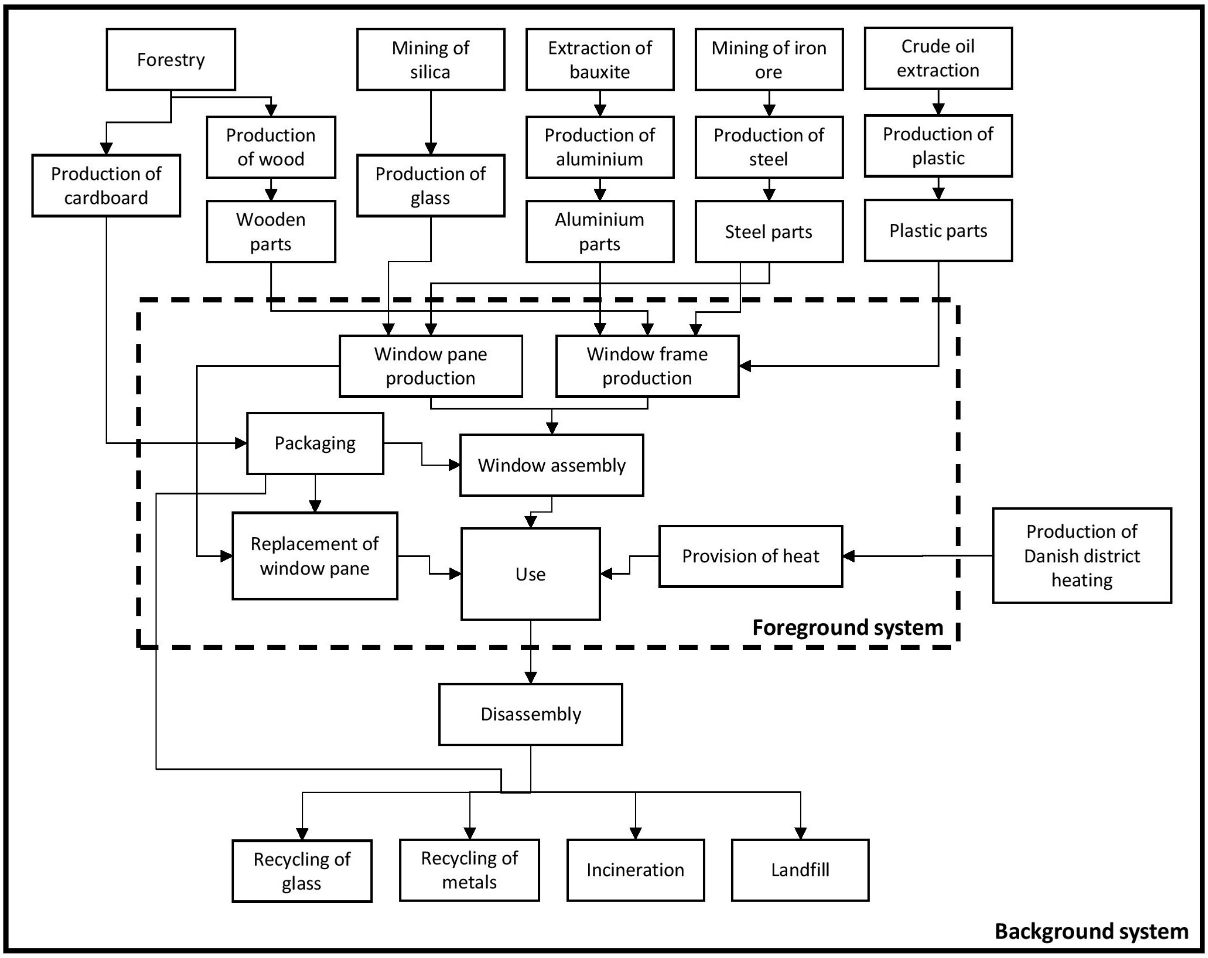

Figure 1: System boundaries representative for our case study of skylight windows. The dotted line delineates the foreground system which covers the production as well as the use of the windows. Arrows represents mass- as well as energy flows.

Upstream processes include extraction of resources, e.g. mining of metal ore, sawmill activities, extraction of crude oil and production of materials such as aluminium and wood profiles used in the production of the window pane and frame.

Assembled windows are after production transported to retailers and subsequently distributed to residential buildings. The use phase includes, in our case, replacement of the window pane and the sourcing of indoor heating compensating for heat loss/gain through the window (i.e. the systems is intended to include the thermal properties of/service provided by the windows). Maintenance (i.e. cleaning of the window is excluded in our assessment), as cleaning activities mainly depend on end-user preferences and hence subjective preferences. The EoL of the windows covers disassembly, transport to a waste receiving/processing facility, and terminal disposal of the materials. Steel and aluminium are assumed to be recycled. Glass from a demolition project often end up as landfill, as the recycling processes of window glass are both expensive and complicated [7]. Hence, here the disposal of glass is modelled as landfill. Wood is assumed to be incinerated while plastics and cardboard are disposed of through a combination of landfill and incineration processes.

Figure 2 depicts the temporal scope of the systems assessed. The skylight window is produced in year 0 (here 2018) and the panes replaced after 20 years (2038) in year 20, 70% of the pane packaging material is assumed to be used again. The disposal of the entire window (frame and window pane) takes place in year 40 (2058). The window has an estimated service-life of 40 years inducing an annual impact during the service-life, on top of the pane replacement, proportional to the additional heat consumption induced by the window.

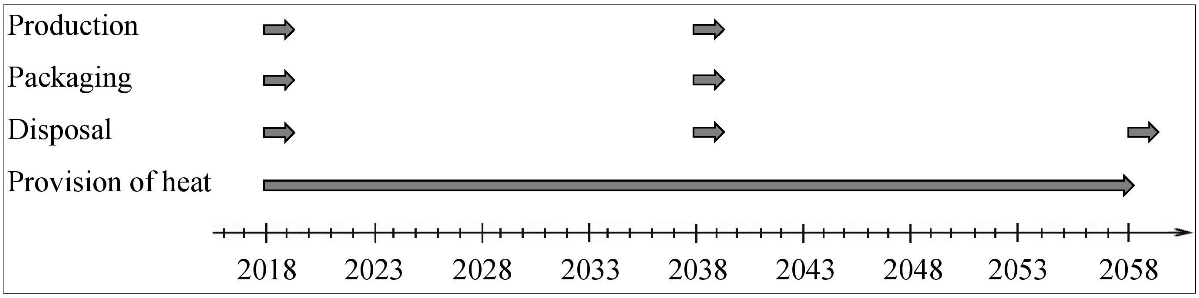

Figure 2: The temporal scope illustrates which years the processes occur. Short arrows indicate an intermittent process, whereas the long arrow indicates a continuous process taking place the entire service of the building in which the windows are installed.

The service-lives applied in our assessment of the windows and the panes are based on average estimation proposed by the Danish Building Research Institute's (SBi) and other industry stakeholders [8].

Our study assesses the service-life aggregated environmental performances expressed as climate burdens induced by installation of double and triple glazed skylight windows. The heat consumption, of the windows during their service-lives, is calculated as if the windows were installed in a newly built house, a renovation project and as if meeting the thermal reference requirements Eref. The provision of district heating (compensating for the heart loss induced by the windows) is modelled according to five different forecasts of the future energy grid. A total of 30 scenarios was hence analysed and are presented in Table 1. The 30 scenarios are split on 3 different "application contexts" of the windows defining the energy balance of the context in which the windows are installed:

- Window installation in a standard/common Danish one family house in the form of the socalled reference as presented by SBi (2018) [9] modelled as a newly built house according to BR18 for a low energy building.
- Window installation in a basic one family house from SBi modelled as a renovation project according to building regulations 1977 [10].
- Using the "raw" energy balance, E_{ref}, as an average window orientation specific energy balance for the window.

The life cycle inventory (LCI) data of the foreground system in terms of manufacturing were provided by the window manufacturing company. The background system was modelled using average processes in accordance with the ILCD recommendations [5]. All systems were modelled using the ecoinvent 3.4 database.

Table 1: The scenario overview shows the 30 scenarios assessed in our evaluation. An "x" indicates the included window type, calculation method and DHG scenario.

Heat grid 4: Hydrogen				x					x					x					x					x					x	
Heat grid 5: Fossil					x					x					x					x					x					x

Practical reasons made it necessary to assume that the technology for production and the handling of EoL would not change within the next 40 years, although this might not be temporally representative (at all – hence a partial dynamic assessment!). The new window pane, which is estimated to be installed after 20 years use of the window, will hence be produced applying the same technology as used today. It is considered out of scope for this project, to forecast such waste processing technology innovations. The thermal energy consumption across the use stage was modelled relying on forecasts. Our assessment is hence applying a dynamic perspective for the energy supply.

3. Results

The Global Warming Potential (GWPs) quantified for the LCAs of double and triple glazed skylight windows covers 30 different result sets. In order to organise the presentation of the results, two default scenarios were selected. The default scenarios include the energy composition grid 1 (i.e. wind, pls. see Table 1), while the calculation of the quantification heat consumption is based on the newly built reference house as presented by SBi (2018) [9].

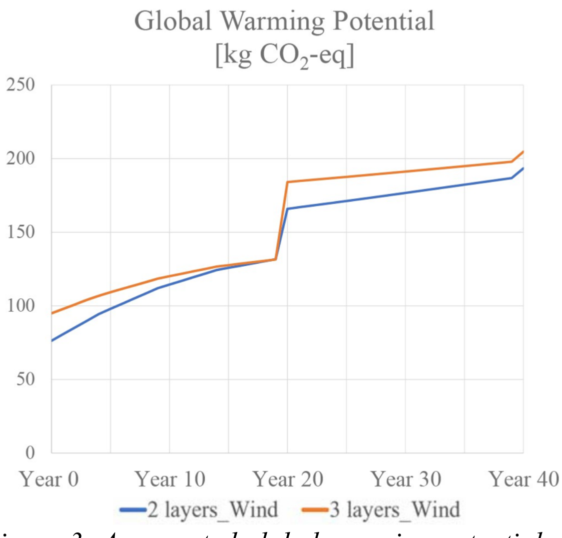

Figure 3: Aggregated global warming potentials, for scenarios 1 and 16. The scenarios are based on DHG 1 (pls. see Table 1), and the energy consumption is calculated for installation in the newly built reference house relying upon a dynamic energy supply.

Thus, scenario 1 for the double glazed window and scenario 16 for the triple glazed window are presented here in the paper (more result combination will be presented during the presentation at the conference), unless otherwise stated.

Further diversification of the results in accordance with Table 1, focusing on energy supplied by wind, biomass and hydrogen are presented and compared in Figure 4.

To assess whether the orientation of the windows will induce changes to the conclusions drawn in the study presented here, different window orientations were also tested and assessed. Double and triple glazed windows were (thermally) modelled as oriented south and north, respectively. The results were compared with the weighted orientation used in the remainder of this study.

Figure 4: Accumulated GWP of double and triple glazed skylight windows modelled in 3 different application situations new building, a renovation project and a reference scenario (i.e. raw energy balance of the window), 4 different energy supply scenarios; 2 layers=2 layered glass, 3 layers=3 layered glass, Wind=wind energy dominated scenario, Biomasse=biomass dominated energy scenario, Bio+=biomass+biogas and Brint=Hydrogen

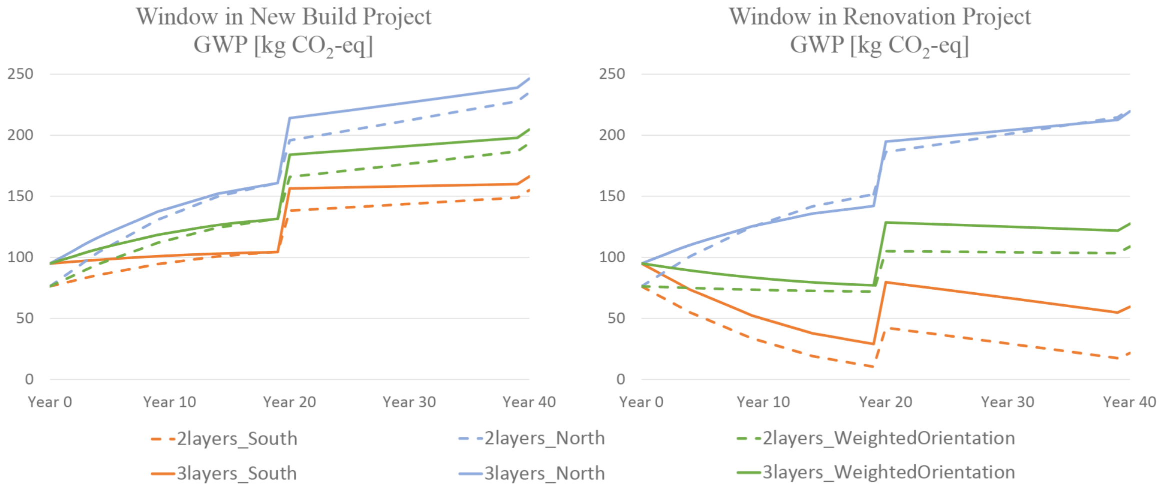

Figure 5: Accumulated GWP of north, south and weighted orientations when windows are applied in the reference house and assessed using a dynamic energy supply. Solid lines represent the 3 layered glass and dotted lines represent 2 layered glass .

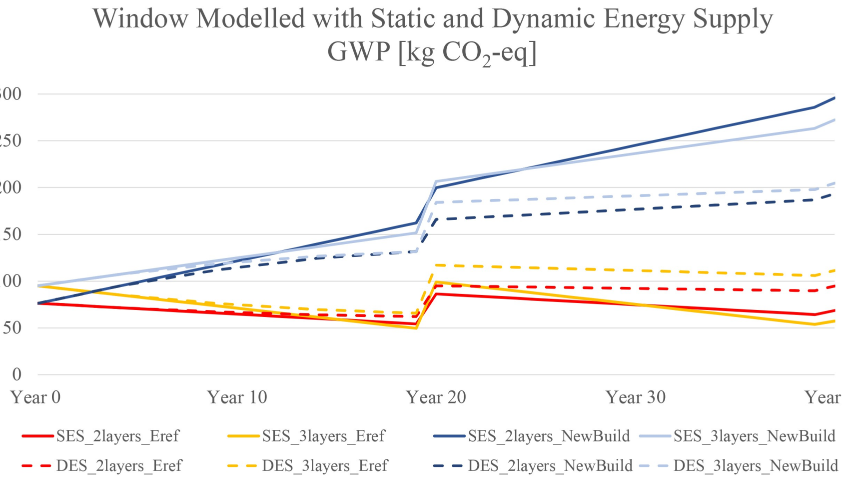

Figure 6: Accumulated GWP of double and triple glazed windows modelled with a dynamic energy supply (DES) and a static energy supply (SES). The colours illustrate the same window (i.e. the same application context and amount of glazing units) modelled with a static grid (solid lines) and a dynamic grid (dotted lines).

4. Discussion

For the application of a dynamic energy grid composition which is highly dependent on wind power, the results reveal that triple glazed windows in terms of GWP are performing inferior to double glazed windows as presented in Figure 3.

Figure 4 shows that the accumulated GWP of the double glazed window is lower compared to the triple glazed window independent of the various dynamic future energy supplies. Figure 4 also shows that the four fossil free scenarios for the future Danish energy grid composition induces similar impacts of comparable magnitude for the same window and applications.

The orientation analysis results as presented in Figure 5 does not deviate from the overall results: The orientation of the window does not change the fact that the GWP of triple glassed windows exceeds that of the double glassed windows if changes in the energy supply, compensating for the energy loss induced by the installation of the windows, is accounted for assuming a sustainable (which for a Danish context most likely will be wind power based) future thermal energy supply.

Results presented in Figure 5 on the time aggregated GWP of the double and triple glassed windows show that double layered glass performed better than triple layered independent of whether the windows are installed in a reference building representing the (recent) historical average building or in a new building complying with the Danish 2018 building requirements. On the other hand, Figure 6 shows the importance of using a dynamic approach instead of a static approach. Indeed, the best performing alternative, in terms of climate change, actually flips from triple layered to double layered when assessing the GWP performance of the two windows applying a dynamic approach.

5. Conclusion

Our results show that, when applying a dynamic energy grid, compensating for the heat loss across double and triple layered windows, and assessing the GWP of these two types of windows, reveals a consistent preference for double layered windows. Introducing a thermal energy provision from a temporally dependent source complying with the Danish energy policy, reveals a more complicated picture. Applying a dynamic energy supply reveals that that flip in preference observed yielding and overall preference for triple glazed windows does not occur if the assessment takes into account a greening of the energy supply. Generally the differences in GWP performance are so small that these are considered within the uncertainties of assessment form, meaning that the correct conclusion to the study is that: *by taking dynamic changes in the energy supply of buildings into account, it is illustrated that there is no (statistically significant) reason to choose triple glazed windows over double galzed if only considering GWP performance of the building and choosing triple glazed windows could yield GWP over-optimized buildings.*

Perimeter blocks in different forms – aspects of daylight and view

Sundborg B[1,2], Szybinska Matusiak B[1], Arbab S[1]

Bengt@dtark.se

Abstract. The perimeter blocks in cities are usually rectangular and follow the streets. The buildings are mostly of similar height within each block. However, perimeter blocks can be developed in many various forms. Geometric options such as chamfered corners, varied building heights and different positioned openings in a broken perimeter block are analyzed in this paper regarding the aspects of views and daylight in city planning. The choice of evaluation criteria is based on scientific discourse in the field of daylighting. As in the new European standard, "Daylight in Buildings", the following three parameters are included in calculations: solar radiation, daylight level and view out. Computer-based daylighting simulations and calculations of view parameters are performed for different designs of the perimeter blocks with equal density, FAR = 1.33. The simulations have been carried out for Stockholm. That means roughly the same shadows as in Oslo, Helsinki, Tallinn, St Petersburg and Anchorage, all close to the same latitude (60°N). In lower latitudes, e.g. Southern and Central Europe the shadows are shorter. Nevertheless, the ranking of the alternatives will be similar. This study confirms that geometrical changes can improve the conditions for views and daylight in the perimeter blocks. The advantages in the tested urban design alternatives are considerable compared to the perimeter block of the standard type.

1. Introduction

Many different aspects shall be considered in the design of buildings. The famous old principle: "Form Follows Function" is important and has great relevance also in the construction of modern sustainable settlements.

However, in the pursuit of densification and economical optimization, the issues of views and daylight are missing in many projects. Those aspects are strongly dependent on the shape of buildings and their close surroundings. This study aims to show how the shapes of urban blocks can be developed to improve the daylight access and the views in urban settlements. The improved quality of daylight and view in the studied alternatives can be reached with the same density Floor Area Ratio (FAR) as for the conventional alternatives. The density is here defined as FAR, Floor Area Ratio = total floor area/plot area. A constant value of 1.33 has been chosen where the entire plot has been enclosed by 10 meters of street, which means a total area of 80 x 120 meters (1,33 corresponds to 2,13 counted on only the built plot of 60 x 100 meters). A Floor Area Ratio (FAR) of 1,33 is a relative low value for central districts but high in a suburban context.

In an economical assessment, based on prices on the market, the improvements in daylight should be weighed against the added cost for the improved building shape. Potential savings in energy consumption for the electric light must be calculated as well as other relevant values in the total economical overview.

2. The Alternative Types of Perimeter Blocks

The book Urban Forms [1] describes the development of the urban block from the middle of the nineteenth hundred until now with many influential European examples and even some American new urbanist projects. The book raises questions how we can keep qualities from the old town districts in our contemporary developments. The French-British quartet of authors advise a detailed look at existing settlements considering their morphology including the scale, the streets and the shape of the buildings. Inspired by this book we examine some very typical urban layouts focusing at daylight and views.

An extensive investigation of the heat energy demand including the daylight aspect was done in 2014 with comparison of many different city districts in Berlin, Paris, London and Istanbul [2]. The approach in this study is different; we consider only a few simplified configurations to quantify and explain the impact of the specific shapes. An important study by Mark DeKay describes how the different geometry of a standard atrium building impacts daylighting conditions [3]. Atrium buildings are often erected as perimeter blocks and DeKay touches on certain variations. We aim at extending the knowledge with research on some more shapes. International comparisons over rectangular street grids show large variation from town to town. Some have quadratic shapes but most of the grids have rectangular shapes with considerably different dimensions (length vs width of the block). The variation of the street grids within a town is smaller. The usual regulations for the urban blocks within a specific city district contain standardised measures of length and width.

This study looks to possible alternative regarding the shape to the conventional perimeter blocks in street grids. Following sustainable design recommendation, the blocks are oriented east-west. Different compass directions will be investigated in future research. Larger urban blocks have the advantage of being able to contain more complicated structures of buildings. Such blocks also create long facades, which is a disadvantage regarding uniformity and has been pointed out by urban theorists as e.g. architect Rob Krier. The assumed size of the blocks has dimensions which are easy to analyse; 100 meter in east-west direction and 60 meter in north-south direction. The scale is representative for the Nordic countries as well as the rest of Europe though the average size of blocks is larger.

The famous study of different built forms by Martin and March had three alternatives: (a) 'pavilions', (b) 'streets', and (c) 'courts' [4]. The third alternative consists of perimeter blocks. In this study differences between several alternatives of perimeter blocks are examined. We look more in detail to the town planning than common in urban studies. The first alternative to the standard perimeter block is the same block with chamfered corners, a modification which is often used. The most famous example is the large extension of the old city during the nineteen hundred in Barcelona. Chamfered, instead of right-angled corners in the court yard have been used from time to time world-wide. The sizes of the chamfered corners in this study are based on functional aspects regarding the windows and following the principle of keeping the same floor area ratio as in the standard block. This principle is true in all alternatives.

Other options to develop the block are openings between the streets and the courtyard. The experience of the neighbourhood depends on how the openings are positioned, i.e. in the corners of the block or in the middle of the blocks. In frequent practical use these two types vary both in proportions and in scale. This study explains the experiencers in physical figures on daylight and sightlines. The two last alternatives with variated heights, 4 and 5, are developed within this project in an attempt to find new strategies. All alternatives have been developed in Sketch Up-drawing, see figure 1.

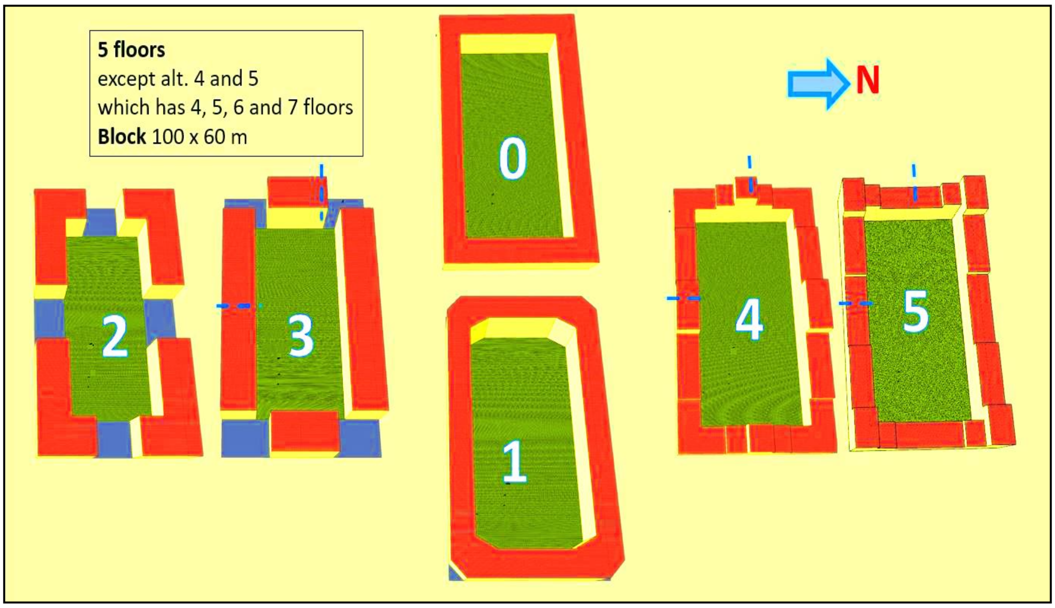

Figure 1. The six different types of urban blocks.

0. The conventional perimeter block (NULL) 0 is followed by five alternatives:
1. Chamfered corners in the outer corners of the building as well as in the courtyard.
2. Openings in a broken perimeter block positioned in the four midpoints of the building.
3. Openings in a broken perimeter block positioned in the four corners of the building.
4. Varied building heights around the courtyard with fewer floors in the corners of the block.
5. Varied building heights around the courtyard with more floors in the corners.

3. Daylighting Strategies in Urban Settlements

It is impossible to create satisfactory daylighting conditions during the whole day in dense settlements. It is always necessary to resolve the priorities between outdoor and indoor spaces as well as which parts of the day and the year. Especially difficult to handle is the sunlight at high altitudes due to the large variation of the azimuth angle (compass direction) during the day and across the seasons, as well as low average solar elevation angles through the year.

To develop strategies for daylight requires a focus on the different times of the day. In people's every-day life the needs and desires vary depending on the type of buildings such as buildings for seniors, offices or kindergartens as well as the activity. A midwinter strategy leads to openings between the buildings in a North/South direction which is opposite to a strategy for the extended summer when the sunlight from east in the morning and west in the evening is highly appreciated. We have many possibilities to formulate goals and evaluation criteria connected to them, and it is easy to calculate many relevant metrics by computers. However, joining strategies together (e.g. making calculations on the yearly basis) often fails because the iterations will converge instead of diverge.

During many years' equinox studies have been very popular among practitioners as well as researchers. But the equinoxes are not suitable to analyze sunlight from east or west simply because in those two days the sun is positioned precisely at the east or west during sunrise or sunset, also it is on the horizon. That gives strong arguments for studies between equinox and summer solstice. The classic Bioclimatic Chart is still relevant, it describes the limits for human outdoor comfort depending on temperature, humidity, air movement and solar radiation [5]. The outdoor temperature in most Nordic cities is not high enough to create comfort (temp. > 20o happens only occasionally) - compare the Chart with climate data as https://climatecharts.net/. Nevertheless, in the cities along the Oslo/Stockholm/Helsinki latitude, the period around May 1st is the time when people start to sit outdoors thanks to the direct sunshine, example on the Nordic climate see figure 2. To improve human comfort by developing spaces with much sunshine/heat, sunlight strategies should be accurately tested. This study is intended to contribute to this development.

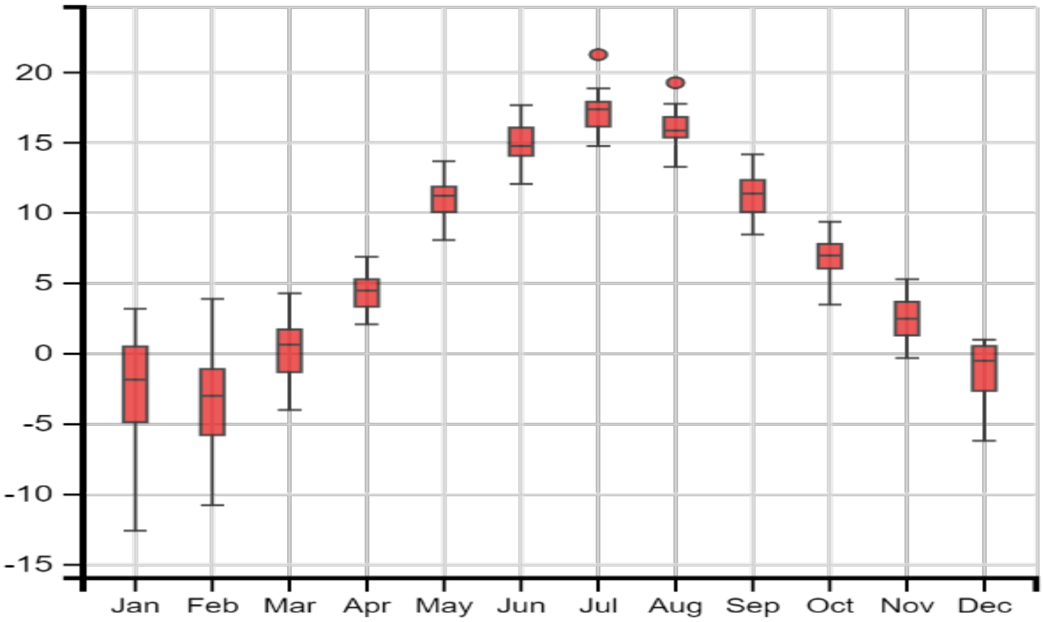

Figure 2. Distribution of monthly mean temperature (C°) Stockholm, Sweden. (data:www.ncdc.noaa.gov/ghcnm/ distribution, © www.climatecharts.net)

3.1 The Shadow Maps

Shadow Maps are important tools in town planning. The shadows from surrounding obstructions as mountains, trees and buildings affect the conditions at the outdoor spaces as well as in apartments. Most of the obstructions are permanent. The shape, size, orientation and position of the building must therefore be developed during careful considerations. The shadow map also specifies surfaces on ground and facades which have sunlight qualities outdoors and indoors. That information can be used by planners to create daylight qualities for the residents.

The comfort zone for sitting outdoors in the sunshine on the balconies and in the courtyards can also expand by windscreens in cold days and by sunscreens in hot days. The needs of daylight vary, both in quantity and quality, between different groups of people and even between individuals. Anyway, we may roughly agree that in residential areas interesting periods to study are in the morning and in the evening because almost all residents are at home, contrary to during noon when people are at work, schools and on weekend trips, etc. This is also the most difficult time for daylighting due to lower sun angles than at noon. Besides the shadow maps for the western sun (representing even the eastern sun in the morning) we also show the less critical shorter shadows in the middle of the day. The western sun represents also the eastern sun in the morning because the shadows are the same although mirrored in the opposite direction.

All the blocks in the study are orientated in east-west direction. The position of the sun is in the west in the shadow patterns at the top, in the other six in the south, see figure 3. Depending on the clockwise movement of the sun the shadows also move. The minutes just before and just after the exact cardinal directions for the sun are especially interesting. All the facades orientated to the south can be in sunshine at 18:07 PM but on the contrary at 18:08 PM the facades orientated to the north are in sunshine (Stockholm, Latitude 59.3, 1st of May, DST = Daylight Saving Time). The shadows for the 1st of May also describe the conditions at the 11th of August. During the 101 days in between the sunlight distribution is better with a maximum at summer solstice.

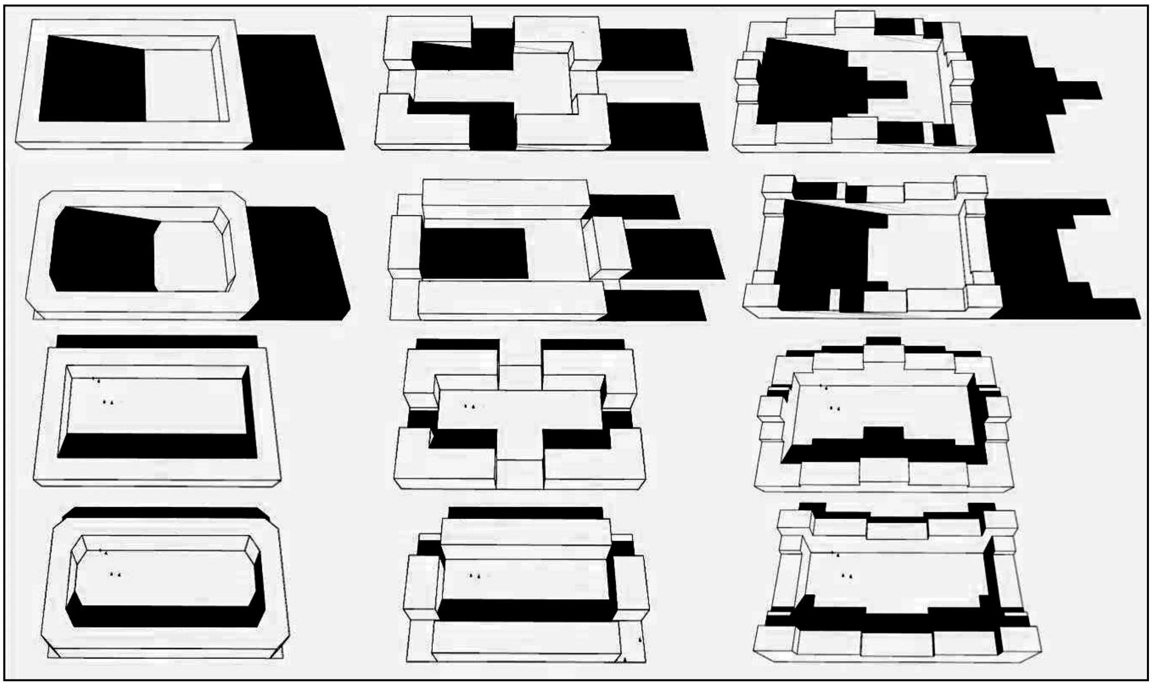

Figure 3. Shadows the 1st of May. Latitude 59,3. The six evening patterns at the top has sun in the west, the six lower patterns are at noon and has sun in the south.

The alternative with its chamfered corners (alt. 1) has very similar shadow patterns as the conventional perimeter block (alt. 0). Both alternatives have advantages. The best in the alternative 1 is the orientation of the windows in the chamfered corners. They result in more diffuse daylight and longer sightlines see table 1 and 2. Considering openings to the courtyard, it is better with the openings in the corners of the block (alt. 3) than in the middle (alt. 2) regarding the facades and its windows. The alternative with lower heights in the corners (alt. 4) has better daylight condition on the windows than the conventional perimeter block with five floors all around. In the alternative with higher heights in the corners (alt. 5) the advantage is a sunny spot in the middle of the courtyard.

4. Assumption of the facades as representative for the windows

The generated data is for the facades except for the ground values. Solar radiation on facades and daylight level on facades are values in our studies to describe conditions at the windows. We assumed that the windows are evenly distributed along the facades. This assumption is common in general studies as ours because no special details or local conditions are known.

5. The Daylight simulations

The methodology of the daylight simulations is based on the scientific discourse in the field of daylighting with origin from an early European collaboration [6] and recently formulated in the EU standard [7]. Each alternative of settlement has been analyzed in a cluster of 3 x 3 blocks, all the same type. The daylight conditions in the six alternatives are described in the following way:

- Sunlight radiation on façades and on plots, average values, during the 1st of May from sunrise to sunset (kWh/m^2).
- Sunlight radiation on the first floor of all facades, average values.
- Vertical Sky Component on the first floor of all façades (VSC), average values. 50% is the maximum value.
- Sky Component on the plot area (SC), average across the plot; 100% is the maximum value including visual access to the whole hemisphere.

The facades on the upper floors have good distribution of sunlight in all alternatives. The challenge is to create good daylight even for the worst cases, that is the first floors. Therefore, we have separate calculations for the first floors regarding both radiations and vertical sky component.

All the simulations are performed with DIVA for Rhino, a well-recognized tool for climate based and static daylighting calculations. The DIVA (Design, Iterate, Validate and Adapt). A plug-in for Rhinoceros software, enables effective calculations of daylight metrics, e.g. daylight factor, using the Radiance/Daysim engine. The climate data for Stockholm was used as well as its geographical location. By keeping the reflection factor of the block surfaces and the ground close to zero (0,01%) the daylight factor script in DIVA was used to calculate SC and VSC.

Table 1. Results of the Daylight Simulations

Model	**Radiation, first floor** (kWh/m2)	**Radiation, façade** (kWh/m2)	**Radiation, courtyard** (kWh/m2)	**VSC, 1st floor** (%)	**SC, courtyard** (%)
Alt. 0	**2.41**	**2.72**	**3.42**	**34.40**	**70.91**
Alt. 1	**2.47**	**2.77**	**3.41**	**35.28**	**69.98**
Alt. 2	**2.45**	**2.75**	**3.65**	**35.28**	**73.17**
Alt. 3	**2.47**	**2.78**	**3.07**	**35.35**	**65.73**
Alt. 4	**2.32**	**2.73**	**3.32**	**33.85**	**69.54**
Alt. 5	**2.33**	**2.72**	**3.55**	**33.70**	**72.39**

The following observations may be done based on the simulation results. With chamfered corners (alt 1) the solar radiation on the facades and the vertical sky component are higher compared to the alternative conventional perimeter block (alt 0). Regarding the courtyard the result are the opposite, higher for the conventional perimeter block (alt 0) due to slightly lower obstruction angles.

With openings to the courtyard (alt 2 and 3) the solar radiation on the facades and the vertical sky component are both higher compared to the alternative conventional perimeter block (alt 0). Regarding the courtyard the result is the highest for openings to the courtyard in the middle (alt 2) and the lowest for openings in the corners (alt 3).

With the same height of all parts of the building (alt 0) the solar radiation on the facades are almost the same compared to the alternatives with varied heights (alt 4, 5) except for the first floor where it is higher. The shadows are slightly smaller along the facades with lower heights in the corners of the block (alt 4) and slightly smaller in the courtyard with higher heights in the corners of the block (alt 5). Further studies are needed to explain all results regarding variations of the height.

6. The Views in the Urban Areas

The quality of views in the outdoor environment depends on people's visual experience. Qualitative details such as beautiful streets with well-designed outdoor furniture and decorative façades are important elements of the visual perception. A good example on opinions and desires about the view from a window is a study at an office from 2015 [8]. Beautiful distant views were not highly ranked as expected which show how important it is to investigate the actual specific situation because human perception is complex. Town planners must exploit opportunities relying on development of the architectural details of high quality. Anyhow, the length of the sightlines is regarded as the positive contributor of the view quality and is reviewed in this research. It may give a basis for the layouts of attractive views.

6.1 The View Calculations

The views in the six settlements of different urban blocks have been compared. That means that the distances of the horizontal sightlines from each window were calculated regarding the obstructing surrounding buildings using the Grasshopper software. All distances are in meters. Two types of distances have been calculated for each window:

1. Average distance to obstructing facades.
2. Perpendicular distance to obstructing facades.

Then the averages from all windows for the whole block have been processed for both values. All distances to the obstructing facades in the surrounding buildings are measured within a 138-degree cone except for the perpendicular distances. The cone represents the average visibility from a window considering the reduction caused by the obstructions in the window frame. In an earlier study about Tower Blocks we calculated that angle [9].

Limitations and assumptions for the calculations of the alternatives (see figure 1) are:

• For the first four block alternatives, model 0-3, all facades have been analyzed in 2D regarding maximum free view, minimal free view, perpendicular view and average free view (m) for one floor (all five floors have the same conditions). For options 4 and 5, all facades have been analyzed in 2D regarding maximum free view, minimal free view, perpendicular view and average free view (m) for all seven floors.

• Each block structure has been analyzed in a cluster of 25 x 25 blocks where the center block refers to the block on which the measurements were made. Each quarter's façade has been served with measuring points at ~ 2 meters intervals and all facades have been analyzed. Each measuring point has 416 (1080 for 360 degrees) range measurements in the 138-degree cone.

• All analyzes of the view have taken place in 2D along the horizontal plane. Max length for free view is set to 1000 m. 90% of the length of the façade has been analyzed, so as not to create measurement points directly adjacent to the building's corners.

Table 2. Results of the View Simulations

Model	**138° width obstruction distance,** average (m)	**Perpendicular obstruction distance,** average (m)
Alt. 0	**36.56**	**35.67**
Alt. 1	**39.24**	**37.23**
Alt. 2	**41.13**	**26.78**
Alt. 3	**43.98**	**36.47**
Alt. 4	**55.68**	**39.61**
Alt. 5	**55.01**	**35.41**

In the case of a closed perimeter block it is better for the views to develop chamfered corners (1 better than 0). In addition, when building a closed perimeter block it is also better for the views to develop a variation in heights (4 and 5 is better than 0) because it offers long sightlines. In the case of a perimeter block with openings, the openings in the corners give longer views. (3 is better than 2). The average distances to the opposite façade are illustrated by colours in table 3 in the first row. The steps are from the EU standard, the chapter for view recommendations:

EU standard: 6 m ≤ **Minimum,** RED < 20 m ≤ **Medium,** YELLOW < 50 m ≤ **High,** GREEN

Table 3. Perspectives of obstruction distances and solar radiation.

Model	Alt 0	Alt 1	Alt 2	Alt 3	Alt 4	Alt 5
138 Width obstruction distance, average (m)						
Solar Radiation, (kWh/m2)						

7. Conclusions

The research shows advantages regarding views and daylight for most alternatives compared to the conventional perimeter blocks. It is quite understandable that openings to the courtyards are effective but the choice between openings in the corners or in the middle of the block depends on the local urban context and actual preferences. If it is the view from the windows and the daylight indoors together with the conditions along the facades which really matters, the first choice is therefore openings in the corners. If there are some conditions in the central part of the courtyard which are important, then the best choice is openings in the middle of the block.

The chamfered corners of the building in the courtyard and in the crossings increases the daylight on the facades compared to the conventional rectangular perimeter block even if the changes are relatively small. The average views are the best in the alternatives with varied height, 4 and 5.

Acknowledgments

This research is part of a project at NTNU, Norway which is administrated by RISE, Research Institutes of Sweden and financed by the Swedish Energy Agency. Special thanks for comments to professor Ivor Samuels, UMRG at Birmingham University and to Ph.D. Sven Christian Ebenhag and Ph.D. Per Olof Hedekvist both at RISE. All calculations of views have been executed by the architects Alexander Stark and Robert Granstam both specialists in parametric design at Sweco Architects.

Lifecycle analysis of finishing products enhanced with phase changing materials

Petr Zhuk[1]

[1]Architectural Science of Materials Department, Moscow Institute of Architecture (State Academy), Rozhdestvenka street 11, Moscow 107031, Russia

peter_05@bk.ru

Abstract. Applicability of phase changing materials (PCMs) in buildings by their integration into the structure of finishing materials structure in the form of particles is especially high as a mean of providing heat-insulation during summer. Materials containing particles with phase changing behaviour are successfully applied at objects with large daylight areas, focused on active utilization of sunlight energy, among others. Utilization of PCM components allows saving considerable amount of energy due to possible refusal of air-conditioning while providing heat-insulation during summer.

The paper deals with the lifecycle analysis of gypsum-based finishing products. Main challenges with respect to the lifecycle of products with PCM components are the preservation of their longevity as well as their potential for reuse/ recycling. Through the example of PCM-enhanced plaster covering and gypsum plasterboard factors affecting the preservation of the advantageous thermal properties of PCMs over extended periods were studied, along with options of refining materials and products containing different amounts of PCM components.

The results of the research allow comparing similar materials with the use of PCM components and without them as well as analyzing the life cycle related environmental performance of PCM-enhanced finishing materials.

Introduction

Thermal insulation during summer is an important aspect of energy-efficiency provisioning in buildings for different functions. It can contribute to both primary energy savings and greenhouse gas emissions reductions, along with an improvement of the thermal comfort. On the economy side, not only energy costs can be reduced, but also investment costs for cooling/air conditioning systems can be reduced or entirely avoided.

One way of providing latent heat insulation is utilization of particles with phase-changing components in finishing materials. In this case excessive solar radiation energy is directed to support phase changing within those materials. It is reasonable to compare the effect of construction materials with phase-changing components utilization with that of building conditioning system utilization. This allows energy saving and achieving better level of thermal comfort during cooling period due to refusal of climate control equipment utilization. Climate control equipment is energy-expensive and requires scheduled change of filters, which can accumulate pathogenic flora. At the same time, different phase-changing components can be used in different construction materials, from concrete slabs [1], heat insulation based on cellulosic fibers [2, 3], gypsum boards to finishing materials such as plasters and paints.

An analysis of the lifecycle environmental impact of all of the above-mentioned materials was performed. Introducing phase-changing components somewhat influences material's lifecycle and, therefore, a problem of comparing similar finishing materials' (both with and without PCM) impact during their lifecycle becomes current. As an example of such materials, gypsum boards and gypsum binder based plaster coverings were chosen.

1. Methods

One of the most important lifecycle aspects in current research is Phase Changing Materials (PCM) operating longevity as components of finishing materials. To assess the longevity, methods harmonized with the Quality Assurance RAL-GZ 896 were used [4]. Results of the research according to this paper suggest defining a number of successfully completed cycles, rating by indicator of cyclic stability as well as data on possible damage situations. During the test it is necessary to exercise control over PCM's functional criteria such as the range of phase-changing temperature and the amount of saved thermal energy. Under the RAL-GZ 896 requirements, definitions of these criteria are made at the start and at the end of the test. During the current research, criteria definition was performed no less than three times, which was necessary to clarify dynamics of PCM's properties change. Changes of samples' mass and thermal conductivity depend on testing samples' size and do not describe properties of a material as a whole. Samples of gypsum plasters and gypsum boards parts with size 20 x 20 cm were tested. Paraffins were used as PCM. Injection of paraffins was performed in two ways: (1) drenching through material's surface and (2) incorporating into finishing materials' structure in the form of microcapsules with diameter from 5 to 10 μm. High-endurance polymeric capsule was used as a shell, which, along with granule size, provides component's stability against different mechanical impacts. Paraffin has the following properties as a PCM: F_p around 25 ^{0}C, ΔH=110 J/g, which substantially corresponds to products under Micronal® trademark. Above-described material's parameters allow reaching maximum environmental thermal energy saving in amount around 110 kJ/kg of material. Under such parameters PCM accumulates excessive environmental thermal energy when its temperature becomes higher than 25 ^{0}C [5]. Incorporation of microcapsules was performed in two ways: (1) through microcapsules' dispersion in tempering water as well as (2) in form of powdered substance, which is mixed with binding agent in form of dry plaster mortar. The amount of granule particles incorporated was similar for both materials. This amount was 3 kg per square meter of finishing's surface. Finally, the lifecycle was defined and analyzed for different production specifications of finishing materials.

As far as the lifecycle analysis is concerned, it was performed using well-recognized methods. In particular, such methods and indicators as CML, Cumulative energy demand, Eco-indicator-99, Ecological footprint, Oekoindex OI3 [6] were analyzed and discussed. For simplicity and due to a limited number of indicators, Oekoindex OI3 method was chosen. The main indicators chosen for conducting an environmental impact assessment during lifecycle were primary energy consumption, global warming potential and acidification. These three criteria are taken into account during the complex Oekoindex OI3 calculation [7].

The important stage during the lifecycle of finishing materials with PCM is the materials' recycling stage at the end of their service life. Different ways of separation gypsum base and paraffin-containing components were considered. The main method being considered was a method of components' separation using moisture. Thermal processing methods proved inefficient due to PCM damage under high temperatures.

2. Results

During materials' functionality testing with regard to heat-insulation during summer, cycling stability was defined. Under this indicator, testing materials corresponded to different classes according to the RAL-GZ 896. In particular, materials with drenching (both plaster mortars and gypsum boards) failed to reach even F-class (from 50 cycles). This was caused by shallow invasion of PCM, wherein plaster mortars survived less temperature load cycles without losing their properties (less than 15), gypsum board samples demonstrated the result of around 20 cycles. Incorporation of PCM granule in form of dispersion or powdered substance showed good results in cycling stability (A-class, more than 10.000 cycles). Testing results are shown in Table 1.

Table 1. Results of cycling stability testing of finishing materials

Name of material with PCM components	Result of test for PCM incorporation as a powder, number of cycles	Result of test for PCM incorporation as a dispersion, number of cycles
Gypsum-based plaster		
Sample 1	12.450	9.500
Sample 2	14.250	7.450
Sample 3	15.150	5.450
Sample 4	20.050	5.500
Sample 5	18.450	8.150
Gypsum board fragment		
Sample 1	22.450	10.650
Sample 2	27.550	12.450
Sample 3	25.350	11.350
Sample 4	23.150	10.600
Sample 5	21.000	11.450

Results shown in Table 1 demonstrate that gypsum board slabs and plaster mortars (with PCM incorporation as a powder) belong to A-class in cycling stability (> 10.000 cycles), while plaster mortars with PCM incorporation as a dispersion belong to B-class (> 5.000 cycles). The cause of low class for this materials group lies in irregularity of PCM components' distribution within the material, including excessive granule proximity to surface. Tests were performed until the loss of ability to consume excessive thermal energy, with a step after every 50 cycles. Supposing that during internal utilization of PCM-containing finishing materials up to 300 phase changings per year can occur (which is approximately 1 changing a day), 10.000 (A-class) provide more than 30 years duration of minimal service life for a PCM-containing material [5]. Plasters with PCM incorporated as dispersion have slightly shorter working life. But working life of such materials with PCM is purely comparable to that of the finishing material itself. Researches show that sometimes results for products (plaster mortars with PCM incorporation as dispersion) slightly differ from results for PCM granule, which is somewhat inconsistent with the RAL-GZ 896 data.

Cycling stability testing results are important for lifecycle analysis because they define, to a great extent, the length of the operation stage. Let's consider production (which in this case will include raw materials preparation), operation and recycling as main stages of the finishing materials' lifecycle. The following discussion will begin from the production stage.

PCM dispersion in tempering water directly during plaster or gypsum board production as well as powder produced by drying this dispersion and added in dry mixes, which are stored in sacks or silos depending on required quantity, can be used in production. Production scheme of dry mix for plaster being researched is shown in Figure 1.

During the production stage energy expenditure for paraffin and granule with PCM should be taken into account. In case of PCM incorporation in form of powder costs of drying under diffusion of dispersion for powder production should be taken into account. In case of PCM incorporation with tempering water as a result of mixing it is impossible to achieve desirable longevity of working life, despite that from the energy capacity point of view this process is less expensive, it is hard to achieve homogeneity in distribution of granule along the gypsum board product or within plaster coating.

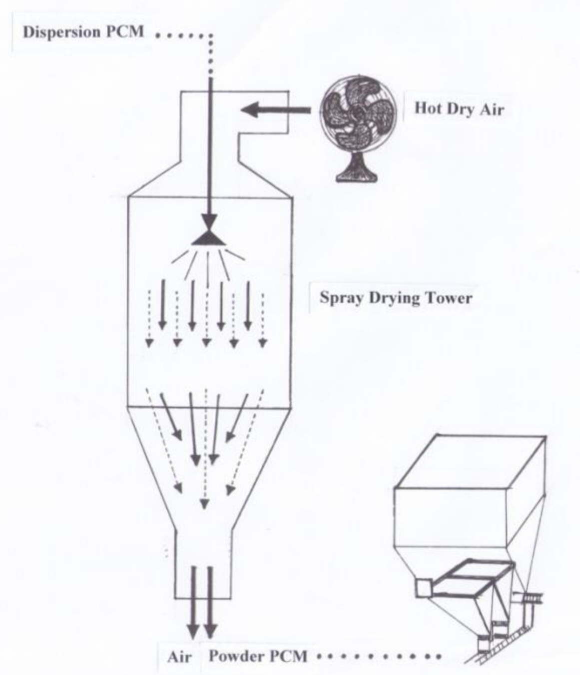

Figure 1. Production scheme for plaster with PCM in form of powder

The assessment results on the basis of the considered indicators for plaster and gypsum board slabs with PCM and without are not a far cry from each other. This proves the efficiency of using PCM components for achieving a passive heat-insulation effect at the material operation stage.

The service life, related to effect of using excessive thermal energy in a room for phase change in granule is different for different finishing materials. Service life depends on a way of granule incorporation into finishing material as well as room composition, window frames size and glaring, environmental conditions of building location, among others. Generally speaking, considerable effect can be achieved during the operation stage by means of rooms' temperature equalization at comfort level, which makes savings on energy cost of climate control equipment possible. Comfortable microclimate can be achieved for certain temperatures without overheating. Furthermore, heat accumulation can be achieved through a certain level of thermal mass or with help of PCM [8, 9 and 10]. Also, paraffin reaction is instant while mass of constructions reacts slowly. Due to PCM components the following phenomenon occurs: an instant significant excessive energy draw-off, PCM concentration close to surfaces of walls and slabs, fast release of energy remains as a result of ventilation. Calculation of microclimate improvement and gain in economic feasibility can be performed with the help of specialized software and programming tools by designing and modeling for certain conditions (for instance, PCM express programs by [5]).

At the final stage it is important to perform a separation of mineral constituent and paraffin granule. In order to do this thermal or moisture related methods can be used. Experience has shown that utilization of thermal methods leads to disturbance of PCM properties related to phase-changing capabilities. Although moisture utilizing methods turn out to be more energy-consuming (even compared to process of recycling finishing materials without PCM), they allow a more thorough recycling. As a result, there are the following indicators of energy consumption and impacts related to global warming potential and acidification (Figure 2). The assumptions and data bases are described below.

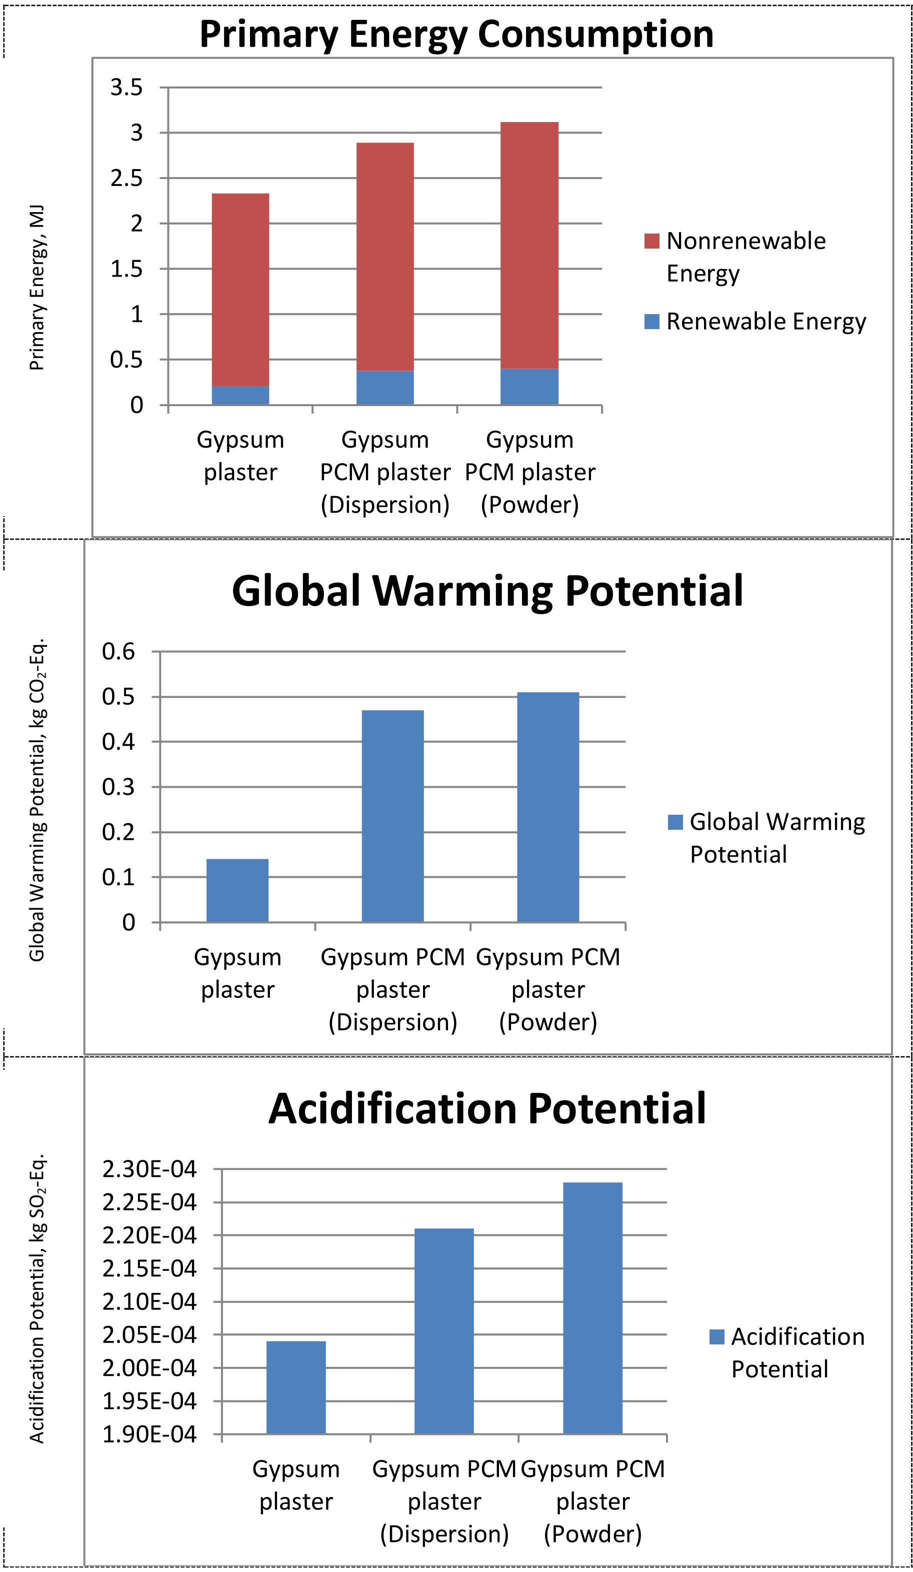

Figure 2. Comparison of three types of plaster based on three environmental indicators. Note: All figures represent the production stage only and are expressed per kg of material

Primary energy consumption during the lifecycle of different technological options is normalized per functional unit, which in case of plaster is 1 kg. Energy consumption during the operation stage was calculated using eco2soft method, developed by the IBO Austrian Institute for Healthy and Ecological Building [7]. Calculations were performed for the lifecycle with the postulated gypsum plasterboard service life of 30 years during operation in Central Europe climate conditions taking into account production and recycling stages. Due to lack of EPD for PCM containing materials a correlation of data received under the given research with the EPD data for similar materials without PCM (in particular, for gypsum plaster) [11, 12].

Taking into account energy saving during the operation stage due to reduction/avoidance of air conditioning energy consumption, which amounted around 100 kWh per annum for a testing room on under roof floor of free-standing residential building (area of surfaces finished with gypsum plaster with PCM was equal to 70 m^2), total energy consumption by lifecycle stages are displayed at the Figure 3.

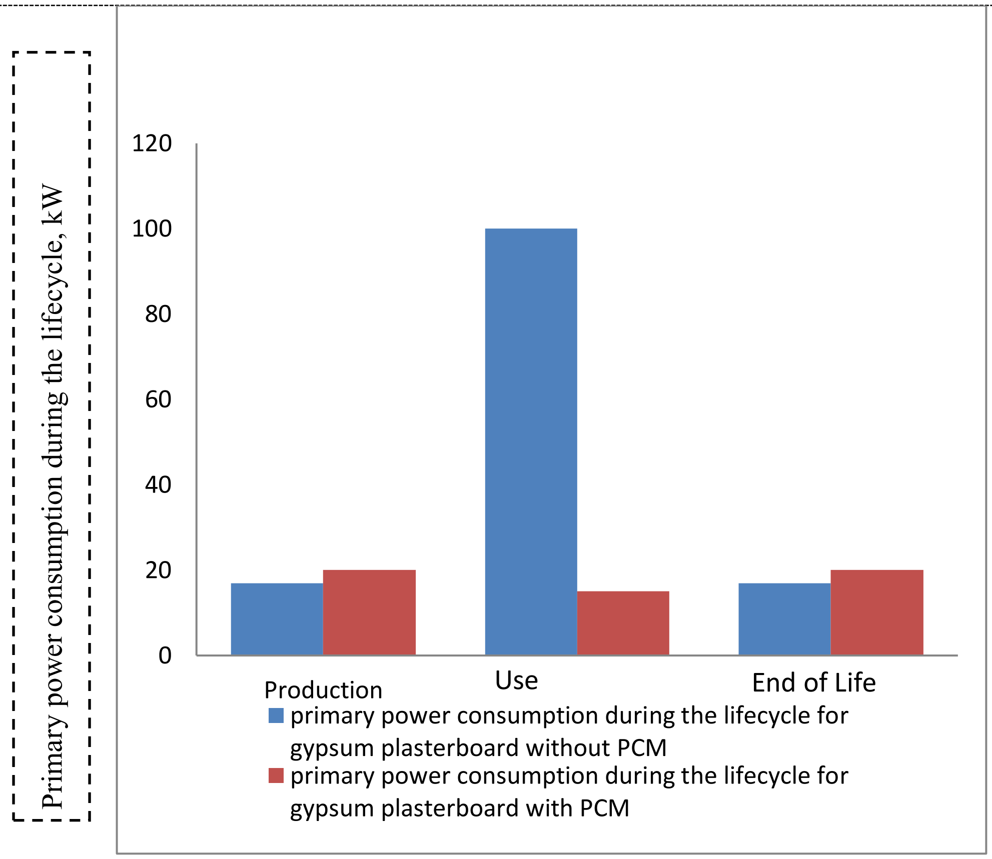

Figure 3. Comparison of primary energy consumption per life cycle stage for gypsum plasterboard with and without PCM

The information presented at the Figure 3 state that saving in energy consumption at the material's operation stage greatly surpasses slightly more high energy consumption rates at production and lifecycle end stages, related to granule with PCM production, incorporation and distribution within plaster structure and problems of components separation during recycling of served-out material. Figure 3 shows the scale of energy consumption that occurs during the lifecycle stages of the plaster, i.e. production, operation and end of life. In addition, it was taken into account that during the operation stage climate control equipment in rooms with the use of PCM can be waived. The figure 3 is a qualitative display of comparative power consumption scales during materials' lifecycles and can be interpreted in such a way that slight increase of expenditures during materials' production and recycling stages a significant effect at the operation stage can be achieved.

A principle, similar to the one used in assessment of B1 (utilization), B2 (maintenance, cleaning) and B6 (power consumption requirement) stages in Environmental Product Declaration (EPD), was used for comparison of primary power consumption values during the lifecycle. Calculation of conditioning costs using simple plaster (without PCM) resulted in approximately 1,5 kW for plastered surface of 67 m^2 [5]. Also the data on plaster consumption for a square meter in kilograms (including the amount of injected PCM) and acceptable original plaster life duration (which is 15-20 years for interior plastering) is known. Therefore, it is possible to make a comparison by functional unit of proceeded surface (1 m^2) or by unit of dry plaster with known consumption (in kilograms). Not only primary power consumption is important for the purpose of accurate comparison, but also other environmental indexes as well as economic and social effects which were not considered in the given research. However, literature sources provide interesting data on these indexes. In particular, CO_2 emission index, calculated through primary power consumption for conditioning of building with gross floor area of 5902 m^2, accounts for more than 100 tons per year [5]. Data on plaster with PCM depreciation life gives indexes ranged from 2 to 5 years, depending on building type, enveloping structures, environmental and other conditions. Based on this data, experts calculate general economic effects occurring on replacement conditioning systems with plaster or other finishing materials modified with PCM.

3. Discussion

Indicator results of environmental impact during the full lifecycle of finishing materials with the use of PCM are generally comparable to indicator results of similar materials without these components [11, 12]. This proves the insignificant environmental impact of PCM production and operation.

Increase of environmental impact can be observed during raw materials preparation (PCM granule production), production of finishing materials with the use of PC components and at the stage of recycling at the end of their operating life. Separation of mineral constituent and granule with organic components provides for higher level of finishing material components recycling.

Considerable environmental impacts can be achieved at all times during the useful life of a building due to significant saving on climate control equipment, because PCM longevity allows calculating for such a long period.

4. Conclusion

Basing on the results of the conducted research the following conclusions can be made:

- one of the most important parameters of finishing materials utilizing PCM is their cycling stability, which, depending on the way of granule incorporation, amounts for decades under given design operation condition and provides for working life of phase changing component comparable to working life of finishing coating as a whole;
- preparation of raw materials (including production of the phase-changing component itself and granule with it), as well as gypsum board and plaster mortars with PCM granule, are associated with a slightly larger environmental impact compared to regular finishing materials;
- at the operation stage due to creation of comfortable conditions in a room without the use of air conditioners and other climate control equipment energy consumption effect is achieved as well as reduction of greenhouse gas emission, expressed as GWP and acidification;
- recycling of finishing materials with PCM requires a higher energy consumption compared to similar regular finishing materials, but this effect is insignificant and does not have a crucial impact on general positive evaluation of finishing materials with PCM lifecycle;
- calculating amount of PCM granule being incorporated in finishing material structure as well as special aspects of their distribution along layers from surface to depths of coating play an important role which allow achieving the most effective heat-insulation during summer.

Utilization of PCM in finishing materials for interiors allows achieving savings when creating a comfort microclimate during summer. This reduction of environmental impact considerably surpasses effects occurring during PCM production, incorporation into material and recycling after the end of the lifecycle, which can last for decades.

Outlook

The main directions of PCM development and utilization must include lowering energy consumption of paraffin production as well as developing effective product's recycling methods at the end of its lifecycle.

kerstin.lange@jade-hs.de

Abstract. The North Sea Region (NSR) contains 22 million houses built in 1950-1985 that cause 79 Mton CO2 emissions annually. Current deep retrofit home renovations are carried out on a limited-scale production and only in small projects. This results in the problem that nowadays renovation costs are way too high and the pace of renovation is far too low. Large scale renovations of existing homes towards energy-neutral are currently not addressed in the North Sea Region. Still, the retrofit of houses in the North Sea Region is essential to reach the European energy and climate objectives. However, the building sector in Europe is not creating the necessary production facilities. The target of the just started INTERREG project INDU-ZERO is to develop a blueprint for a production facility that can produce wide suitable renovation packages at a high volume and low cost.

1. Introduction

The North Sea Region (NSR) contains of a wide range of outdated housing (one-family houses and apartment buildings with poor insulation and high energy demands) built between 1950 and 1985, that do not meet the present-day and future energy and living standards. These households in each country in the NSR all have a structural demand for heat (heating and hot water) and electricity. In order to meet EU environmental objectives, the NSR countries all need to focus on renovation, resulting in energy-neutral houses in order to reduce CO2 emissions. At the moment, mostly manual production facilities exist that can offer renovation solutions (often based on timber frame construction) for a maximum of 500 homes per year. As a result, the costs of renovations are high and the quality varies too much. Due to the high costs only a small number of homes per year are deep-renovated at the moment. Large scale renovations of existing homes towards energy-neutral are currently not addressed in the NSR region.

In the EU-funded Interreg project INDU-ZERO (Industrialisation of house renovations towards energy-neutral) the aim is to develop a blueprint for a production facility, based on Smart Industry and Circular Economy, that can produce wide suitable renovation packages at a high volume (15.000 units/year) at low cost (50% of current price). The consortium of the just started project consists of industry, government and knowledge institutes of six countries in the North Sea Region. This transnational collaboration is needed to combine all necessary knowledge and experience and to guarantee adoption of the project results.

The structure of this paper is as follows: In chapter number 2 the European background of the outdated housing situation and the consequences are described. In the third chapter a review of existing research projects which target the sustainability in the building sector is given. In chapter 4 the INDU-ZERO approach is described. In the fifth chapter the first results of the first deliverables are described, followed by the sixth chapter where the next steps will be specified. The last chapter contains a short conclusion.

2. Background in the North Sea region

Renovating the current houses in NSR is a serious challenge for meeting EU objectives. On the one hand, the potential of houses to be renovated is high. On the other hand, the market failure in the building industry hinders a faster renovation pace.

2.1. Potential of houses to be renovated

There are a total of 22 million houses and apartments in the North Sea Region (calculated on the basis of TABULA Building Typologies) [1] that should be renovated to become energy-neutral within the scope of this project. The number of outdated houses of the NSR partners within this project scope per country are: Belgium 500.000, The Netherlands 4.3 Million, Germany 4,8 Million, UK 9,6 Million, Norway 810.000 and Sweden 1,2 Million. The current CO2 emission of an outdated house is about 3,6 tonnes per year per house. To meet the EU 2030 objectives, almost 2 million houses per year would have to be renovated in the period 2018-2030 in the NSR. With the current state of technology, a small number of renovation packages per factory can be produced and a very limited number of such factories exist. The capacity of the current factories is to a large extend used for new buildings. For the NSR, an insignificant number of renovation packages can be produced at the moment. The NSR therefore seriously lacks production capacity.

2.2. Market failure in the building sector

Unfortunately the EU energy and climate objectives in the NSR cannot be significantly influenced by the building sector at the moment. Currently, the INDU-ZERO partners experience that the building sector has looked only locally and regionally at one project at a time. This is why the production of renovation packages for renovating houses towards energy-neutral is still small-scale. Each house or apartment is served by means of tailor-made offers and most of the work is carried out manually. Due to the local approach, the costs for renovating houses to energy-neutral range between € 80.000 and €120.000 per house/apartment. In addition, the quality of the work varies due to the manual approach, so that no uniform performance guarantee can be given. No standardized renovation solutions are available for the EU market on a large scale. As a result, the cost for individual or low scale renovations into energy-neutral housing is too high to persuade house owners. Main reasons for the market failure of the building industry are:

1. Workload in the industry is high at the moment;
2. Suppliers experience these types of developments as a threat for their existing business;
3. In the current supply chain the producers and providers of (end) products are mostly Small Medium Enterprises;
4. The industry invested in traditional structures;
5. Lack of an upscaled Original Equipment Manufacturer (OEM) position that is found in other market segments;
6. The industry by itself will not initiate the proposed breakthrough in this project and has no incentive for innovation.

In order to meet the long term EU climate and energy objectives, the NSR outdated housing stock needs to be renovated into energy-neutral. These renovations must be solutions which will be suitable for the next 30 years, in order to meet future climate and energy objectives.

3. Research Review

Other research projects in the field of energy efficient building exist. They focus on different aspects than the INDU-ZERO project.

Build with CaRe: The aim of the Interreg-funded Build with CaRe project was to mainstream energy efficient building design by raising awareness and increasing knowledge of the potential of energy savings. In collaboration with the building sector, a transnational strategy for increasing energy efficiency in buildings was developed. Within the project, an education and information programme was carried out to change behaviour in the complete building chain. This aided the setting up of a transnational knowledge and information network.

Transition Zero: Transition Zero is an EU Horizon 2020-funded project, carried out by Energiesprong, to establish the right market conditions for the wide-scale introduction of net zero energy homes across Europe. The aim is to kick-start net-zero energy refurbishment markets in the UK and France, using the social housing sector as a catalyst. This should be achieved by introducing performance-based solution requirements on integrated refurbishment packages and by establishing long-term, warranted energy performance contracts. Therefore, the regulatory and financing conditions for net-zero energy refurbishments have to be improved.

More Connect: The social and environmental urgency of large-scale integrated retrofitting of the European building stock is widely acknowledged and supported by Member states. However, as the European building sector is fragmented, it has not been able yet to devise a structural, large-scale retrofitting process and systematic approach. The aim of the EU Horizon 2020-funded project is to overcome these barriers by applying prefabricated multifunctional renovation elements which have the potential to reduce costs, renovation time and disturbances for occupants. At the same time, quality and performances (both in terms of energy efficiency as indoor climate) should be enhanced.

Faster and Better to Zero on the Meter (SBNoM): As the technical feasibility of zero on Meter (NoM) has been proven, the objective of this project is to accelerate and improve the industrialization of such renovations. This should be achieved through a chain approach in which supply and demand are linked. This involves the industrialization of NoM, standardization and the offering of recognizable 'packages' for these renovations. The costs should be reduced by industrialization and smarter installations or material use.

The INDU-ZERO approach is based on the findings of the above mentioned projects and knowledge. Automation and the development of a factory was not part of the former projects.

4. The INDU-ZERO approach

The overall project objective is the innovative up scaling and industrialisation of renovation solutions towards energy-neutral for NSR homes built in the 1950's to 1985's (which are in general of poor quality with respect to energy consumption, indoor climate and comfort), to lower costs, improve quality and increase the implementation of the renovations in the current housing supply in NSR.

Therefore, two main targets have to be achieved:

1. A smart factory blueprint which in itself is replicable in many countries will be developed. A production facility for thousands of renovation packages should not only be suitable for one type of house or one type of country, but consider the requirements of different countries. Otherwise, it would require different developments and factory designs, which would address a limited amount of houses, and therefore reduce the chance of realising mass scale renovation. Thus, this approach requires many countries to be involved to develop a factory design that is flexible and replicable throughout many NSR countries.

2. The developed elements of the renovation packages will be tested and produced for showcasing. The newly developed renovation packages will be produced and mounted as showcases in different NSR countries. However, the production will still be done in a conventional manufacturing process. The construction of the smart factory itself is not part of the project.

To design the blueprint for a Smart factory suitable for manufacturing renovation packages for renovation towards energy-neutral, the following steps have been identified:

- A selection of a maximum of three renovation packages has to be identified. These three renovation packages have to be suitable for all partner countries.
- Based on the chosen packages the concept process of automating the manufacture of the renovation packages for façade and roof components has to be developed. Therefore, suitable automation tools, e.g. robots, conveyor belts, drilling tools etc. have to be designed and/or selected. The automated production process of the renovation packages has to include factory lay-out, logistics, production data management, installation, building information management and simulations.
- Based on the designed processes, a Virtual Reality model (VR model) will be developed. This quiet new method of virtualization is chosen to present the projects´ results not only to the scientific audience but also to a wider range of target group like potential house owners or investors.
- The developed renovation packages will be produced as prototypes for testing. After testing, the renovation packages will be produced for showcasing. In selected partner countries, a real retrofit of an existing house will be implemented.

5. First results

For developing wall and roof elements, the structure of the elements and the materials to be used has to be determined. Four types of composing elements were considered as a starting point: Timber frame structure (TF), metal frame structure (MF), structured sandwich panel (SSP) and structural insulation panel system (SIPS). After a short description of the potential structure of the roof and wall elements, the evaluation and decision process of the choice of structure is depicted.

5.1. Overview on structures of wall and roof elements

The four structures to be compared base on different construction methods and materials.

- Timber frame structure (TF): Wood framing, in construction, is the fitting together of pieces of wood and sheets to give a structure support and shape. Modern light-frame timber structures gain strength from rigid panels (plywood and other plywood-like composites such as oriented strand board (OSB) used for parts of wall sections). In between the gaps joists insulation like glass- or mineral wool is placed. To meet stringent insulation demands, like for example in the Nordic countries, an additional insulation layer made from expanded polystyrene foam (EPS) can be placed on one side of the element. On this, the outer cladding is applied. A ventilation gap is needed to keep the timber and insulation dry. [2]
- The metal frame structure (MF): The main structural components of light metal or steel framing are made of galvanised cold formed steel sections. These can be prefabricated into panels or modules. In between these metal frame sections insulation like glass- or mineral wool is placed. On an additional insulation layer on the outer side, the outer cladding can be applied. Depending on the insulation that is used, a ventilation gap could be needed. [3]
- The structured sandwich panel (SSP): SSP, like structural insulation panel systems (SIPS), are used in the construction industry. [4] The SSP is a sandwich structured composite which consists of an EPS insulation and an OSB sheeting positioned between two layers of fibreglass. The OSB serves as a mechanical attachment layer to provide fastening opportunities. These layers form a light but very strong panel. Like in the other panels, an outside cladding is possible.
- The structural insulation panel system (SIPS): SIPS, like SSP, is a sandwich structured composite. It usually consists of an insulation layer of rigid core glued between two OSB

panels. The core insulation might be expanded polystyrene foam (EPS), extruded polystyrene foam (XPS) or polyurethane foam (PUR).

5.2. Assessment

The methodology used to prioritize the kinds of structure of the wall and roof elements to be further developed in the project based on a semi-structured decision process in three expert groups. For the assessment of different structures and materials each group of experts had to assess the design of the structures timber frame (TF), metal frame (MF), structured sandwich panel (SSP) and structural insulation panel systems (SIPS) on the following predefined criteria:

- Costs: The concept of total cost of ownership (TCO) is used for the assessment of each technology. Total cost of ownership do not only consider the purchasing price of a product. Moreover, all direct and indirect costs involved in buying and using a product over its life time are counted in to help buyers and owners decide on different alternatives. [5]
- Circularity: The renovation packages to be developed in the project should be based on the principles of circular economy and optimized for low embodied energy. Circularity describes the sustainability of a product considering its whole live cycle. Circular building concepts and Cradle-to-Cradle frameworks imply radical changes for the construction sector and have to be considered. [6] [7]
- Effectiveness: Effectiveness describes the effort to make a good insulation panel with integrated technology like heating and ventilation. Characteristics like thermal insulation or thermal bridges, sensitivity to humidity, deformation or delamination have to be considered. The possibilities for upscaling automation the production process are also taken into account.

In a first step, the characteristics of the four structures with regard to costs and circularity were discussed, taking the timber frame structure as the starting point. The results were fixed on a two-dimensional coordinate system (see figure 1). Next, the characteristics of the four structures with regard to costs and effectiveness were assessed. The results again were fixed on a two-dimensional coordinate system (see figure 2). In order to finalize the assessment, the results were discussed in the peer group to aggregate the findings in a joint figure.

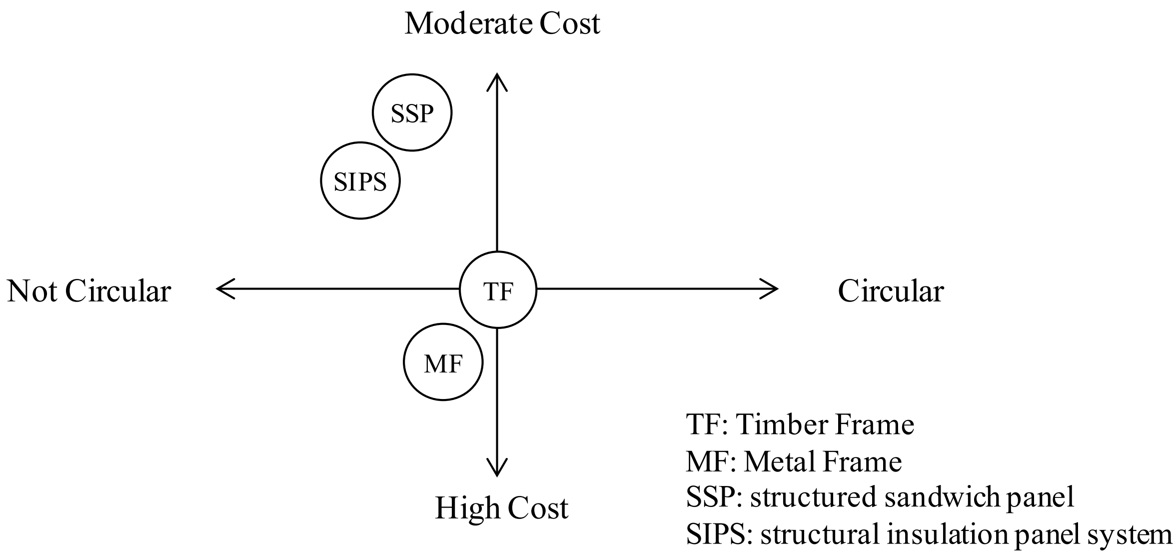

Figure 1. Assessment of structures – Circularity and Costs

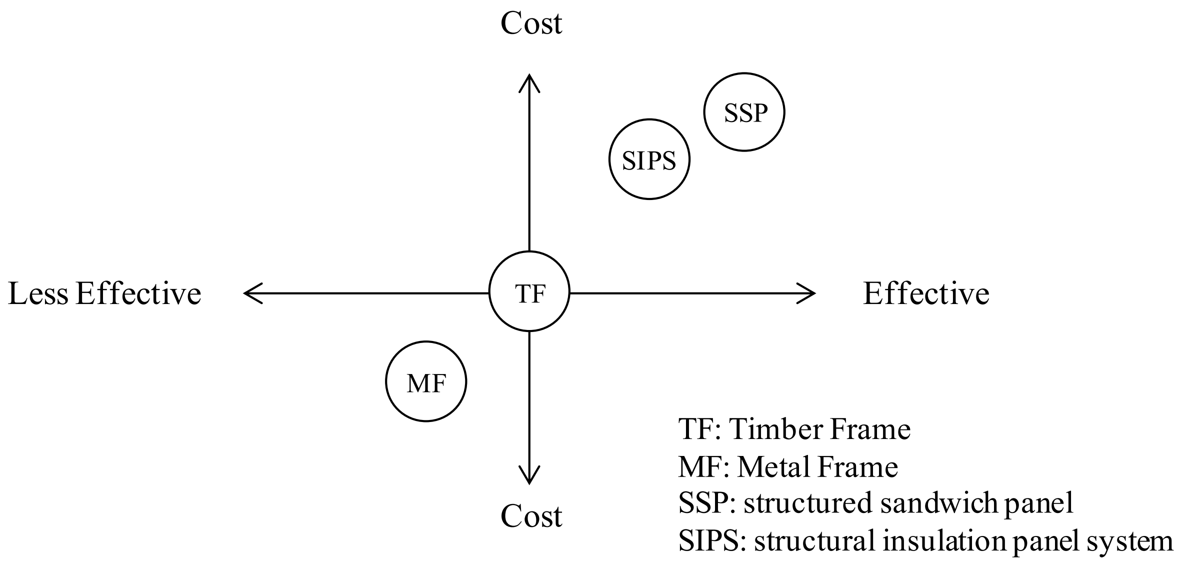

Figure 2. Assessment of structures – Effectiveness and Costs

The positioning of the four structures in the coordinate system was a long and controversial process. Different points of view had to be balanced. To give a short overview, main arguments for each structure are depicted in the next section.

5.3. Discussion of main criteria
All structures and their advantages and disadvantages had to be evaluated and compared. Therefore, not only the as-is-situation has to be considered. Also potential future developments had to be discussed.

Timber frame structure (TF):
Circularity: A timber frame wall consists of different materials each with its own circularity. Main materials of the wall elements are: Timber frame, glass- or mineral wool insulation, oriented strand board (OSB), expanded polysterene foam (EPS) insulation, damp barrier foils and the cladding. In theory each component could be separated and recycled on its own. However, actual wood frame constructions are difficult to disassemble as there is contamination due to adding spray foam in corners, adding glue to between panels or (chemically) treating materials to make them resilient. Although timber frame has a potential for a good circularity this treatment has a big negative impact on the recyclability of the used materials. Timber has a low carbon footprint and is renewable. Softwood species are fast growing and some are grown widely across (northern) Europe. Untreated softwood can be downcycled in wood based products or as fuel.

Effectiveness: Wood has relatively good thermal insulation values compared to other building materials. As the frame is self supporting, the choice of insulation can be tailored to the environmental situation. Softwood when exposed to humidity can deform and create air gaps. Thus frame and insulation need to be kept dry and ventilated to prevent sagging. Looking at the production process it is important to note that timber frames can also be prefabricated into panels or modules.

Cost: Timber is relatively expensive per volume. However, softwood is cheaper than hardwood, even when it is FSC certified.

Metal frame structure (MF):
Circularity: A metal frame wall consists of several different materials with their own circularity. Main materials of the wall elements are: Steel frame, glass- or mineral wool insulation, chipboard (OSB),

EPS insulation, damp barrier foils and the cladding. Like wood frame constructions, these are difficult to disassemble due to the addition of spray foam or glue. Raw materials are non-renewable. The production of steel has a high carbon footprint. It requires a lot of energy and material and releases CO2 during the process. Still, steel is quite easy to recycle. Steel frames even have a possibility to be re-used.

Effectiveness: Because of the 'c shape' of the metal frame, insulation is held in place very well and hardly any sagging occurs. As the frame is self supporting, the choice of insulation can be tailored to the environmental situation. However, there is a big risk of air gaps where the insulation does not fill up the frame correctly. Metal itself has very bad thermal insulation values. There is a very high chance for thermal bridges. Thus, an additional layer of insulation is needed to dampen this effect.

Cost: Metal frames themselves are quite expensive to produce.

Sandwich panels (SSP):
Circularity: As the structured sandwich panel (SSP) and the structural insulation panel system (SIPS) are sandwich composed panels, an end-of-life recycling and reuse is difficult. Although some components might be easy to reuse, most components are glued together. Thus, separating materials is difficult and labour intensive.

The virgin raw materials for the production of OSB have a low carbon footprint. FSB certified OSB is available. Raw materials can contain recycled woods like chipped construction wood. However, OSB needs high heat and pressure to be produced, just like plywood, particleboard and MDF. The reuse of OSB is difficult due to its relatively low durability. Recycling of OSB is difficult as well. OSB waste is usually incinerated and used for energy. Moreover there are limited possibilities for downcycling (e.g. downcycled boards).

Effectiveness: The main advantage of SSP modules compared to SIPS modules is the size and thus the handling possibilities. SSP walls and roofs usually consist of one or two large panels (up to 15m). This minimises the mounting effort and thus the construction time at the construction site. Moreover, this minimises joints which minimises air penetration. Because of the EPS foam which is an integral part of the wall (less gaps) the insulation core and raw insulation values are good. As SSP panels have very few internal structures, the insulation value is very homogenous and thermal bridges are eliminated. The production process can easily be automated due to the structure of the panels.

Cost: OSB, used in both sandwich structures, is less expensive than plywood and similar fibre/composite boards.

Structural Insulation Panel Systems (SIPS):
Effectiveness: SIPS walls and roofs usually consist of multiple smaller standard size panels. Linking these requires the mounting of timber beams in the wall which is an additional time consuming process at the construction site. Moreover, this diminishes the R value locally. One particular weakness of these SIPS panels is air penetration at joints or penetrations. Still, due to the hard foam insulation core, raw insulation values tend to be good.

Cost: OSB, used in both sandwich structures, is less expensive than plywood and similar fibre/composite boards. Looking at the insulation core of the SIPS module, costs for EPS are low. Other materials like extruded polystyrene foam (XPS) or polyisocyanurate foam (PIR) or polyurethane foam (PUR) are more expensive. The production process can be automated.

To conclude, the sandwich structures result to be more promising when developing a smart factory with the aim of reducing the cost of retrofitting houses on a large scale. The assessment of the effectiveness shows that the SSP modules even outmatch the SIPS modules. First, SSP is cheapest due to the use of EPS and OSB, both cheaper as other components in the SIPS module. Second, the SSP production process is less complex as less components and materials have to be handled. This results in a reduced construction time and costs. A further argument is the possible size of the SSP modules which can lead to a minimised mounting effort and thus a reduced construction time at the construction site. However, the circularity of the sandwich panels is not assessed that good compared to the timber and metal frame structures. To reduce the effort of separating materials and thus to improve circularity, the connection between different layers and alternatives for the OSB and EPS will be investigated in the next steps. Future developments and solutions could be found in debondable or environmentally friendly glue or mechanical connections like click systems.

6. Future Outlook

The next decision will deal with the selection of the house types to be renovated. Depending on the house type, the renovation packages and the wall and roof elements as well as their production process in the smart factory have to be designed.

For each partner country (Netherlands, Belgium, Germany, the UK, Sweden and Norway) the housing stock regarding existing house types (e.g. detached house, demi detached house or terraced house) has to be analyzed. The challenge of this step lies in the differences in the types of residence in all the different countries. Moreover, different roof types for each type of residence have to be considered. In the end, three house types have to be identified which are of interest for all partner countries.

Following these basic decisions on module structure and type of residence and roof, the production processes for these modules have to be identified, analyzed and optimized for a smart mass production of modules for retrofitting houses in the North Sea Region.

7. Conclusion

The aim of this transnational approach is different to current regionally centered projects in the retrofitting sector of existing houses. The practical implication lies in the development of a blueprint for a smart factory which is able to produce house elements on a large scale. Up to now, high-volume solutions for renovations towards energy-neutral are still not available. In order to ensure the right choice of module structure this paper describes the research implication of the step of assessing different common types of walls and roofs. Based on this decision as well as the choice of the type of residence to be considered, the next steps of developing the smart factory will follow. Here, the automatization process, robotics and logistical aspects will be focused.

stephan.maier@tugraz.at

Abstract. In 2015, the United Nations released the 2030 Agenda for Sustainable Development, adopted by 193 countries, containing 17 Sustainable Development Goals (SDGs). The goals address social as well as economic and environmental challenges in a holistic approach. Participating university members of the Alliance of Sustainable Universities in Austria (ANU), a cooperative work platform that promotes sustainable development at universities in Austria, picked up on this impulse by developing approaches for universities to address SDGs in research and education. The article presents the cooperative process of developing a project with the aim of supporting political decisions for SDG achievement, establishing the SDGs in research and education and intensifying collaboration between universities. Besides interactive workshops and methods to develop the project, a mapping supported the team to find well-established and also underrepresented SDGs in research at universities in Austria.

1. Introduction

The challenges of the 21st century, such as climate change or biodiversity losses, are of high complexity, requiring holistic approaches [1]. Here, the 17 Sustainable Development Goals (SDGs) with their 169 targets released as Agenda 2030 aim at all spheres of sustainable development including social, ecological and economic aspects.

In order to break down these goals to distinct implementation tools, a stakeholder integration on different levels is necessary. Political approaches evolved to be "siloed" in their respective corners of their spheres of action [2]. This also contributes to the problem that SDG achievement is still far away and often "blurred" through spill-over effects and other obstacles difficult to capture. Indicators are an important and helpful tool to measure progress, but it must be ensured that the appropriate criteria are applied. Scientific support is necessary to outline options that can be taken for SDG achievement and to critically reflect on SDGs and targets. Presumably, in some cases this will need the introduction of additional indicators to the ones applied so far.

The role of higher education institutions (HEIs) can be described as follows. As "change agents" HEIs drive forward sustainability through problem-oriented real-world research, critically reflect on goals, integrate sustainability into research and education and thus educate future decision makers. They can give scientific advice for decision-making through science-policy dialogues [3].

In Austria, universities are articled to the performance agreements (German: Leistungsvereinbarungen) which each university contracts with the Austrian Ministry of Education, Science and Research every three years [4]. These performance agreements contain the basis for the content-related development and strategic profile formation of the universities. In the framework of the performance agreement period of the years 2016 to 2018 the Austrian Ministry additionally invited the universities to intensify their pioneering task for a sustainable and future-oriented development of society, environment and economy according to the Brundtland Report from 1987 [5] in order to engage with the increasing global challenges. Austrian universities as autonomous educational and scientific entities also create their own development plans where they explicitly concretize their profile formation and define their overall concepts including content like future development goals, strategic orientation and measures.

The project UniNEtZ (German: Universitäten und Nachhaltige Entwicklungsziele, Universities and Sustainable Development Goals) has been developed in order to support political agenda setting in Austria, to integrate sustainability into research and education and to strengthen collaboration between universities. The aims of UniNEtZ are summarized as follows:

- Development of a catalogue of options on how the SDG might be achieved in Austria, taking a systemic approach to achieve measures compatible with all SDGs
- Address SDGs in universities in research, teaching, life-long learning, responsible science and in university management
- Identify research needs and develop research projects across universities
- Create added value through cooperation and new combinations of knowledge
- Improve interdisciplinary co-operation within and between universities
- Interaction with stakeholders from politics, administration, economy and civil society
- Attempt at interaction with the "other 50%", those people left behind, as socially vulnerable groups, e.g. long-term unemployed people)
- Build capacity amongst researchers, teachers and students regarding the issues addressed by the SDGs

2. Project development and methodological approaches

2.1. Project development

Since April 2017, several workshops have been launched in order to sharpen the project's goals and develop the scope of the bottom-up initiative UniNEtZ. In a first impact-workshop in May 2017, participants from different universities and the Austrian Federal Ministry of Education, Science and Research (BMBWF) identified factors that stimulate a successful implementation of sustainability at universities and help to realize the planned project. According to the participants, there are several factors that are effective in supporting the operationalization of the further process on different levels (see Table 1). As driving variables, the group identified three factors: support by the Austrian federal government ministries, a central coordinating project management and an SDG mapping to identify research focus areas of the involved institutions.

Table 1. Success factors that help to achieve the defined goals of the UniNEtZ project. The factors were identified during a workshop in May 2017 with stakeholders from universities and Austrian ministries (Source: adapted from FASresearch 2017 [6]).

Type of variable	Success factors applied to UniNEtZ
Drivers: preconditions and requirements for the process, lever in the initial project phase	• **Federal ministries**: support and interest of the political stakeholders involved • **Project management**: central project management and coordination • **SDG Mapping**: identifying research strengths of the participating universities in order to orientate the further process accordingly and help to focus thematic fields
Make-or-break variables: necessary for the process	• Clear **target definition** of the project • **Innovation**: development of new knowledge and building of new cooperation • **Thematic focus** based on competencies and demands
Outcome variables: indicators measuring if the defined goals are approached	• **Awareness-raising** at universities • **Network** of motivated people • Integration into **tasks of the university** • Integration and interactions with other **societal stakeholders**
Buffer variables: factors directly impacting the goal, must be clarified in advance, support the process	• **Resources**: financial incentive structures for the project support • **Interactions**: consider various interactions between SDGs, targets and indicators

Based on the identification of these factors, further workshops focused on sharpening the goals of UniNEtZ (see section 1) and developing the project framework were organized. Once the scope of the project had been outlined, the universities started to integrate the core ideas of the project into the performance agreements for 2019-2021 between universities and the BMBWF. The universities involved have been in a constant dialogue with each other and with the ministry in order to drive forward the implementation of the structural framework conditions of the project. By December 2018, the integration of UniNEtZ into the performance agreements was completed.

Parallel to the project development, information events helped to gain a clearer picture of the SDGs and related topics. For example, experts such as Keywan Riahi (IIASA) gave inputs on the role of universities in sustainability transformations during a workshop in June 2017. Further, the question of how interactions between scientific and societal fields could be strengthened was a core topic during the project development. Figure 1 shows the timeline of the project with a development phase, thematic focus setting and official start of working on SDG options.

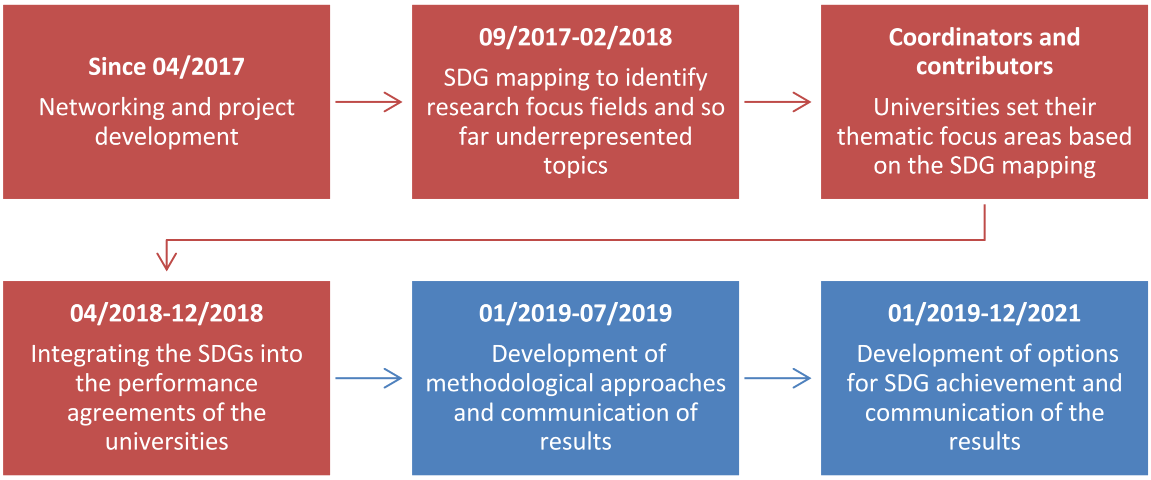

Figure 1. Project timeline since 2017: Red boxes indicate completed milestones. Blue boxes show current or future working packages.

In addition to the structural project development, intensive dialogues helped to integrate important stakeholders from the BMBWF into the process. Both, workshops and bilateral talks with respective stakeholders were held on a regular basis. During a presentation workshop in May 2018, the results of the SDG mapping (see section 2.2.) and the preliminary integration of the project UniNEtZ into university structures at that point were presented and exchanged with stakeholders from the BMBWF, other ministries and the Federal Chancellery.

2.2. SDG Mapping

In order to support the process of finding focus areas for each university, an SDG mapping was conducted from September 2017 until February 2018 [7]. As a method a mapping tool was developed in an interdisciplinary process with a duration of about half a year. Data on publications and project activities from 13 universities were investigated according to SDG relation and thematic focus fields. In total, about 15,000 publications and 17,000 projects from the period 2013-2017 were extracted from the internal research documentation systems of the involved universities and made available for the mapping.

The mapping is based on a keyword catalogue, containing about 1,000 keywords in English and German. To develop this catalogue, the Agenda 2030 was screened for prevalent words as a first step. Synonyms were derived from these words in a semantic approach, and these were matched with keyword lists from other studies [8]. In an iterative process, these keywords were discussed with stakeholders from the partner universities and tested via the search tool. The tool is based on a Python script, which screens the available data for respective keywords and displays matches. Titles and abstracts of the available datasets were screened with the developed keyword catalogue, retrieving statistics on the distribution of the SDGs. These give an insight into the thematic focus areas of the universities.

It could be shown that some SDGs are “mainstreamed”, e.g. SDG 4 (Quality education), whereas other SDGs represent instead the niches covered by individual universities, e.g. SDG 3 (Good health and well-being). This also reflects the current participation of universities in UniNEtZ.

2.3. Coordinators and contributors for the SDGs

Based on their previous activities, the universities decided to on take roles as coordinators (in German *SDG Leiter_innen*) and/or contributors (in German *Mitwirkende*) for specific SDGs. These coordinative and contributing roles have been integrated into the performance agreements of each university. If a university is coordinator for a specific SDG, the responsible team coordinates all activities related to this SDG and gathers the inputs of the contributing universities. Contributing members help to gather expertise and knowledge in order to develop measures for determining how the SDGs can be realized in Austria. Both coordinators and contributors have very close involvement with the SDGs, their specific goals and indicators (see Figure 2). To date (03/2019) 19 coordinations and 58 contributions have been covered by the following universities and institutions including Alpen-Adria University Klagenfurt, Danube University Krems, Graz University of Technology, Johannes Kepler University Linz, Medical University of Innsbruck, Montanuniversität Leoben, Mozarteum University Salzburg, University of Applied Arts Vienna, University of Graz, University of Innsbruck, University of Music and Performing Arts Vienna, University of Music and Performing Arts Graz, University of Natural Resources and Life Sciences Vienna, and Paris Lodron University of Salzburg, University of Veterinary Medicine Vienna, Climate Change Centre Austria, Geological Survey of Austria and Central Institution for Meteorology and Geodynamics.

The mixed backgrounds and interdisciplinary setting of the project enables a synthesis of available expertise to approach the SDGs holistically. However, each specific SDGs will not only be approached from different disciplinary backgrounds, but bridges and interdependencies to other SDGs will be considered as integral parts of the project with the aim of identifying synergies and trade-offs. These interdependencies will need to be viewed from the beginning of the project in order to develop holistic solutions and options for measures on how to implement SDGs.

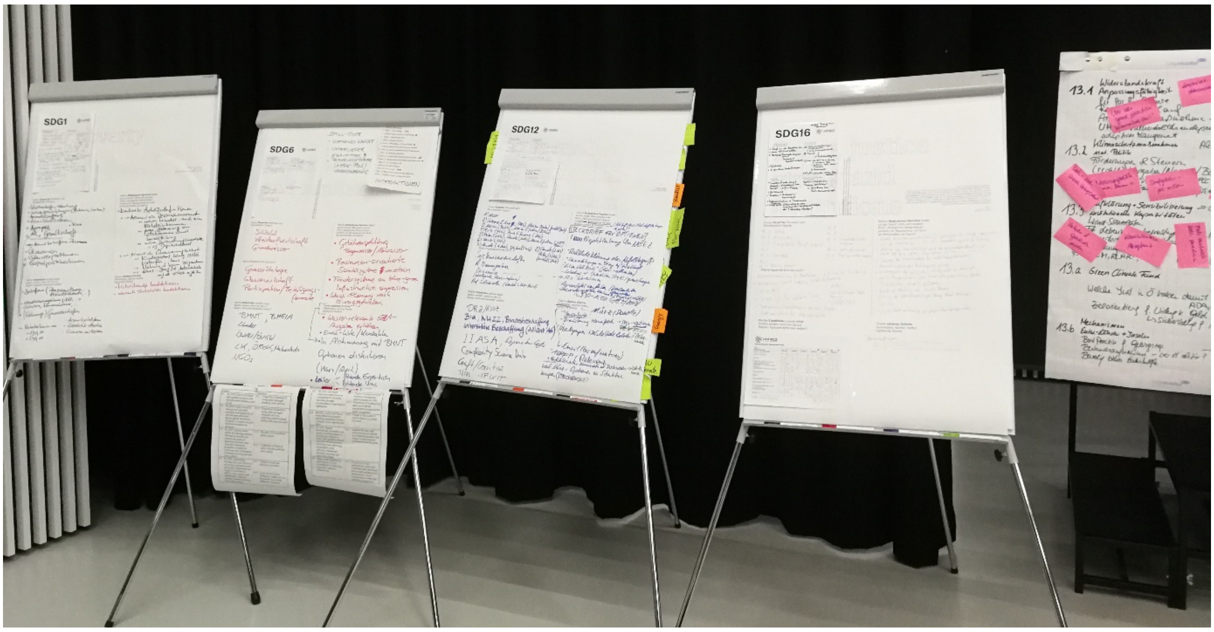

Figure 2. First working session on the SDGs – brainstorming available expertise, definitions of the SDGs and its targets and related indicators (Source: Kernegger 2019)

2.4. *Artistic formats*

Artistic formats are integrated into the methodic scope of the project as a means of achieving innovative approaches for the SDGs and will continue to support a) thematic approaches towards the SDGs and b) communication with the public and different stakeholders. The official UniNEtZ kick-off event 21st - 22nd January 2019 is an example of how artistic formats of the kind enable alternative approaches to the topic. In the scope of the event, students and associates of the University of Applied Arts Vienna prepared the format "Knife, Fork and Pen" that gave impulses for a creative brainstorming process on the SDGs during the lunch break (see Figure 3). “Knife, Fork and Pen” turned out to be a productivity-enhancing tool for elaborating the first contents during the kick-off meeting lunch break. The long dining tables were covered with paper tablecloths and divided according to the SDGs. An assigned seat number

on the table ensured a sound mix of people and ideas in to the context of their thematic backgrounds. 8 to 10 people per SDG introduced and discussed contents and ideas during the first course of the meal. After the sounding of a gong the SDG was changed by assigning a new seat number. All the ideas and suggestions that were developed during the 3-course menu and the accompanying three discussion rounds were written down on the paper tablecloths.
A project-internal working group will continue to foster such formats and support the project team with methodological innovations and communication approaches.

3. Structure and special aspects

3.1. Governance structure of UniNEtZ

The UniNEtZ project currently has the active involvement of 15 universities and three scientific institutions in an open consortium. This means more institutions can join the project at any time during the working process. By anchoring the project into the performance agreements between the universities and the BMBWF and the signing of a Memorandum of Understanding, the 18 institutions have committed themselves to implementing the objectives of the project within the next three years. UniNEtZ aims to (i) develop an options paper for the Government to achieve the SDG objectives, (ii) strengthen the networking of scientific institutions within Austria, and (iii) promote the anchoring of the principles of sustainability in research and education. The institutions involved are thus complying in this project with the demand of the BMBWF, which states that universities should take more responsibility for real-world problems and societal needs (Third Mission / Responsible Science).

Several different organizational units operate within the project, acting on a strategic or operational level (see Figure 4 and Table 2).

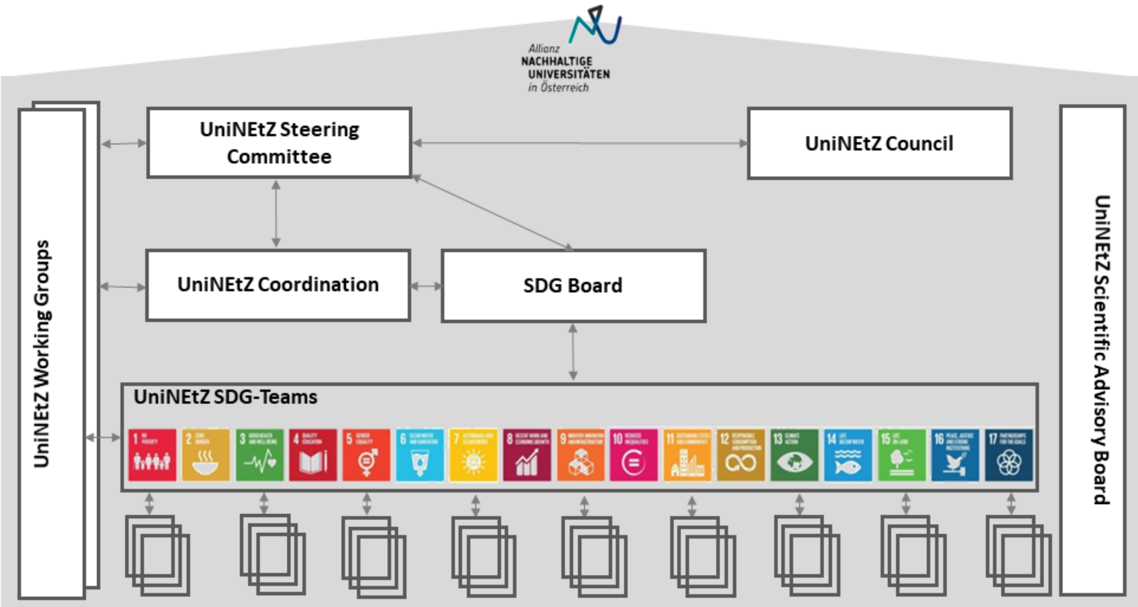

Figure 4. Structure of the UniNEtZ project.

Table 2. Structure of the UniNEtZ project with the different organizational units acting on a strategic or operational level.

Function	Description
UniNEtZ Council	This committee takes strategic and financial decisions in the project. Each participating institution, including the group of students, has one vote.
UniNEtZ Steering Committee	This committee leads the project and is active on a strategic as well on an operative level. It consists of three persons.
UniNEtZ SDG Board	This board works on methods and contents related to SDGs and possible options. Its members coordinate the activities for each SDG and guarantee the linking of all SDGs. Every SDG has one vote.
UniNEtZ SDG teams	These SDG teams compile the options to fulfil the SDGs related to Austria-related challenges. Further, they consider interactions with other SDGs and abroad.
UniNEtZ coordination	This level represents the operative central coordination of the project. It is the central contact point for all committees and members.
UniNEtZ Scientific Advisory Board	This committee (to be set up) is composed of scientists, politicians and economists. It accompanies the project with scientific and strategic advice.

3.2. Options to achieve the SDGs

Within the three years project duration, SDG-related options will be developed for how to contribute to achieving the SDGs in Austria. In this context, an option is supposed to be policy relevant but not prescriptive. Thus, no recommendations will be made, but the options will be presented to the government as a support for decision-making processes. Every option must be assessed regarding synergies and trade-offs with other options, all targets and indicators. Option packages can possibly be identified to mitigate disadvantages and strengthen synergy effects. The scope of possible options is limited to solely to those that lie within a political mandate for Austria; however, special care will be taken to include options that help reduce negative spill-over effects making the achievement of the SDGs more difficult in other countries, especially developing countries.

When developing an option, a scientific standard must be adhered to. This guarantees traceability, reproducibility and comparability. Within the project, there will be a specific working group to develop an adequate methodology (WG methodology). Further details will be outlined in the current months. One of the main goals of the WG is to develop a concept to merge the options of the different SDGs in a systemic model. To ensure a scientific standard, (i) an analysis of the actual situation and developments will be made on the basis of existing data and statistics. Here, it is important to critically illuminate the quality of the data and their relevance to the research question. (ii) Furthermore, a system analysis will be performed for the influencing factors considering different system limits. For this purpose, positive and negative feedback loops in the system (synergies and trade-offs) are given particular consideration. (iii) The solutions proposed so far in Austria and their effectiveness must be discussed. (iv) A literature and practice analysis of solutions implemented in other countries should be carried out. (v) Based on these steps, the systems diagram can be improved and will then serve to make sure no relevant leverage points yielding additional groups of options have been overlooked.

3.3. Students – partners on equal terms

There is no doubt that students are the biggest stakeholder group at universities. The most important responsibility of universities is to enable students to strengthen their reflective faculty and that teachers and students jointly work together in order to develop contemporary action knowledge [9]. Hence, if HEIs intend to act as change agents in a credible manner and thereby attempt to foster a transformation towards sustainability, it is crucial to open up a space for a collaboration with students, where they are seen as partners on equal terms.

Within UniNEtZ, such an involvement is taken seriously as a main concern and was discussed in particular at the kick-off event in January 2019 by a working group consisting of students and professors of various universities. It was decided that students will be formally represented by the student association *forum n*. Founded in November 2018, *forum n* aims at building up an Austrian-wide network of student initiatives and individuals in the context of sustainability. In doing so, *forum n* is contributing to the development of a sustainable and thus future-orientated higher education landscape in Austria. The *forum n* is part of the UniNEtZ Council (Figure 4) with the same voting right as all the other universities. Besides this structural embeddedness on eyelevel, students have the possibility to contribute to any SDG they are interested in, whereby a particular focus is on SDG 4 – Quality Education. Hence, UniNEtZ is an important platform for students to participate in an interdisciplinary dialog with scientists from different universities and disciplines. Furthermore financial support is also granted to facilitate the involvement of students, e.g. at UniNEtZ-events (e.g. meetings of SDG groups), and to enable them to set up their own projects related to UniNEtZ. An eyelevel collaboration of this kind recognizes that students can act as crucial change agents and multipliers not only at their universities, but also in their societal environment during their studies and beyond as future decision makers. The structures and "modi of collaborations" which will be implemented within UniNEtZ can serve as basis for how a continuous and long-term cooperation of *forum n* and the Alliance of Sustainable Universities in Austria can be realized. In this sense, the "eyelevel approach" of UniNEtZ can also serve as a best role model for other networks or projects where students should be involved as partners on equal terms.

3.4. Ethical aspects and guiding principles

Agenda 2030 and its SDGs can be understood as a global effort to overcome the challenges originating from the Anthropocene and its multiple and complex processes of change. There is wide agreement that this is no longer a simple interplay of action and impact on the challenge side and reaction and adaptation on the response side. Thus, solutions which have been successful for quite some time are also no longer adequate as they miss the complexity and the, both spatially and temporally, multi-scale character of the challenges.

As a consequence, there is an ever-growing understanding that this challenging situation, which might even be seen as a key question for the survival of the human-environment Earth system as a whole, can only be mastered by a comprehensive socio-ecological transformation. Transformation means not purely addressing the challenges but reflecting on and rethinking of the value system on all scales [10], from the individual to group and societal level, which is seen as a key driver of all human activities [11]. Only when addressing these ethical aspects, can the systems at risk be transformed.

Within this value system sustainable development respectively the SDGs may be seen as the guiding pole star. That does not mean that SDGS, targets and indicators are applied and investigated, uncritically. On the contrary, they are brought into question, evaluated according to ethical principles and, as a result, further applied or discarded.

Against this background, the UniNEtZ consortium is fully aware that ethical aspects must be guiding principles of all research activities within the project. By doing so, the consortium is not only contributing to the idea of responsible science but in a further sense is making it become a reality. All in all, UniNEtZ can be characterized as a value based and society-oriented project by which the 18 contributing institutions show their willingness and potential in the newly arising field, the purpose of a University's Third Mission in order to address societal and economic challenges within the cultural-environmental sphere.

4. Excerpt of first results

In this section we present an excerpt of first results within the ongoing UniNEtZ project. The networking and exchange of information between the participating universities is already taking place on a comprehensive scale. Through numerous workshops within each SDG, the first necessary steps have been taken to meet the requirements of the UniNEtZ project. It is interesting to observe how different ideas and approaches within the individual SDG groups are discussed, brought together and implemented.

As already mentioned, one of the crucial tasks of the project is the systemic consideration of interdependencies among all developed options in order to holistically identify synergies and trade-offs. For this reason, a 2-day workshop has already been held under the title "Systemic approach for a holistic consideration of options”. In the course of this workshop, the participants were introduced to the basics of system dynamics and the modeling language. Finally, attempts were also made to develop systemic interdependencies within selected SDGs, with a focus on the correct application of the modeling language. Figure 5 shows some impressions from the workshop where a systemic approach was applied to the exemplarily selected topics “waste” and “education”. Systemic interdependencies as well as impacts were related to these topics.

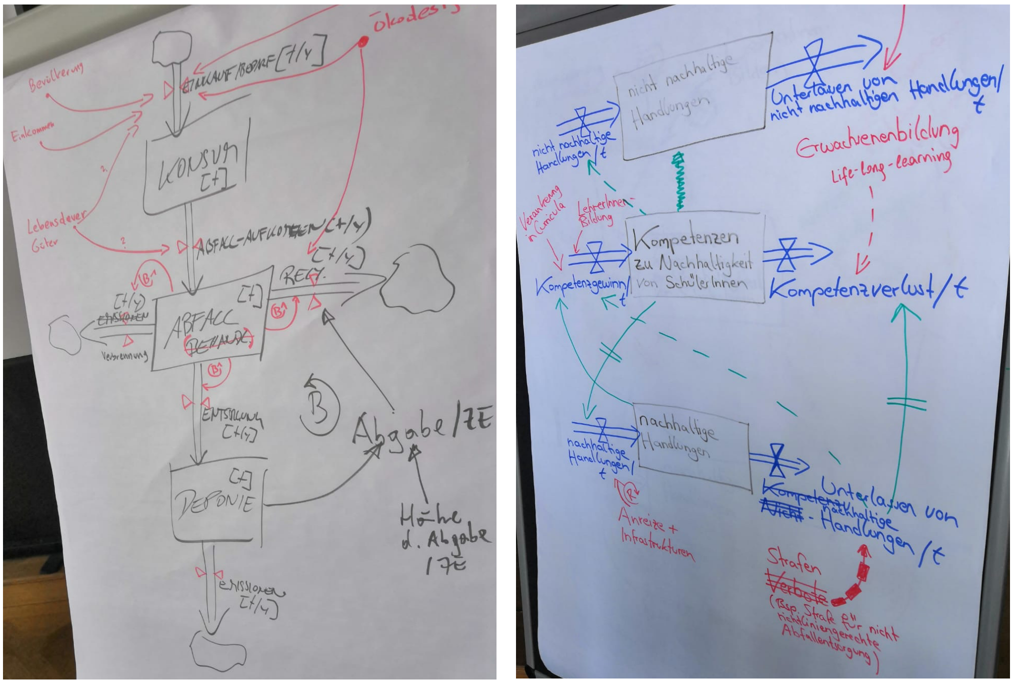

Figure 5: Application of a systemic approach within exemplary topics (Source: Working Group Sustainable Construction Graz University of Technology 2019)

Another ongoing activity is the continuous involvement of students in the SDG topic as well as in the UniNEtZ project. As an example here, a master's thesis, which has already been completed, can be mentioned. The topic of the thesis was the *investigation of the systemic approaches' application within SDGs in the last years and the identification of relevant fields of action in the field of sustainable construction*. Another positive aspect is the interest and willingness of students to present and disseminate the contents of their master's theses at conferences (e.g. SBE19 or ENOVA19).

5. Conclusion and Outlook

By setting the structure for collaborative work between the participating institutions, the framework conditions for working on options for how to achieve the SDGs has been laid. There is solid expertise available to work on the SDGs. During the next months, the team will work towards a first report, outlining the methodological approaches in developing measures for how to achieve the SDGs and giving examples of options. Following the identification of the research strengths a first step has been taken on working in a more targeted manner on the SDGs.. In order to fill existing gaps, expertise will be further extended in the near future by involving further stakeholders and partners. Appropriate methods and communication formats on how to involve these stakeholders will be developed.

One important group to be addressed is that of the students, as drivers of sustainability, change agents and future decision makers [12-13]. In order to integrate sustainability into higher education, investigating which topics and approaches are already contained in university curricula can help to focus the agenda more towards sustainability issues and real-problem based education and research.

Architectural Education for a Post-Fossil Future

Roswag-Klinge E, Pawlicki N, Crabbe M
Natural Building Lab Technische Universität Berlin

roswag-klinge@tu-berlin.de

Abstract. The transformation to a post-fossil future will require us to radically rethink the way that we live, build, consume and educate. Currently in Europe the construction sector is responsible for nearly 40% of direct and indirect CO_2 emissions [1] and 30% of waste [2] generated. With these numbers only increasing, young designers will carry a huge responsibility for reducing the sector's impact on the environment. Yet in many cases architectural education continues to place form-making in the centre of the curriculum at the expense of an understanding of the complexities of planning in a post-fossil future.
Since its inception in 2017, the Natural Building Lab (NBL) at the Technische Universität Berlin has been exploring new methods of architectural education with the premise that new models and formats are needed in order to equip young designers with the tools they will need to affect change in a rapidly changing, globalised society. The projects undertaken by the Lab up till now have put an emphasis on self-determined learning as the vehicle to involve students proactively in urban-change processes. The first built projects from the Lab, while in diverse contexts, all combine circular, LowTech construction principles with the performance of natural building materials to produce a vision for a post-fossil architecture, often designed and realised by students in trans-disciplinary collaborations. The paper will look at the challenges facing architectural educators and how the Natural Building Lab is aiming to frame its pedagogic strategy based on the realities of resource scarcity and climate change.

Figure 1. NBL Collaborative Design Workshop, TU Berlin fall 2017

1. Introduction – The Big Picture

The current “perfect storm” of social, political, economic and ecological conditions internationally shows little evidence of abating despite the increasingly dire warnings of leading experts. In 2015 the Stockholm Institute for Climate Resilience published an update on their 2009 research on Planetary Boundaries, of the nine boundaries they identified three are already beyond the “zone of certainty”, three more are already close to their limit and two cannot yet be scientifically quantified. [3] Sadly, the indications that pursuing a policy of growth of any cost would eventually lead to us to calamity were already identified in 1972 by the Club of Rome. Meanwhile international policy such as the UN’s Sustainable Development goals, the Paris Climate Agreement or any number of high profile climate legislation seem unable to make any real empirical progress with political institutions increasingly paralysed by the rise of a new politics of populism fueled by an increasing disenfranchisement with the political establishment across the political spectrum. Encouragement can be had from the increasing mobilisation of a new generation of climate advocates such as Greta Thunberg or the gains made by green parties in the 2019 European Parliament elections in the wake of the Extinction Rebellion protests. Nevertheless, the outlook remains bleak and it is now certain that within a generation the realities of climate change and resource scarcity will require us to completely rethink the way that we live, work, consume and interact with each other and our environment at all scales.

Despite on-going sustainability efforts and increasingly earners public discourse and activism, the building sector remains responsible for around 40% of the European energy consumption[1] and 50% of the overall use of material resources. In addition, around 60% of the waste in Europe (approx. 750 Mio. Tons) is classified as construction and demolition waste (CDW)[2] generated by the building sector. The challenges facing the building sector to meet the targets set out in the Paris climate agreement are enormous and span scales and the traditional disciplinary boundaries.

2. The Post-Fossil Architect

In order to face the challenges facing the profession in times of upheaval, there is a huge potential for architects to use their specific skill set to co-produce new knowledge that can help society combat the challenges posed to the built environment by climate change. However, this will require us to reconsider the position of the architect in a wider societal context. Architects occupy a difficult position in the climate debate, because on a basic level, an architect is someone who designs and constructs buildings – traditionally ever more, bigger and more resource intensive buildings. This is why clients appoint architects, and it is without a doubt seen as our key competency and it is the service for which we usually receive financial remuneration. Furthermore, designing buildings receives the most focus in our education and it is the skill with which we generally most identify ourselves – nearly all of our institutions, associations and presumptions are built on this premise.

For the next generation of young designers scarcity will be the theme that dominates discourse in the profession for the near future. The way that the dynamics of material scarcity will affect all aspects of our lives is only just beginning to be researched. Yet the way that we define and understand scarcity as a concept has potential to open new fields of agency for design practice. Working within the limits of externally defined boundaries has always belonged to the creative process of architecture and design – typically the architect is forced to work within the limits of the site or budget provided by the client in order to be able to realise their masterpiece. However, when we consider design practice as more than just the creation of a series of more or less beautiful of objects, and more as an intervention in an increasingly complex series of processes that react to existing systems and contexts, then working with scarcity is already an unavoidable part of our remit.

Over the last decade neoliberal economists and politicians have used scarcity as the legitimisation for a number of highly damaging austerity measures, cutting social support, infrastructure and services in the name of limited resources. Jeremy Till formulates the central presumption at the heart of this idea of scarcity as a false belief that, “human needs are unlimited, but the means to achieve them are scarce” [4]. In their essay “Design of Scarcity”, Goodbun et al. challenge this idea and argue for a new understanding of scarcity as a dynamic socio-material condition, one arising from the uneven distribution of power and resources and one which can be designed and influenced, rather than an inevitable endgame for the global consumer economy [5]. This understanding of scarcity has serious implications for design practice and provides the framework to imagine a new and expanded field of agency for designers more able to affect change in a rapidly changing globalized society where the challenges posed by climate change span institutional and disciplinary boundaries.

3. The University

Yet despite these challenges architectural education at most international universities is still largely based on the model of the École des Beaux Artes from the early 19th century **Error! Reference source not found.**. The daily image at the nearly 60 architecture schools in Germany for example is characterized by work and presentation formats that put students in competition with each other and design studios set up as a masters studio with a teaching person who sets the content and task. A lack of reference to 'reality' - the architectural practice and the challenges of the non-academic world - is often formulated as a critique to this system. According to the UNESCO/UIA Charter, the only paper on architectural education that is globally agreed on, ‘greater diversity is needed […] in architectural education and training‘.

In times of scarcity of resources, where the effects of climate change are threatening the lives of many people and leading to global migration and conflict, architects are also calling for a radical shift in thinking. An important approach is the training of young architects, who have the ability to reflect critically, to independently develop new solutions and thus to be aware of their responsibilities as planers. In order to make global urbanization and construction processes socially, ecologically and economically sustainable and thus future-oriented, architecture practice and education must use a cooperative working method across the borders of disciplines and social classes.

4. Learning Approach

The Natural Building Lab (NBL), which was founded at the end of 2017 at the Institute of Architecture of the Technische Universität Berlin, is seeking a methodology to address imbalance by enabling students to learn in a self-determined and collective process. Many of the cornerstones of the concept deliberately challenge existing notions of authorship and authority established within the university and professional context. This section will outline some of the key aspects of the Lab’s learning approach and how they relate to the idea of a post-fossil architect outlined above.

4.1. DesignBuild Methodology

The DesignBuild methodology dates back to the Community Design Movement in the US in the 1960s, whereas similar approaches can be witnessed before that time in schools like the Bauhaus, Talisien West or the Black Mountain College. Today there are more and more architecture schools worldwide undertaking projects where students are physically involved in the realisation of their designs in collaboration with local communities and NGOs. Networks like the DesignBuild XChange Network [7] and the Design for the Common Good network [8] are showing the power and the relevance of this global movement.

The first DesignBuild Studios in Europe, apart from the endeavors of the 1920s and undertaking regular, yearly project cycles were established in the late 1990s – the Mexikoprojekt (Prof. Ingrid Götz, TU Berlin), the DesignBuild Studio at TU Wien (Peter Fattinger) or the Live Projects at Sheffield School of Architecture. For 20 years a huge number of projects was realised by different chairs at TU Berlin. The EU funded research project “European DesignBuild Knowledge Network” (EDBKN) [9] initiated by Ursula Hartig, Simon Colwill and Nina Pawlicki at Habitat Unit (TU Berlin) as part of an international consortium developed criteria for DesignBuild projects and has set up the international network dbXchange.eu.

Definition of DesignBuild and its methodology by EDBKN: DesignBuild Projects are components of higher education in the field of built environment that allow students to be physically involved in the materialisation of their designs. DesignBuild Projects must: be based in higher education; have a brief, budget and timeframe; be built; have students involved in the design AND construction of the project; be of architectural, social, cultural, scientific, technical or artistic relevance. The Natural Building Lab is carrying on the DesignBuild tradition at TU Berlin.

4.2. Trans-disciplinary Collaboration

The image of the architect established by the modernists was of one expert who could control the building process from the start to finish. The complexity of the contemporary building process requires skills and knowledge that go well beyond the expertise of one discipline. This has resulted in a fractured field where experts from different disciplines struggle to integrate their different areas of knowledge into a linear, phase-based design process, which is often not conducive to collaboration. By integrating input from other disciplines at an early stage of the design process and fostering a truly collaborative instead of competitive spirit, it would be possible to eliminate many of the process-based difficulties that arise and thus improve the efficiency of the project process by recognizing synergies, opportunities and problems at an earlier stage. Yet while inter-disciplinary working remains a popular buzz word in the industry, in reality restructuring processes to truly enable trans-disciplinary collaboration is a huge challenge and requires a bottom-up rethink. It is of huge importance that the different disciplines become used to working collaboratively during the early stages of their studies.

4.3. Co-production and Co-ownership

We see a changing role for designers in a societal context, one of the architect as a moderator and facilitator. There is a huge potential for architects to use their unique skill set to integrate skills, knowledge and input from project actors into complex design processes by working on an equal level. Only through an integrated and participative methodology can true shared ownership of outcomes be achieved. By placing a high value on this input from actors outside of the profession, it is possible to co-produce knowledge and foster a shared authorship. Thus architecture becomes a tool and vehicle to instigate bottom-up change in society, as opposed to being limited to an artistic service only available to the few.

Figure 2. Building Cycle, structural test, January 2018

Figure 3. Community Collaboration, Building Cycle December 2017, CRCLR hall, Berlin Neukölln

4.4. Self-determined learning

Heutagogy is an emerging field of research into the effectiveness and practice of self-determined learning processes [11]. With the proliferation of digital media the way in which we access and consume knowledge has changed beyond recognition and pedagogic methods and institutions are struggling to catch up. Traditionally universities place a high value on the one-way transfer of knowledge from teachers to students and this is the premise upon which accepted teaching formats and institutions are built. Yet when we move from the perspective of “knowledge hoarding” to one of “knowledge sharing”, we begin to unlock the true potential of a two-way learning process for both the “teacher” and the “student” (Fig 2 and Fig 3). Furthermore with the ease in which digital media allow us to access new knowledge, there is a potential for institutions to place a renewed focus on skills (how to apply knowledge) and most importantly values (why to apply knowledge).

5. Teaching, Research & Practice

The main activities of the Natural Building Lab can be roughly grouped into three disciplines – learning, research and practice, with synergies and overlaps existing between them. For instance, a DesignBuild studio project can easily incorporate aspects of all three themes as will be discussed later in this paper. The emphasis is on blurring the boundaries between these often-separated aspects of architectural practice at an institution by focussing the sharing of knowledge between projects. This section will briefly outline the way that the approach is applied in these three fields.

5.1. Learning (The Studio)

The central part of the Lab's learning approach is the design studio, in which 15 to 35 students in the Bachelor or Master program collaboratively produce solutions to a changing set of themes. One of the challenges of the studio format is an established culture of competition among students, one born out of the competitive nature of design practice – the design competition being the traditional battleground in which architects pitch their ideas against each-other to win a contract. Yet the anonymous design competition reduces the scope of an architect's services to an artistic/technical service, especially because the competition always starts with a fixed and non-negotiable brief. Basing the studio format solely on the reference of a design competition hugely limits the creative potential of the process and only serves to further entrench a culture of "knowledge hoarding".

As a critique to this culture NBL studios place an emphasis on collaboration by encouraging participants to work in larger groups of 4 and upwards, sometimes even the whole studio will work together on one project. This forces students to confront themselves with the challenges of working in large and diverse groups, whether by finding ways to reach a consensus among a group of individuals from varying cultural backgrounds or by learning how to best utilise the varying skills and interests of group members, they are able to develop skills essential for a collaborative and open-minded design practice.

The studio also fosters collaboration by challenging the accepted formats of presentation and tutorials, where an emphasis is usually on the students being given direction by a panel of experts within a highly charged and hierarchical atmosphere. This format retains then principle that the instructor somehow is possessed of the answer, and to obtain it the student must follow the rules [12]. NBL's key format is a weekly stand-up discussion set up as a circle, this challenges the established hierarchy between teacher and student. Prior to the discussion of a project another group is identified as responsible for feedback and this group will start the discussion. Members of the chair will join the discussion but not pass judgement on a given project, the emphasis is on a collaborative learning process for student and teacher alike. This method, working on an eye level within the whole team promotes the self-discovery of the students and enables them to contribute each with their own qualities to the process. Another challenging culture is the value of students work, typically students work for the whole semester on a design studio, which after a presentation is added to the portfolio and then forgotten. Furthermore, students are not deemed as capable or responsible enough to work with real clients or materials – first one has to learn the technical skills before being able to apply them in practice. The DesignBuid methodology clearly challenges this tenant and the application of this in practice will be discussed in a further section. Yet the benefits and potential of giving students the opportunity to apply their ideas in a real context greatly changes how they consider the ownership of their ideas.

An NBL studio will always aim to provide students with the chance to work with real contexts, actors and materials during the design process. By providing this context for their work, participants gain valuable experiences that are for their future practice. (Fig 4.)

5.2. Research (The Lab)

The subject of what constitutes research within the field of architecture is one that has always been discussed controversially. Especially the question of whether design in and of itself can be considered as a form of research is one that is especially bitterly contested by thinkers on both sides of the divide. The Natural Building Lab aims to place research within the context of shared knowledge production integrating it into the other disciplines of research and practice. With an established expertise in the field of natural building materials and a strong link to a number of projects completed by the office ZRS Architekten Ingenieure, the NBL is able to provide a bridge between new and experimental concepts and its applications for users on the ground.

Design studios can be conceived on the basis of findings from a research project, as with the award-winning project Infozentrale auf dem Vollgut which will be discussed in more detail in the following section. In that case providing students with access to ideas and concepts about the use of recovered timber as a resource for new construction, which eventually led to the realization of a pavilion, allowed the research project to showcase its findings in a larger scale and more prominent case study project than would have been otherwise possible. Furthermore, the experimental nature of the project provided further findings and knowledge, which could be reintegrated and furthered by the research team. Again, in this instance the idea of individual authorship is challenged by the production of new knowledge in a collaborative integrated process.

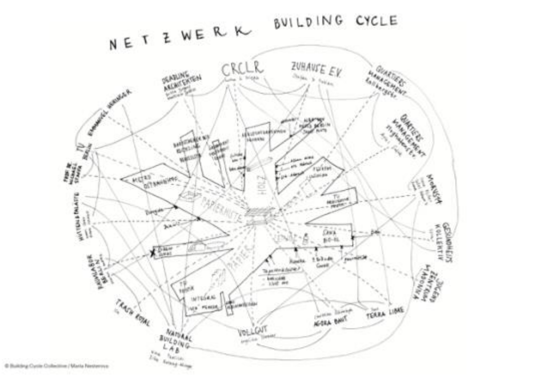

Fig 4. Building Cycle network, partner connection and material resourcing

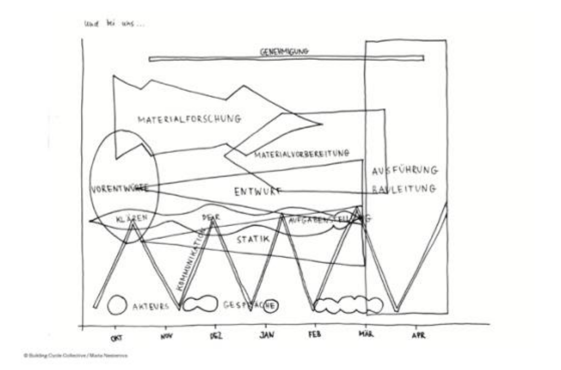

Fig 5. Building Cycle, workflow, design and construction

5.3. Practice (The City)

The NBL emphasizes a *critical* architecture practice based on a critical understanding of external conditions, in this case external to the context of an architecture school. This practice can take the form of hands-on construction and experimentation in 1:1 or an application and testing of ideas developed in the studio to a real context.

Often design projects will be initiated with the set aim of designing and realizing a building task. Architectural design often takes place on paper, or increasingly on a screen, and while it is possible to teach the theory of construction, there is no substitute for hands on experience. The realities of a DesignBuild project also show the inadequacy of seeing a building project as a linear process in which a series of phases are completed one after another (Fig. 5.). This mindset limits the ability of different disciplines to locate synergies at different stages of the project by always focusing on one complete package of work at each stage of the process, an aim which understandably becomes the focus of each party's attention.

The opportunity to experiment in 1:1 with real materials gives students the chance to apply their knowledge responsibly in a creative context. The Lab is also equipped with a 300sqm research and workshop space where 1:1 prototypes, pre-fabrication processes and research on earthen materials can take place all year round. Furthermore, the NBL Hub, one of the results of the first master studio in

2017/18, is a 70 sqm reversible arch structure based on the idea by Leonardo Da Vinci designed to be transported by cargo bike and assembled by 2 people within 10 minutes. The Hub provides a mobile outpost or workshop space and can be used to provide a space for events and encounter in the neighborhoods where projects are based (Fig 6 – 8).

Figure 6. NBL Hub transported by cargo bike

Figure 7. NBL Hub, assembly

Figure 8. NBL Hub, mobile outpost

6. From Building Cycle to "Infozentrale" – the first NBL project

The "Infozentrale auf dem Vollgut" was designed and realised by a group of 36 students as part of the BUILDinG CYCLE design studio from the Natural Building Lab at the Technische Universität Berlin in Winter Semester 2017. In co-operation with the research project RE4, a building embodying circular construction principles was realised from waste materials as a DesignBuild project, offering an answer to questions relating to resource-positive construction in an urban context and embodies a new method of architectural production for a post-consumer society. In the opening weeks of the project the student groups undertook a material research, where innovative low-tech constructive elements were created using a wide range of waste materials Through this research the groups established a network, through which they were able to source larger amounts of the waste materials used for the building – recovered timber and cardboard. The load bearing structure of the building is formed from timber recovered from local demolition sites and a dismantled architectural installation from the International Garden Festival 2017, thus providing a second usage cycle for this valuable resource. The 8m x 10m roof structure is formed by a pre-stressed grid of layered and interlocking re-used timber beams with reversible connections designed for disassembly. For the wall elements an experimental system was developed utilising stacked upcycled cardboard fruit boxes filled with shredded paper as insulation and covered with recovered large format posters and plot drawings – common waste materials within the architecture faculty. The project embodies circular construction principles and serves as a prototype for a LowTech post-fossil architecture based on the realities of resource scarcity and climate change (Fig 9 and Fig 10).

Figure 9. Infozentrale, installation roof construction, timber beam lattice grid

Figure 10. Infozentrale, raw construction, timber beam grillage, fixed columns

During the design and construction phase, the students networked with around 200 participants on and around the site in order to get a deep understanding of the situation and to anchor the project locally and to resource materials for building (Fig. 4). The project set new standards for the Natural Building Lab's work and achieved feats above and beyond the aims set at the project's outset. The entire pavilion utilised connections and materials that could be easily executed using hand tools and with the minimum of previous experience, as such the building sets a standard for a LowTech building system that can be adapted and reformed by the end user. Thus the project sets itself up as an alternative to the standard and highly commercialised standard methods of architecture production typical of the fossil-economy. Furthermore the project succeeded in establishing a number of new material networks and cycles within the neighbourhood, connections which have been documented and can be further built upon in further projects. As a DesignBuild project the studio succeeded in integrating a wide range of inter-disciplinary collaborations both within the university and with actors on the Vollgut Areal and from the surrounding neighbourhood. The finished Infozentrale (Fig 11 and Fig 12) serves as an embodiment of these principles and as a built prototype for a post-fossil architecture based on the realities of resource scarcity and climate change. The Infozentrale has since been awarded as a runner-up in the Deutsche Holzbau Preis 2019 and with a special prize in the Holzbau+ Competition 2019.

7. Taller Tropical, Moravia, Medellin

The Taller Tropical Moravia is the latest in a series of interventions which seek to promote environmental education in the Moravia neighborhood of Medellin, through the collective construction of a community space for meeting and learning. The project was conceived by the Moravian community leaders and international students, within the framework of Urban Lab Medellín | Berlin, a cultural and academic exchange between the two cities that began in 2016 with the goal of developing local solutions for global challenges.

Starting with the premise that the integral and sustainable development of cities can only be built collectively, the platform linked inhabitants, civic movements, NGOs, artists, students and professionals from different disciplines, and actors from the private and public sectors; to discuss, research, design and build together. During summer schools in Medellin and Berlin, workshops, events, conferences and interventions were held in the public space, such as the renovation of the Tropical Oasis Stairs in Moravia.

Throughout this process, scenarios and strategies were developed to transform Moravia into a sustainable model neighborhood. At the Berlin Summer School in July 2017, 9 Moravian leaders raised the idea of converting El Morro areas into a laboratory for environmental and food education. This proposal called "Sowing Life" (Sembrando Vida) was elaborated with students of several universities and the inhabitants of Moravia. Due to a certain slowness of reaction from the public administration, the project could not be executed this year. However, the process has raised awareness on the issues that the project sought to address, a wide network of allies and a wealth of knowledge. The community continued asking that the project be carried out and promoted the development of a Plan B: the Taller Tropical Moravia in September 2018. The project is a collaboration with and based on previous projects at Habitat Unit, TU Berlin (Fig 13 – 15).

The Taller Tropical was designed and realised by an inter-disciplinary design studio at the Natural Building Lab with architects and civil engineers. During the realisation phase participants collaborated directly with local tradesmen, a Columbian bamboo construction collective, local school children and members of the local community. The project is the embodiment of shared ownership, authorship and production and an example of how a small intervention can instigate larger change processes in an international context.

8. Conclusion & Outlook

After nearly four semesters of activity, a broad network of projects and partners has developed around the Natural Building Lab, and this continues to grow with each new project. We understand the Lab as a network through which diverse actors can co-operate in activities aiming to induce long-term societal change for the betterment of the planet and those who inhabit it. With the first class of NBL "graduates" departing the university this Autumn, we are excited to see how this network will develop and how the values and skills learned during student's studies can be applied to the wider working context of post-university graduate jobs. Certainly, every semester has seen a core group of studio participants forming a "collective" to further pursue the themes and collaborations introduced during the semester in the longer term. This is a very encouraging dynamic and shows that giving students the opportunity to work with real people, places and materials allows them to develop the confidence to pursue their ideas independently and to position their ideas with the context of wider societal and architectural discourse. Furthermore, it allows students to form their own ideas about the role of an architect in a societal context based on these experiences.

The Lab's network is also growing to encompass a number academic and industry-based collaborators for research projects spanning from the circular potential of earthen building materials to questions surrounding what we can learn about a climate adaptive and resource efficient architecture from pre-fossil cultures. The findings from these projects set the basis for further integration of teaching, research and practice activities.

In conclusion the challenges facing young architects in times of scarcity are huge and will require them to question the established norms and preconceptions existing in architectural practice at large.

Only by placing an enhanced emphasis on the collective over the individual and collaboration over competition will the sector by able to successfully navigate the dramatic changes that will be required to remain relevant in the face of climate change and resource scarcity. The Natural Building Lab is seeking to equip young designers with the knowledge, skills and values they will need to define a new role and potential for architects in a post-fossil society (Fig 15).

Affordance-based Design Method: A Case Study of University Campus

Gupta D[1], Uma Maheswari J[2]

[1]PhD Scholar, Department of Civil Engineering, Indian Institute of Technology Delhi, India
[2]Associate Professor, Indian Institute of Technology Delhi, India

durvagupta492@gmail.com

Abstract. Development of a built environment encompasses urban design, land use, transportation system, and accommodates patterns of human activity within the physical environment. Holistic development of built environment requires a multidisciplinary design team of urban planners, architects and sustainability advisors from an early design stage. Literature and industry-practices show growth of designer's techniques and competencies, sustainable development capabilities, and user-centric prospective in the early design. However, there is a lack of systematic method and all-inclusive approach to design a built environment. Thus, proposed research aims to develop a design method which is user-inspired, stakeholder conducive and environmentally conscious from an early design stage. To achieve this aim, an affordance-based design method is proposed and demonstrated through a case study of university campus. Affordance-based design method has been used for design of complex systems by capturing user needs, stakeholder ideas and generating design options. The proposed design method provides decision-making guidelines to designers, design space to incorporate stakeholders, and affordances to achieve sustainability. The proposed design method has potential to shift design and development of built environment from designer-controlled process to systematically organized process.

1. Introduction

The goal of urban design of built environment is to improve the quality of life, enhance system efficiency and limit environmental impacts. Built environment encompasses all forms of buildings; civil engineering infrastructures both above and below ground such as transportation system, utility systems, and telecommunication systems; and landscapes around buildings [1]. Urban design of built environment is closely linked with the user behavior and requirements. The design of every system of built environment is initiated by analyzing the user needs. Designs are more effective when user needs are considered and retained throughout design and development of built environment [2]. Observations from design practice suggest that user needs are considered at the start of the development but are often neglected during detailed design due to inadequate user-centric approach.

Another important aspect linked with the built environment design is the need for coordination among key stakeholders such as civil engineer, architect, MEP designer, and environmental advisory during designing, planning and constructing. However, stakeholder coordination is still a bottleneck in the design management [3]. Additionally, sustainable development goals of 'sustainable cities and communities' recommend environmentally conscious design of built environment. Green building certification programs and energy efficient technologies are some initiatives in this direction. However, incorporating environmental measures in a design process is multidisciplinary in nature and thus becomes a challenge [4].

According to the Royal Institute of British Architects, the design process consists of three sub-stages: concept design, developed design and technical design [5]. Hence, the three aspects, viz. user requirements, stakeholder integration, and environmental consideration should govern the design in all the three sub-stages. However, in practice, sequential design process is not being ensured.

To address this gap, the research extends affordance-based theory to devise a structured approach for design of built environment. Maier and Fadel have applied affordance-based theory to the design of artefacts [6]. Various systems of built environment can be treated as artefacts and designed by following a set of procedures to fulfil the needs of user. This structured approach is termed as Affordance-based Design Method (DM) which aims to incorporate user needs, stakeholder coordination and environmental consideration. The proposed DM is demonstrated through a case study on urban design of a university campus. The observations from the case study are discussed in the light of existing literature to emphasize the potential of proposed DM.

2. Literature Review

Several engineering design theories have evolved over time as summarized in Figure 1. Design has been addressed using two theoretical paradigms. First is Simon's Sciences of the Artificial (1969) based on normative, rational and structured approach. It follows certain rules and procedures, and popularly discussed under design as 'science' [7]. Second is design as reflective practice given by Schon's (1983). It aligns with industry practice driven by practitioners' creativity and ideas rather than a set of rules [8].

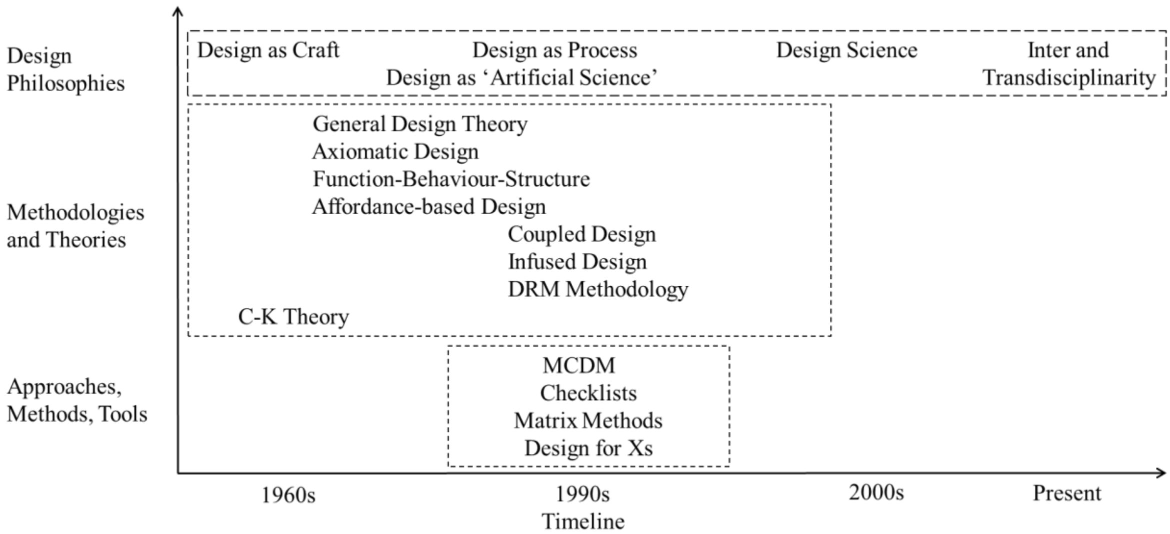

Figure 1. Evolution of Design Theories

Other major theories in engineering design research are – German systematic engineering design by Pahl and Beitz [9], Axiomatic design by Suh [10], Total design theory by Pugh [11], C-K theory by Hatchuel and Weil [12], Design research methodology (DRM) by Blessing and Chakrabarti [13], and Function-behavior-structure methodology by Gero [14].

Maier and Fadel [15-17] argued that existing engineering design theories are insufficient to provide a systematic design method. Thus, they formulated an affordance-based design method. The concept of affordance was first introduced by psychologist James J. Gibson during 1979 in the domain of ecological and perceptual psychology [18]. Later, Norman applied the affordance theory to the design domain and demonstrated human-computer interaction [19]. Maier and Fadel brought affordances in engineering design by asserting user-artefact interactions [6]. The term *affordances* of an artefact means what an artefact should provide or offer. It is described as a set of interactions between artefacts and users, designers and users, and a pair of artefacts, as shown in Figure 2. The complex nature of these interactions give rise to two types of affordances – (i) Artefact-User Affordances (AUA) describes interaction between an artefact and users; and (ii) Artefact-Artefact Affordances (AAA) describes interaction within artefact subsystems.

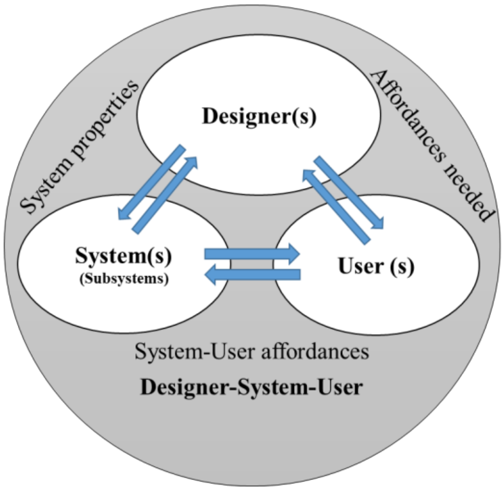

Figure 2. Affordance Interactions within Designer-System-User Structure [6]

The design of built environment is similar to the design of product. Hence, systems of built environment can be considered analogous to artefacts. In built environment design, AUA describes the relationship of a system's users with the system design, whereas AAA describes the complex interactions taking place between key stakeholders and technical aspects of the system. AAA makes it easier to communicate and concurrently design the systems. The concept of affordance in built environment design is suitable because it entails relationship between two systems, incorporates users, and allows proper use of functions of a system in design. These features are included in the DM.

3. Affordance-based Design Method (DM)

Maier and Fadel (2006) defined two fundamental affordance-based methods: a high-level affordance-based design process and a method for designing individual affordances. Previously, high-level affordance-based design process has been applied on several case studies of product design [20-22]. Some prominent works which followed affordance-based design method are generation of consumer specific design specifications [23], and automation of embodiment and detailed design phases of product design [24]. These studies demonstrate the benefits of systematizing and structuring the design process [25, 26]. Thus, affordance-based design method can be perceived as sequential method which can be adopted at the design stage. However, this method has been applied so far only in product design.

The proposed DM is similar to the existing affordance-based method in product design. Figure 3 is a schematic representation of the proposed DM which consists of two steps. In the first step, value adding and non-value adding affordances are identified and user information module is prepared. Then, a designer information module is prepared to enlist technical inputs for the affordances and develop a generic affordance structure. The module guides designers about what affordances they are expected to provide through a system. It also ensures that any affordance associated with a system are not missed. Further, affordances are prioritized based on the preferences of users and designers. Thus, the first step generates an organized affordance structure at the specification level based on system-user affordances.

In second step, individual affordances are chosen, and their detailed affordances are created. User-groups associated with individual affordances were also mapped. Then, system properties that affect the affordances were identified. Further, properties of other systems that affect the individual affordances were documented. Next, targets and bounds for each property were determined. Since built environment design is constrained by building codes and bye-law, all such constraints associated with affordances were identified at this step. Prescribed numeric range of these constraints adds a quantifiable parameter to a design. At this point, designer gets the understanding of properties, targets, bounds and constraints of the system that affect the affordance. The second step was repeated for all individual affordances to populate detailed affordance structure. Then, effects of the property settings of an individual affordance on other affordance were analysed. This provided a comprehensive affordance structure for the system design. Such a comprehensive affordance structure will support generation of multiple design options.

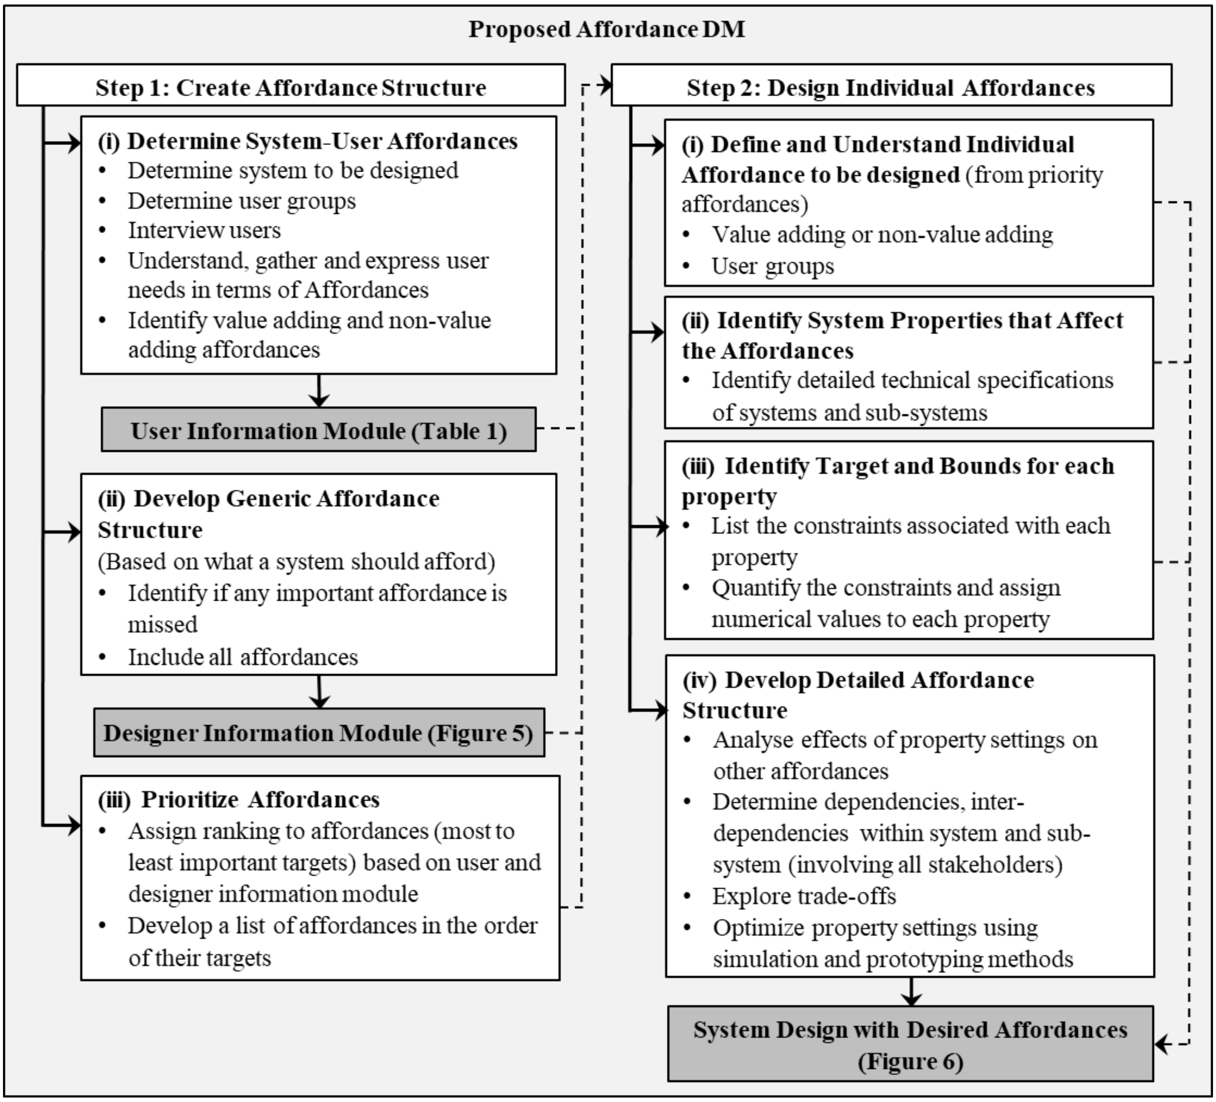

Figure 3. Framework of Affordance-based Method

4. Case Study

The application of the proposed DM is demonstrated through a case study on the design of a mobility network system in the built environment of a university campus. The campus consisted of hostels for students, residential buildings for employees, academic buildings and community buildings. The anticipated growth of campus population is 25%, and its design aims to provide sufficient built-up spaces, building services, utilities and mobility networks in future. The scope of the case study is limited to identifying the affordances and system parameters of mobility network.

The data was collected through participatory action research. The first author participated in the series of design meetings held among users, client and designers. User needs were identified by the designers through five focused group-discussions with the user-groups listed in Figure 4. Each group was represented by five to seven users and the average length of each discussion was three hours. The data collected from the group-discussions was used to develop a designer-system-user structure as shown in Figure 4. This structure forms the basis of designing affordances for the case study.

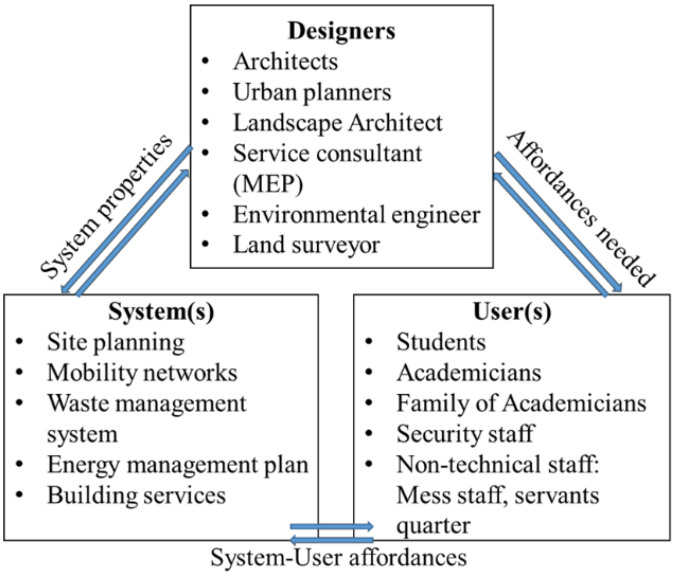

Figure 4. Affordance related Interaction within a Designer-System-User Complex Structure

The collected data from the participatory meetings was analysed for the design of mobility network system using the proposed affordance-based DM. Table 1 shows resultant User Information Module with value adding and non-value adding affordances for mobility network design (Figure 3, Step 1 (i)).

Table 1. Affordances for Mobility Network

Value adding affordances (positive)	**Non-value adding affordances (negative)**
Provide thorough fare movement within campus to all users	Minimize traffic conflicts at some points
Connectivity of campus with the city	Reduce travel time
Facilitate pedestrian movement to all users	Reduce trip length
Integration of all modes of transport system	No Congestion at peak hours
Incorporate comfortable, energy efficient and sustainable ways of transport	Reduce extent and distribution of roads in campus
Provide safe and secure pathways	Reduce urban heat island effect
Access to visitors/city people	
Maintain and maximize green cover	

Next, subsystems of the mobility network such as parking spaces, pedestrian pathways, and vehicular traffic system were identified (Figure 3, Step 1 (ii)). Corresponding technical input for the affordances led to a Designer Information Module as shown in Figure 5. One of the affordances–to reduce urban heat island–is selected for the illustration of 'designing individual affordance' (Figure 3, Step 2 (i)).

The characteristics of Urban Heat Island (UHI) which affect the design specifications of mobility network were listed by the designers. Alongside, potential interactions among the characteristics of UHI and the specifications of other systems were identified. For example, UHI is affected by building design, building form, building orientation, along with roof and wall design. Shaded blocks inscribed in circles

A1-A2 of Figure 6 depict interactions of UHI affordance with the design specifications of mobility system (Figure 3, Step 2 (ii)).

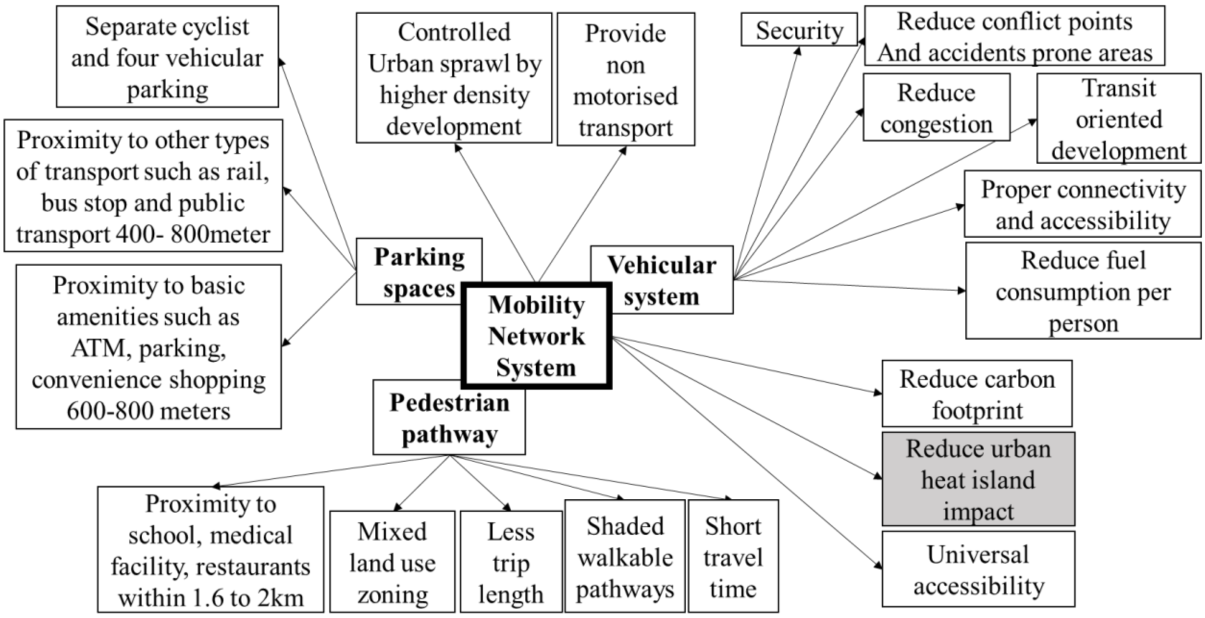

Figure 5. Generic Affordance Structure for Mobility Network System

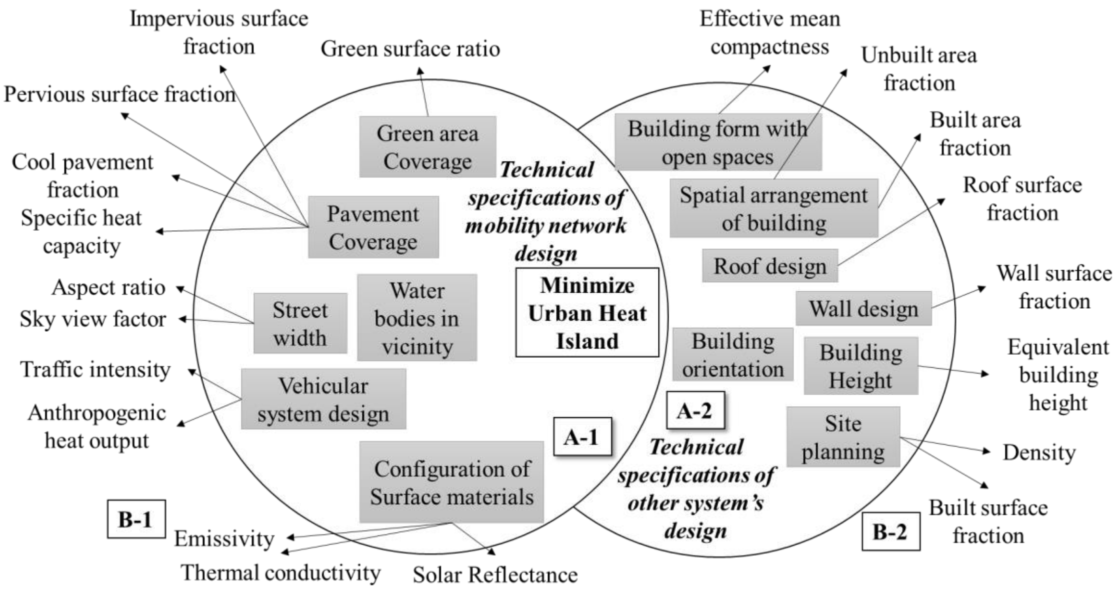

Figure 6. Detailed Affordance Structure to Minimize Urban Heat Island Impact for Design of Mobility Network

After analysing the first level of interaction in A1-A2, next level of interaction (Figure 3, Step 2 (iii)) quantifies associated characteristics of UHI as shown in zone B1-B2 of Figure 6. For instance, 'street width' is a specification of mobility network which is associated with UHI affordance. Street width is quantified using two parameters, 'aspect ratio' and 'sky view factor'. Aspect ratio is the mean height-to-width of street canyons, and sky view factor is the fraction of sky hemisphere visible from ground level. By optimizing these two parameters, UHI can be minimized in mobility network design. Similarly, other design specification can be translated into quantified parameters which will help in simulating alternate design options, analyzing trade-offs and optimizing the system design. Quantification of these parameters will be based on bye-laws and standard code of practice. This provided a detailed affordance structure for one affordance (Figure 3, Step 2 (iv)).

Subsequently, the detailed affordance structure was extended to all affordances to obtain an overall mobility system with desired affordances. The resultant affordance structure will guide the designer as to what the system should offer and how the design should proceed with affordances.

5. Discussion

In the selected project, the designers have approached the design of university campus based on their experience and prevalent architectural knowledge. This approach is similar to design as reflective practice given by Schon. In contrast, this research has applied affordance-based DM, which comes under the theory of design as 'science', on mobility network design of university campus. In this research, the concept of affordance is applied to the design process only for problem definition and conceptual design of built environment. The affordance-based DM (Figure 3) demonstrated through the case study improves the existing design process in the following manner:

- DM paves a way to capture the user needs in the form of affordances and allows them to interact with the designer knowledge and system properties (Figure 3, Step 1(i)). Such systematic consideration of user needs cannot be ensured through existing design process. The study can also be extended to subsequent stages of detailed design and technical design.
- Example of UHI illustrates that DM allows the sustainable target values to be incorporated while deciding bounds and targets of affordances that the design is intended to provide (Figure 3, Step 2(iii)). Though, the presented case study showed the analysis of only one sustainable target, multiple sustainable targets can be analysed using simulation techniques and the DM. Detailed affordance structure will also provide information about parameters required for simulating design options.
- DM traces the web of interactions between systems and subsystems by formulating multiple affordance structures and coordinating multiple stakeholders (Figure 3, Step 2(iv)). For example, affordance structure in Figure 6 visualizes the collaboration of architects, energy analyst, civil engineer, and contractors for site planning, site zoning, and surface material selection. Such extensive affordance structure will guide decision making and assist in trade-off analysis during a design.

Overall, the DM provides a mechanism to transform the information available from users and designers into technical information which drives the conceptual design process. Further, sequential and structured affordance-based DM aids in the evolution and transition of myriad ideas of users, designers and other stakeholders into cohesive concepts which would be eventually be reflected in the designed built environment.

6. Conclusion

Despite extensive literature on managing the design process, there is lack of systematic and all-inclusive approach for incorporating user needs, stakeholder interactions and sustainable values in a design. To address these issues, this research has developed an Affordance-based Design Method for the design of built environment. This affordance-based method is drawn from product design. Potential application of proposed Design Method is demonstrated through a case study on the design of mobility network in a university campus. The research findings suggest that by deploying a sequential analysis in the early design stage of complex systems like built environment, it is possible to incorporate user needs, improve stakeholder coordination, and achieve sustainable dimensions. Evidence from the research indicates that affordance-based DM enhances capability of designers by guiding them through management of design information. These inferences establish the potential of affordances in the design management.

This paper has reported an ongoing research on the development of an Affordance-based Design Method through an example of design of mobility network system. Future research will refine the proposed method by implementing it on design of other systems and their interactions. After refinement of the method by optimizing and prototyping design options, it will be validated by implementation in real-life built environment projects to illustrate its advantages and eventual drawbacks.

maria.perzon@bengtdahlgren.se

Abstract. Residential and commercial buildings give rise to about one fifth of the greenhouse gas emissions in Sweden. One important goal of the City of Gothenburg is to be a climate neutral city with fair emission levels of greenhouse gases in 2030. In order to reach this goal, a demonstration project has been initiated with the aim to build a fossil free preschool - Hoppet. Hoppet will be built with a minimal climate impact and with no fossil resources. This includes everything from production and transport of materials to energy usage in the building. The fossil content and the climate impact of a standard preschool has been calculated, to be used as a benchmark for Hoppet. The result shows that all 250 building products in the reference preschool have a climate impact but finding fossil free and climate neutral alternative products has been found challenging. The climate impact of the building products in the reference preschool is calculated to more than 220 kg CO_2-eq. per m^2. Strategies to decrease climate impact for Hoppet preschool has been developed. For example, product development and innovation has been identified as key issues as well as increased collaboration between different actors in the construction industry. Communicating the project internationally is of high importance to find partners and innovations that don't exist in Sweden as well as to engage other stakeholders to help transform the building sector.

1. Introduction

The City of Gothenburg, in Sweden has set very ambitious goals to take an active role in mitigating climate change. In 2030, Gothenburg is to be climate-neutral, with a sustainable and fair level of greenhouse gas emissions, in order to contribute to the 1.5 degree-target **[1]**. As one of the first municipalities, Gothenburg has set goals, also including emissions occurring outside the city's geographical boundaries, from production of services and goods that are consumed within the city **[2]**. Construction has been identified as one of the city's activities with the largest climate impact. The City of Gothenburg has high standards for energy efficiency in all new construction projects, but so far, no restrictions when it comes to climate impact for building products. The City of Gothenburg is planning to build a lot of residential and public buildings in the coming years. Investments of 8 billion SEK (about 760 million EUR) are planned for 2020-2023.

During the last 10-20 years, the Swedish building sector has been focusing on energy efficiency measures and accordingly, greenhouse gas emissions from heating of buildings have decreased by more than 80% in 1997-2017 [3]. The next challenge is to reduce climate impact from the manufacturing of building products and from fuels used in transportation and on the construction site, considering all parts of a building´s life cycle.

In 2017 the city council of Gothenburg decided to give the city administration a big challenge – to build a fossil free preschool – Hoppet (the name can be translated both to "The hope" and "The leap"). Hoppet is to be built with as much fossil free material and climate neutral construction solutions as possible. The preschool will be finalised in 2021. Another goal for Hoppet is to promote fossil free building products and identify methods and strategies with the potential to be scaled up and eventually to be applied to all building projects in Gothenburg.

1.1. Fossil free construction and system boundaries

The innovation project, Hoppet considers all parts of a building's life cycle, as presented in figure 1, from extraction of raw material, manufacturing of material and products, through transport, to the energy usage at the construction site. Operation and maintenance of the building is also included, as well as demolition. No fossil-based material should be used as raw material and no fossil fuels should be used in production processes, in transportation of products or at the construction site. Reuse and recycled fossil based products are accepted as an alternative to products based on virgin fossil raw material. To minimize the overall climate impact, it is important and to consider the life cycle of the building, in this case in a one hundred years perspective. Thus, for example emissions of greenhouse gases, such as carbon dioxide released when limestone is converted to cement is included.

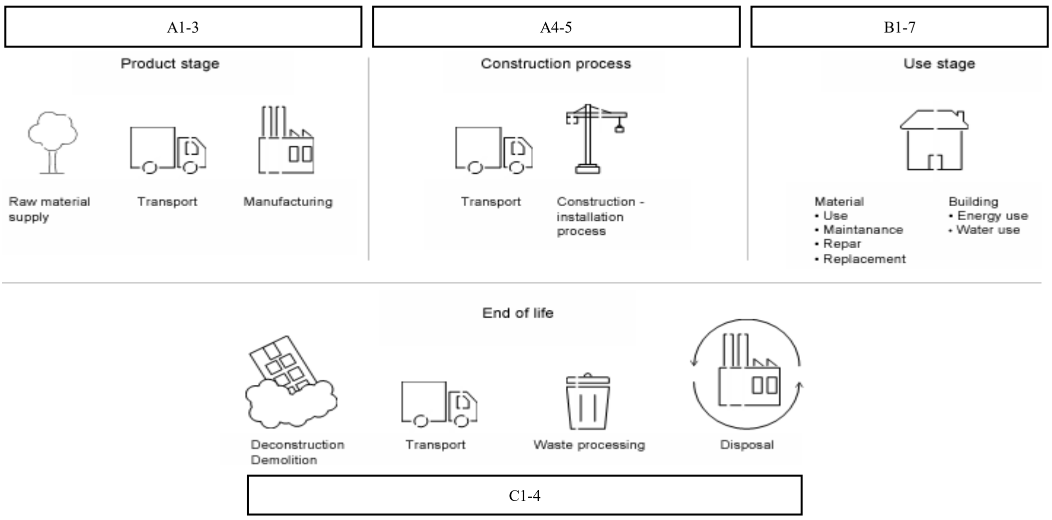

Figure 1. Life cycle stages for a building. Production of building products is referred to as building stages A1-A3, transportation to site is A4 and construction processes is A5. Operation and usage of the building, including energy usage and maintenance, is referred to as stages B1-7. End of life is referred to as C1-4.

2. Methodology – reference preschool and strategies

To get a better understanding of what challenges we need to manage, a first step was to make an inventory of a standard preschool, Byvädersgången, built by the City of Gothenburg. An inventory of the petroleum-based content was made, and a climate impact assessment was carried through for Byvädersgången, which is similar in size as Hoppet. The results are presented in this study, followed by the identified strategies for succeeding in constructing a fossil free preschool.

2.1. Inventory of fossil content in the reference preschool

The preschool, Byvädersgången is considered to represent a standard preschool, built by the City of Gothenburg. The starting point for the inventory was the 230 building products in the preschool registered in the Swedish material evaluation system, Byggvarubedömningen [4]. As a first step, an investigation was carried through to identify the petroleum-based content of all 230 building products. Fossil fuels used in the production processes and transports have not been included in this inventory.

2.2. Climate impact assessment of the reference preschool

As a second step, the climate impact of the preschool was assessed, including lifecycle stages A1-A4 and A5.1. The product list for Byvädersgången in Byggvarubedömningen was supplemented with data for missing products and quantities from contractors and subcontractors. In total, around 20 products were added to the product list. A newly developed calculator for the Swedish construction sector "Environmental impact calculator for construction" has been used to calculate the climate impact [5]. Each product and its climate impact has been compiled in the calculator. When selecting climate data, the following ranking order has been used:

1. Climate data from environmental product declarations (EPDs) with specific or generic data. [6]
2. Climate data from EPDs for similar products. EPDs for products from the same supplier have been prioritized.
3. Generic climate data for the product.
4. In cases where neither EPD nor generic data for the product have been found, generic data for the containing materials have been used to calculate the climate impact.

The ranking order has been verified by IVL Swedish Environmental institute [7]. Generic data in the calculator has been used to calculate climate impact of transportations of products to the construction site (A4) for each building product. Energy usage at the construction site has not been included.

The total climate impact of Byvädersgången has been calculated as the sum of the impacts of the purchased products, according to equation 1.

$$Total\ climate\ impact_{preschool} = \sum_{i=1}^{i=n} [Product(kg) \times Climate\ impact\ (kg\ CO_2 eq./kg)]_n \qquad (1)$$

The list of materials for Byvädersgången is based on purchased quantities, hence waste material on the construction site is included (A5.1).

2.3. Strategies for fossil free construction

In order to reduce the climate impact from construction a large part of the construction industry has joined the initiative *Fossil Free Sweden* and created a roadmap for a Fossil Free Construction Sector. The roadmap describes what technological solutions need to be developed, what investments need to be made and what obstacles need to be removed. In the roadmap it is concluded that there need to be a higher focus on the climate impact from the manufacturing of building products and from fuels used in transportation and on the construction site. Therefore, different strategies were identified in order to reach this goal and several of them have been applied in the project Hoppet. Additional strategies have been identified within the project Hoppet through an iterative process where different stakeholders in the industry has participated in workshops and seminars initiated by the Hoppet project team. [8]

3. Results – reference preschool

The results from both the inventory of the petroleum-based content and the climate impact of the reference preschool is presented in this section.

3.1. Results – Petroleum-based content

The result of the inventory of the 230 building products for Byvädersgången is presented in figure 2 and in table 1. A large part of the products is petroleum based, but to various extents. For example, 16% of the building products consist of 80-100% petroleum-based content. [9]

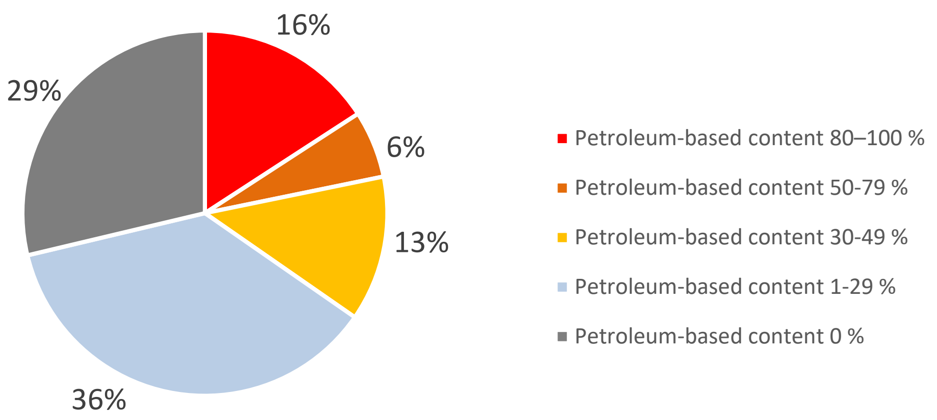

Figure 2. The proportion of the total number of building products (%) in the reference preschool, Byvädersgången. The products are sorted into groups with various share of petroleum-based content.

The result indicates that about 70% of the building products for Byvädersgången consist of materials with petroleum-based origin. The remaining 30% products mainly consist of:

- Metal in plumbing installations; pipes, valves, dampers and mixers (reinforcement in concrete is not included in the inventory),
- Cement or concrete for foundation, staircase, facade, roof and outdoor environment,
- Different types of insulation of stone or glass wool as well as some type of plasterboard,
- Ceramics and leca blocks for bathrooms, kitchens and the outdoor environment,
- Wood products outdoors and in interior decor.

From a life cycle perspective, building products without fossil content can have a large climate impact. For example, the processes for extraction and manufacturing of metals, cement and concrete are energy-intensive and have large climate impact. In addition, limestone in cement and concrete could be classified as a fossil material, which has not been considered in this investigation. Other product groups, such as wood products can in some cases have a relatively high climate impact due to emissions from transports and production processes.

Tabell 1. Building products with various share of petroleum-based content, in the reference preschool

Categories	Products
Red products (petroleum- based content 80-100%)	Pipes and plumbing products, insulation. electrical products, waterproofing and plastic film, foil etc.
Orange products (petroleum-based content 50-79%)	Pipes and plumbing products, cables, artificial grass, foil, surface layers etc.
Yellow products (petroleum-based content 30-49%)	Cables, finishes, concrete joints and color etc.
Blue products (petroleum-based content 1-29%)	Cables, paint, concrete joints, plumbing products, doors and windows, insulation
Grey products (0% petroleum-based content)	Plumbing products (metal), concrete and cement, steel profiles, wood products, leca blocks and ceramics

3.2.

3.3. Results – Climate impact

The results from the calculations are presented for different building components as well as for groups of building products, in figures 3 and 4, respectively. The allocation of building products to the different components, in this investigation, is presented below:

- Basic reinforcement and basic construction: edge support, support walls, factory concrete, primer, concrete base elements and insulation,
- Climate shell and frame: Concrete, insulation, steel profiles, windows, exterior doors, roof boilers, roof drainage, wind protection panels, window drives, sheet metal, rubber strips, sealing layers, plastic foil, sealants and joints,
- Frame supplements: plywood, plaster, coarse concrete, screed, fire joint, internal doors, concrete staircase, leca blocks, fire joint, freezing room joint, steel profiles, walls,
- Plumbing and ventilation: ducts, pipes, dampers, well, motor, donors, housings, insulation, mixers, luminaire grease, WC chair and shower set,
- Electrical and telecommunication systems: cables, VP pipes and flex pipes,
- Transport system: elevator,
- Surface layer: Paint, topcoat, joint, floor, underlay, substructure, washer, tile, panels, adhesive, adhesive floor, linoleum, fire paint, vapor barrier/primer, sealing membrane and plastic mat,
- Other furnishings: cabinets, hatches, drawer fronts, closets, countertops and counters.

The following products have not been included: escape routes, luminaires, push buttons, screws, fasteners, handles, cover strips, ventilation grilles and cover plates etc. in the kitchen/activity rooms. These products have been excluded due to lack of information and/or that the product is not considered to be a significant part of the building's climate impact.

The results from the calculation show that the climate impact of the preschool is 223 kg CO_2-eq per m^2 BTA. Climate shell, frame, foundation and frame supplements together represent 80% of the total climate impact, see figure 3. About 40% of the total climate impact can be allocated to the climate shell and the frame. Surface layers and plumbing represent 12% and 6% respectively. In figure 4 the climate impact for different groups of materials is presented. Products made of concrete, prefabricated concrete, steel and sheet products and insulation have a significant climate impact.

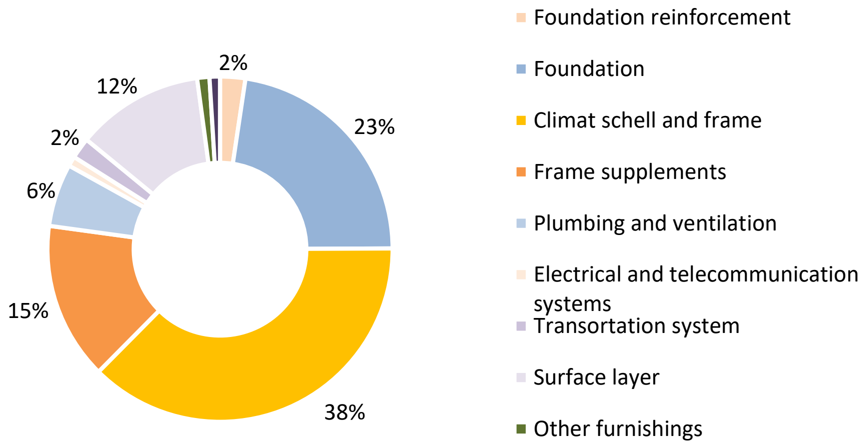

Figure 3. Climate impact of construction components in the reference preschool, Byvädersgången. Life cycle stages A1-A4 and A5.1 are included in the analysis.

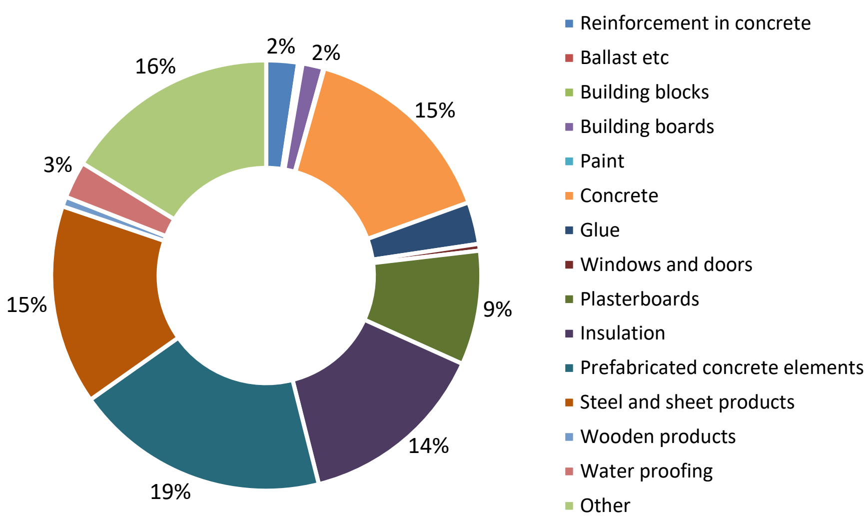

Figure 4. Climate impact of building products in the reference preschool, Byvädersgången. Life cycle stages A1-A4 and A5.1 are included in the analysis.

4. Strategies for fossil free construction

After investigating possibilities for replacing construction materials, by doing a thorough inventory, the project found a sparse selection of fossil free building product already available on the market. The project group then concluded that innovation and new ways of using existing materials were necessary. This, in combination with guidelines from the roadmap for a fossil free construction sector and seminars with stakeholders in the industry, resulted in the establishment of a strategy for progress:

- Biobased building products
- Reused and recycled building products
- Exclude and minimize usage of materials
- Requirements for building products in a life cycle perspective
- Fossil free construction site

Communication is also a vital part of all the identified strategies. Communicating our requirements is important for engaging the appropriate contractor and supplier of building products and to inspire other organizations to set similar requirement to achieve a transformation of the construction business towards climate neutrality. Further research and development is needed for the transition to a fossil free construction sector. Therefore, Hoppet has initiated and take part in several research and development projects, which are described in this section. It is also important to communicate the project internationally to find new partners and innovations that don't exist in Sweden as well as communicating the ambitions of the project to engage other countries and cities to make similar demands.

4.1. Biobased building products

Replacing fossil-based building products with new and existing biobased products is crucial to reduce the climate impact in the building sector. Hoppet tries to promote and highlight such initiatives and initiate research when needed.

4.1.1. Thesis work - Climate impact from wooden construction techniques

In January 2019 a thesis project was initiated focusing on investigating the climate impact and the resource problems related to various wooden construction techniques. Today, many different sectors of the society are looking to the forest for resources, such as the fuel industry, the packaging industry, the plastic industry, the textile industry, etc. Although the forest is a renewable resource, there is a risk that withdrawals of wood resource could become greater than the re-growth. To avoid this, Hoppet want to find the most effective way to utilize the forest raw material and analyze its climate impact. [10]

4.1.2. Research project – Wood foundation

Wood foundations are one part of a building where wood is used to a very small extent. Traditionally, concrete is used. To move towards increasingly biobased buildings, the foundation is a part of the building where an important minimization of the climate impact can be achieved by using more biobased materials. In this project, the ambition is to investigate the possibilities for industrialized production of wood foundations and to evaluate the technical performance. The project involves actors from the wooden house-building industry, developer and research institute. [11]

4.1.3. Research project - Fossil free glue and paint

Today's glue and paint products are largely based on components with fossil origin. In the research project called "Glue and paint", the aim is to replace fossil components with biobased solutions. By developing more components based on forest raw materials, the glue and paint of the future can become fossil free. The project was running from April to December 2018 and was a collaboration between research institutes, chemical companies, property developers, municipalities and many more. The aim is to find grants to continue the project. [12]

4.1.4. Research project - Policy for sustainable bio-plastics

Today, there is a large uncertainty regarding questions relating to ‘how’ and ‘if’ biobased plastics are socially and environmentally sustainable alternatives to the traditional fossil-based plastics. These uncertainties may be one of the of the obstacles to a large market breakthrough for biobased plastics. This project aims to create possibilities and guidance for sustainable decisions made by organizations which manufactures, contracts or uses biobased plastics. Further, barriers and drivers for conversion to biobased plastics will be analyzed and an action plan for how the barriers can be handled will be presented within the research project. [13]

4.2. Reused and recycled building products

Reused and recycled products have a great potential to replace products made from virgin raw material. Even though Hoppet is a fossil free preschool, products with reused or recycled fossil materials will be allowed. It is important to create recycling methods and logistics systems that can enable circularity both for fossil materials and biobased materials in the future.

4.2.1. Research project - Circularity index

This research project is an investigative project with the aim of increasing the use of circular materials. The goal of the project is to develop a new tool, Circularity Index - CIX, which can be used by the construction industry. The development of the CIX-tool will contribute to reducing both climate and environmental impact in construction projects. It is also an important step in creating conditions for more circular building projects in the design stage. The tool will be developed for a test bed, but the experience and the tool will be publicly available and usable for other projects. The project started in January 2019 and will continue for one and a half year. [14]

4.2.2. Research project - Re:pipe

Hoppet is engaged in a research project called Re:Pipe. Re:Pipe aims to recycle plastic material from old pipes into new pipes, alternatively re-using installation waste to produce new pipes. Funding for two years was granted from the Swedish Energy Agency in February 2019. [15]

4.3. Exclude and minimize usage of materials

There is a large potential in minimizing and excluding materials with fossil content or high climate impact. This is a relatively easy approach, possible to apply for any construction project, which in many cases also saves money and decrease emissions from transports. For Hoppet, for example these measures are discussed:

- Using integrated solar panels, which replaces the need of both installing roof tiles and solar panels,
- Avoiding toilet groups outside of the core of the building, which minimizes the pipe lengths,
- Using one combined technical system for lighting control, ventilation control and alarm system,
- Making more detailed solidity calculations to avoid unnecessary material in the framework.

4.4. Requirements for building products in a life cycle perspective

The results from the inventory of Byvädersgången show that it is vital to promote products with low climate impact in a life cycle perspective. A public organization, as The City of Gothenburg can do that by setting demands in the public procurement process and requesting data for greenhouse gas emissions verified by an EPD or similar. For Hoppet there will be a partnering collaboration with the contractor, to ensure that all measures are made to fulfill the goal of the project. In the procurement process all offers will be evaluated not only by financial performance, but also by cooperativeness and ability to contribute to the climate neutral goal in the Hoppet-project. Transportation of building products to the construction site also give rise to greenhouse gas emissions, but fossil free alternative biofuels are available at the market and will be required.

4.5. Fossil free construction site

The construction of a building is not the main source of climate impact in a life cycle of a building, but still have challenges to handle. For example, there are not a lot of working machines available on the market running on electricity or biobased fuels. The project group has recently started a collaboration with Business Region Gothenburg, responsible for business development in our region, to involve more actors to implement similar requirements to decrease climate impact from construction sites.

5. Concluding discussion

The assignment for Hoppet is to build a fossil free and climate neutral building. After searching the market for fossil free and climate neutral building products, the conclusion is that today it would be impossible to exchange all approximately 250 building products in an ordinary preschool to fossil free and climate neutral alternatives. Besides scouting for new materials and products, our work has been initiating research projects and trying to convert other actors and building owners to demand fossil free and climate neutral building products. However, we have found many companies that are starting to decrease their climate impact and to convert their products using fossil free or recycled materials. All promising, new and old products have to be evaluated and conscious decisions of what to use in Hoppet have to be made.

One initial goal was to create a general ranking method for material evaluation that could be used for comparing all different products or construction components. But after investigating the fossil content and making the climate assessment it became obvious that this would not favor innovation and development. Nor would it stimulate a change in attitude in the building sector. Instead, for Hoppet, decisions will be made on a case by case basis, evaluating product by product to include the potential for a product to be climate neutral in a long-term perspective. For some product groups, the fossil content can be the most challenging to replace. In that case it is most important to stimulate the development of a biobased alternative. For other products it might be the long transportation distances that have the largest climate impact. For those products it would make sense to promote them by purchasing them, resulting in stimulation of start-up of production sites closer to Gothenburg. The aim in Hoppet is to always choose products where all steps are fossil free and have the lowest possible climate impact, but when it is not possible to find such products the project aims to promote products with the possibility to be climate neutral in the future. During spring 2019, a more detailed system for product evaluation in the design process will be developed.

The benchmark is that the solutions, systems, products and materials we choose should meet all our requirements. The City of Gothenburg's Technical Requirements and Instructions for construction exist to ensure poison free environments, energy efficiency, moisture proofing, good indoor environment and the ability to efficiently manage and operate the properties. If a fossil free solution would contradict any of those requirements, there will be a discussion with the technical specialists on how to proceed.

The task is highly challenging, but in close collaboration with experts, researchers, innovators, entrepreneurs, suppliers and decision-makers we think it is possible to build fossil free. Maybe not for the first preschool, but in a long-time perspective. To inspire change and make a progressive development, an interest and understanding of the importance of fossil free materials and methods needs to be created in all stakeholders in the construction business (nationally and internationally). Hoppet, as the first fossil free demonstration project is an important part of this progress.

Passive houses for active students – Providing knowledge about eco-efficient buildings

Jedliczka G

OeAD-Housing Office, Ebendorferstraße 7, 1010 Vienna

guenther.jedliczka@oead.at

Abstract. The OeAD-Housing Office is a non-profit organisation in the area of international cooperation in education, science and research in Austria. We cooperate with our parent company OeAD-GmbH as well as various Austrian student residences and partner universities worldwide. The main responsibility is accommodating international and national students in Austria's university towns. Our success story started with the construction of the first halls of residence built according to the passive house standards world-wide in Vienna in 2005. Since its completion, the OeAD-Guesthouse Molkereistraße has accommodated 280 international students and guest professors per semester. We are successful in managing a total of 8 student guesthouses in the passive house design constructed in Vienna, Graz and Leoben. This paper describes the benefits of passive houses and raising awareness for eco-efficient buildings. We focus on two OeAD-Guesthouses in Austria and highlight their design, architecture and what it is like to live in both of them. Upon request we are also able to propose the OeAD-Guesthouse PopUp dorms. As we want to share our knowledge with the rest of the world we initiated 2 summer universities which pay attention to ecological buildings and the financial and economic system. We also draw attention to several awards we have won during the past years.

1. More than 20 years of applied sustainability

The OeAD-Housing Office (=OeAD-WohnraumverwaltungsGmbH) is a non-profit organisation in the area of international cooperation in education, science and research in Austria [1]. It cooperates with its parent company OeAD-GmbH as well as various Austrian student residences and partner universities worldwide. Our main responsibility is the annual accommodation of over 12,000 international students and guest professors in Austria's university towns and since 2016 we also accommodate national students.

Mr. Günther Jedliczka became the CEO of the OeAD-Housing Office in 1998. He studied business and economics at the University of Economics and Business in Vienna. While pursuing his studies he spent two months in London and one month in Paris which helped improving his language skills and his personal growth. Back in 1999 Ernst Ulrich von Weizsäcker's book "factor4" served as inspiration to construct a passive house.

The starting point of this initiative was the construction of the first halls of residence built according to the passive house standards world-wide in Vienna in 2005. Since its completion, the OeAD-Guesthouse Molkereistraße, 1020 Vienna, has accommodated 280 international students and guest professors per semester. Since then we are successful in managing a total of 8 student guesthouses in the passive house design constructed in Vienna, Graz and Leoben. We have also expedited the construction of student dorms in the passive house design in Austria, as well as the retrofitting of existing dorms with photovoltaics systems, with the goal of reducing ecological impact both during construction and during the subsequent supply of energy.

The concept of a passive house is economically profitable in terms of energy expenses and benefits are evident within the company. By means of a regulated ventilation system a passive house creates a comfortable atmosphere and prevents stuffy air mold formation due to insufficient ventilation which helps reducing the operating costs.

Many students come into contact with the topic of eco-efficient building for the first time when they move to any of the OeAD-Guesthouses, while others chose one of our guesthouses because of the passive house standard. When moving in, each student receives information about the concept of the house and a basic manual with general instructions like airing or water saving. Suffice to say, staying in one of our passive houses is cozy, energy-saving and environmentally-friendly. According to today's state of the art technology it is the best and least expensive method to produce a comfortable room climate.

In each OeAD-Guesthouse the residents receive the information about the quality of the tap water and the importance of waste separation. In order to avoid the consumption of paper, the residence contracts are sent out only digitally (by email). The OeAD-Guesthouses as well as the OeAD-Housing Offices are centrally located in each university town and can easily be reached by public means of transportation. We also encourage students to use bicycles and provide storage places/rooms and even rent bicycles to them.

In the Housing-Offices fair trade coffee and fruits are provided. On a regular basis movie nights and panels are hosted to educate about the sustainable use of our planet (concerning fair fashion, climate change etc). The facility management also hosts training sessions about the ecological use of detergents.

In the OeAD-Guesthouses we provide fully furnished accommodations so the students do not have to purchase new bedding, dishes or kitchen ware during their (short term) stay. We also provide energy saving lamps in the residences.

There is a very high acceptance of the passive house concept by the residents. Due to the short dwell time of the students in the residence, between a few months (international students) up to some years, and the following change to other forms of living, most residents move out with the wish to continue living in a building with a passive house standard which helps to raise awareness for eco-efficient buildings. Especially students of technical studies, like constructional engineering or architecture, find a great interest in the concept of passive houses. International students popularize the building concept and a direct multiplier effect arises.

2. Highlighting two OeAD-Guesthouses

2.1. OeAD-Guesthouse GreenHouse in Lakeside Aspern [2]

Figure 1: Main facade - Sonnenallee

Back in the year 2005, there were first discussions with Mr. Christoph Chorherr (spokesman of the Green Party in Vienna), DI Josef Lueger (Federal Real Estate Company) and Mag. Günther Jedliczka (CEO of the OeAD-Housing Office) concerning the construction of a student residence in the seaside town of Aspern. An important prerequisite for the location of a new home in this largest urban development area of Vienna was the proximity to the subway and thus a connection to the universities within 30 minutes. After it had been ensured that there was a subway connection to Aspern during the construction phase, the OeAD-Housing Office was looking for partners for this pioneering project. In July 2010, 6 architecture firms were invited on the basis of a competition to present ideas for a student residence with the minimum standard passive house. The project was chosen by aap.architekten ZT-GmbH, which had developed a convincing concept with the goal of zero energy standards and were experienced in participatory processes and their knowledge in the field of ecological and energy-sufficient construction.

The OeAD-Housing Office, the Austrian Youth Movement (ÖJAB) and the Housing Association for Private Employees (WBV-GPA) jointly realized a forward-looking project in a new district – a highly efficient passive house for 313 international and Austrian students and the architecture should visualize this ambitious project.

Due to the three different home operators, an interesting mix of the residents and thus also an important impulse for the new district was developed. The WBV-GPA has also taken on the role of developer and installer.

At the time of its opening, GreenHouse was the world's first certified Passive House Plus (PHI) student residence, accompanied by a research project on electricity storage and monitoring energy consumption. In 15 reference rooms, 5 in each component, an extended monitoring with various measurements takes place. For precise control of the energy balance of the building, calibrated heat meters, energy meters, electricity meters and water meters, temperature sensors, window contacts, humidity sensors, etc. are used distributed throughout the building. The meters are equipped with bus modules and communicate directly with the building management system (BMS). The research project is being carried out by ASCR (Aspern Smart City Research) and Siemens.

The energy sources of the future for the urban development area are at the time of the design of solar energy, the energy from the air, which is recovered by the comfort ventilation with heat recovery in passive house construction and geothermal heat from the earth.

For economic reasons, the building had to be implemented in concrete construction with a full thermal protection facade. By an alternative development proposal, deviating from the original requirements of the master plan, a more compact structure could be implemented, which reduces the built-up area, at the same time ensures better tanning of the occupant rooms on the courtyard side and offers more living space and less development areas for the same area.

The compactness of the structures and the clear structural design grid across all floors, the use of semi-finished parts, prefabricated elements and floor slabs in the shell construction as well as the space-optimized development system allow for moderate construction costs despite high equipment quality and excellent energy values. Professional quality assurance and process support in the execution planning as well as in the construction work by the project management contributed significantly to the sustainability.

The rainwater is seeped through infiltration baskets in a core of the earth at the site. The water consumption is significantly reduced by flow restrictors and by fittings with extended cold water range, as the requirement for hot water in dormitories is above average. .
To achieve the zero energy standards, a centralized ventilation unit with 2 parallel rotary heat exchangers with heat and moisture recovery and special filters has been developed to reduce energy consumption. In the course of the research project, the ventilation could be carried out on demand and the energy consumption could be reduced. The residual heat requirement is covered by Fernwärme Wien.

SUMMARY

In dormitories, energy consumption is much greater than in classical residential buildings because of the large number of small apartments, each with its own kitchen. As a result, all components that consume electricity within the building must be optimized and extremely reduced. Reaching the Passive House Plus Standard under the given financial conditions (residential funding from the Community of Vienna, Passive House funding and research investments) required intensive collaboration among the building owners, the users and a team of architects, building physicists and building service technicians, who focused on this goal. The project received Gold ÖGNB (Österreichische Gesellschaft für Nachhaltiges Bauen, Austrian Sustainable Building Council) certification; a level of this certificate was required for all buildings in the district. In addition, the building owners and users chose to have the Passive House Institute certify GreenHouse.

From Passive House to Passive House Plus

The building was constructed as reinforced concrete with insulation in the façade upstairs and a curtain wall of boards as the façade on the ground floor and in parts of the floors upstairs. The U-value of the external walls is 0.10 W/(m^2K), while the U-value of the flat roofs with sloped insulation is 0.07 W/(m^2K). The wood-aluminium windows with triple glazing have a Uw-value of 0.80 W/(m^2K).

In 15 reference rooms (three in each building section), energy consumption, temperature, humidity, water consumption and window ventilation were extensively monitored. ASCR (Aspern Smart City Research) and Siemens conducted the research project.

Reducing energy demand

The following steps were taken to reduce the building's energy demand (Figure 2):

Central comfort ventilation (Figure 3) with parallel rotation heat exchangers (operation is based on CO2 levels) (Figure 4) and special bag and mini-pleat filters (F9) to reduce the ventilation system's flow resistance. A volume flow of 6,000 m^3/h per rotation exchanger. Heat recovery (EN308) 90.58 %, moisture recovery 73.14 %.

Daylighting in the first-storey common room and in the circulation areas.

LED lights throughout the building.

Motion detectors and light-dependent resistors in all common areas.

Optimisation components that consume power and avoidance of standby functions.

Elevator with energy recovery from the brakes.

Excellent insulation of distribution lines.

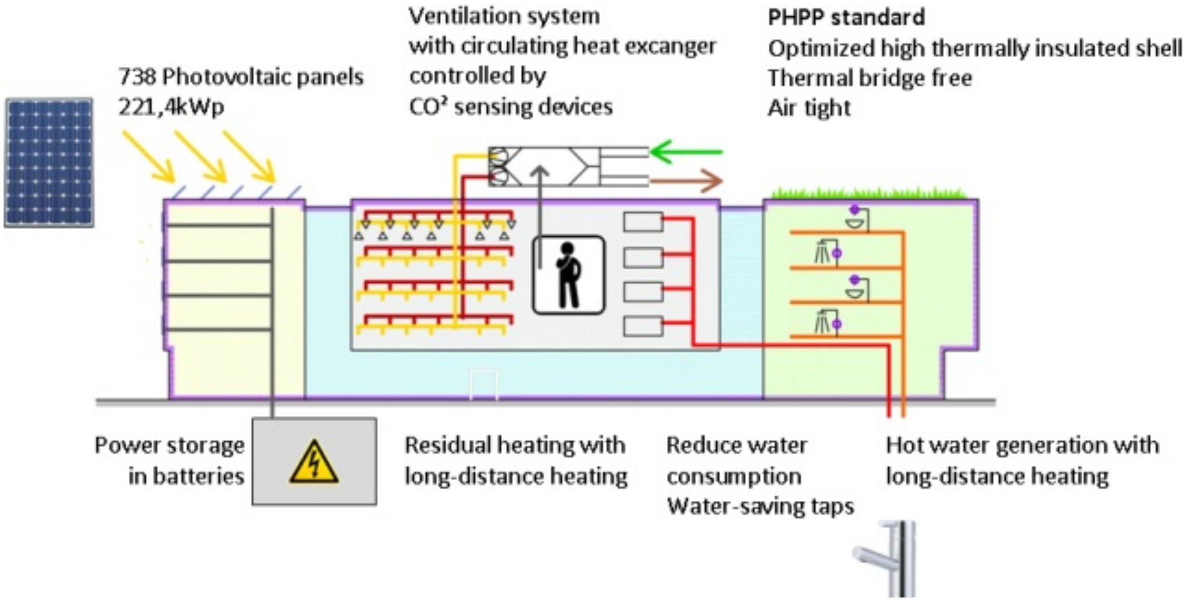

Figure 2: Building services

Figure 3: TROX X-CUBE ventilation system

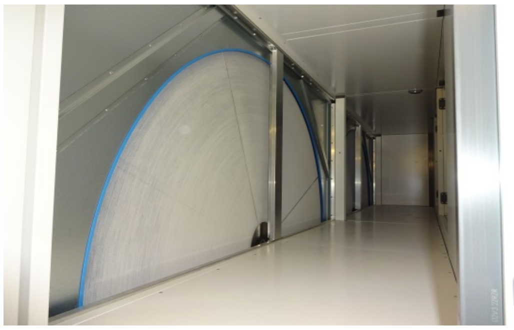

Figure 4: Rotation heat exchanger

Photovoltaic array

An essential component towards the Passive House Plus Standard is the photovoltaic array. 738 solar panels 300 Wp monocrystalline facing east and west were installed on the roof.

Total nominal output: 221.4 kW
Total production annually: 215,865 kWh
Total CO2 savings annually: 25,903.8 kg

As part of a research project, excess electricity from the solar array is stored in batteries (Figure 4) for later consumption in the dorm:

Battery system, AC
Lithium-iron phosphate cells
Maximum constant output: 150 kW
Storage capacity: 170 kWh

Table 1. Building data OeAD-Guesthouse GreenHouse

Key data	
Plot area	3,820 m²
PHPP treated floor area	2,000 m²
Mean heating demand based on PHPP	11 kWh/(m²a)
Heating load based on PHPP	9 W/m²
Primary energy (PE) demand	101 kWh/(m²a)
Airtightness n_{50}	0.24/h

2.2. OeAD-Guesthouse mineroom in Leoben [3]

Figure 6: Street façade – main entrance ©J.Konstantinov

The OeAD-Guesthouse mineroom was opened on October 1, 2016 after only 11 months of construction. This student residence is a contemporary home for 201 international students during their time in Leoben. The close connection of the region and the university to nature and its resources should be reflected in the building. Therefore, e.g. quotes from the mining sector, with which the city and the university have been connected for generations, can be found in the building.

This first global high-volume passive house was constructed as timber framed structure and is klima: aktiv GOLD certified. The certification by the Passive House Institute Darmstadt has also been carried out and the Passive House Plus Standard was achieved.

The building is located on Josef Heißl-Straße at a height of ground floor up to the 5th floor and set off to the north by one floor. Smooth facades form a clearly defined counterpoint to the subsequent demolished development structure. The facades are accentuated by colored frames around the large windows of the common rooms and by loggia-like recesses in front of the living areas of the residential communities in which plant troughs with kitchen herbs are arranged.

The structure was developed from a perimeter block development, which opens to the lower development in the west. Thus, courtyard and garden are protected from street noise. The components are staggered at the height of the ground floor up to the 5th floor and from the ground floor up to the 3rd floor and thus adapted to the smaller-scale development of the neighboring plots. By lowering the southern connecting tract, the tanning of the inner courtyard is optimized. On the southern facades, "green walls" of plant troughs were provided, which positively influenced the microclimate in the street and courtyard. The recessed and transparent ground floor zone provides an insight into student life as well as views into the courtyard and creates a weather-protected meeting zone in front of the building.

Inspired by the liveliness and the play of colors of the ore stone, the formally clear structures were covered with a plastic, multi-colored wooden formwork. The pre-grayed shuttered formwork, which repeatedly bursts out of the smooth, untreated larch wood formwork, runs vein-like over the building and will gradually discolor irregularly in various grays, browns and reds.

With the exception of the entrance area - the basement and the two staircases - the entire building was built in timber construction. The outer walls consist of a prefabricated, with mineral wool-finished timber frame construction, mostly having no supporting function. Horizontal bracing is provided by partition walls made of cross laminated timber wall elements in conjunction with glue laminated timber ceiling panels. About 1,900 m^3 of wood were used in the building for the supporting structure and the facade, thereby binding approx. 2,000 tons of CO_2. Partition walls and ceilings are fitted with plasterboard liners to meet the fire and sound insulation requirements. Beams and columns were over-dimensioned to burnup and could therefore be left visible.

The door cut-outs of the cross-laminated timber interior walls were turned into mobile furniture. Tables, benches, stools and sideboards bring the wood character back into the living and common areas. The house offers a wide range of residential and common areas. Single apartments, double rooms as well as shared apartments for 2-5 residents enable the students a differentiated housing offer. On each floor, so-called parlors offer individual retreat areas. There are common areas such as the extended living room, a launderette, music practice room, meeting and study rooms, gym and a multi-purpose room for chilling out and celebrating on the ground floor. In the courtyard, there is seating and table tennis, and in the garden wooden decks for lounging can be found.

Table 3 gives an indication of the key building data and building physics, with Figure 9 highlighting the measures taken with regards to the building equipment.

Additional to the building envelope, also power-consuming components have been optimized, whilst standby functions were avoided. The entire object was equipped with LED lighting, and the general areas are supplied with motion detectors and twilight switches. A space or empty piping for possible battery storage has already been provided and there is also the possibility to charge e-bikes and electric cars. The elevators are equipped with braking energy recovery.

By means of water saving, valves with an extended cold water range (cold water in the middle position), the hot water consumption, which is above average in the houses of the OeAD-Housing Office from experience, should be reduced. In line with that, the residual heat demand and hot water generation are covered by district heating (process waste heat from VOEST Alpine Stahl).

The ventilation system plays a big part in reduction of the overall energy demand. Here, the TROX X-Cube ventilation system (Figure 7) with 2 parallel rotary heat exchangers was used, which has an air volume flow of 4,500 m³/h per exchanger. Additionally, special pocket and pleated filters are used to reduce the flow resistance of the ventilation system. Further details to be highlighted are the re-heat number (EN308) of 90.58% and the moisture content of 73.14%.

Table 2. Performance indicators (PHPP)

OeAD-Guesthouse mineroom

Airtightness	n_{50} = 0.27/h
Heating demand	17.6 kWh/(m²a)
Building heating load	10 W/m²
Primary energy need	76 kWh/(m²a)
PER-demand	37 kWh/[m²a)
Producing renewable energy	87 kWh/(m²a)

3. Comparison of guesthouses of the OeAD-Housing Office

As visible from Table 4, most buildings use district heating for heating and hot water generation purposes. Out of the following 12 houses, 3 are situated in Styria (Steyrergasse and Zinzendorfgasse in Graz and Mineroom in Leoben), also, the passive house buildings Molkereistraße, GreenHouse and Mineroom accommodate the highest number of students (graph 2).

Table 4. Comparison of OeAD-Guesthouses

Object	Year of construction	Students	m²	Construction	Heating	Hot water generation	Ventilation system with heat recovery	PV [kWP]
Molkerei-straße	2013	278	6,338	Solid building	District heating	District heating	yes	n.d.
Simmer-inger H.	2009	110	2,778	Solid building	District heating	Local electric boiler	no	12.42

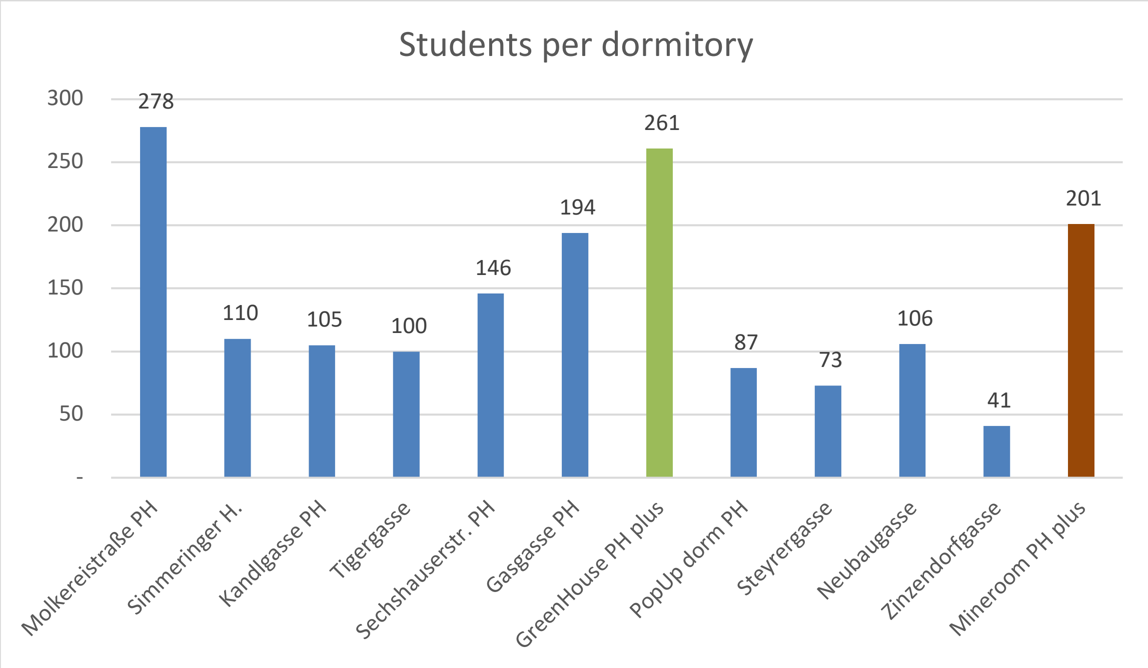
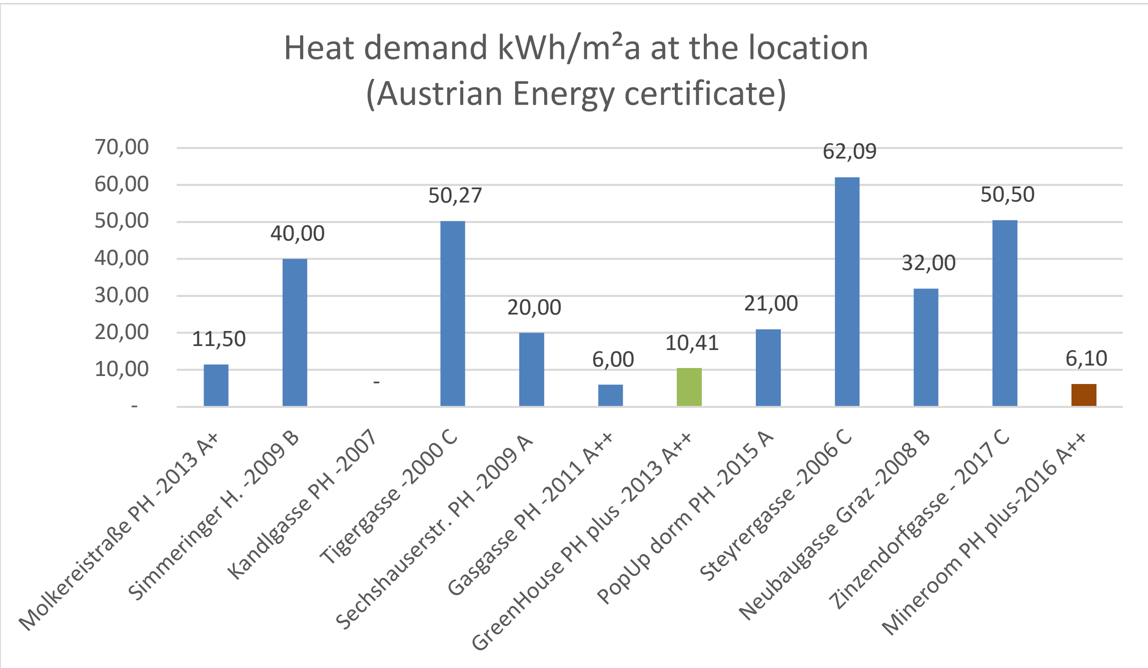
Mineroom	2016	201	6,000	Timber construction	District heating	District heating	yes	116.4



Graph 2: Overview students per dormitory

Compared with the other guesthouses, the passive house buildings have a significantly lower heat demand – depending on the heating system in use. Graph 3 displays the heat demand for each of the 12 buildings for the year 2018, while also taking into account the energy category.

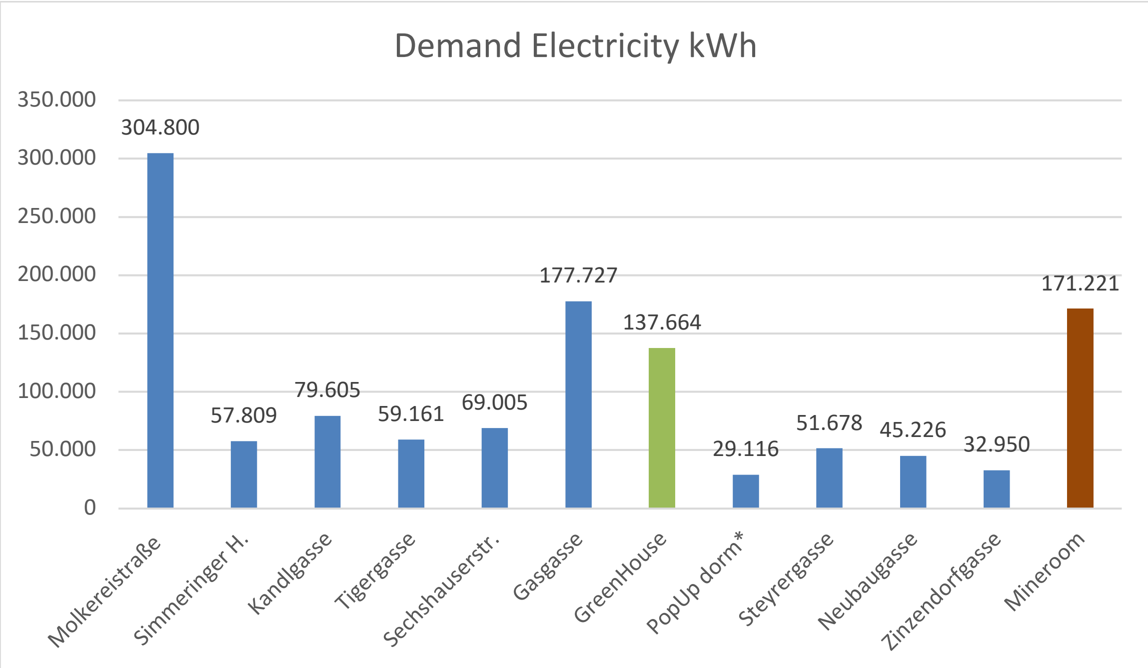
There was no data available for the guesthouse in Kandlgasse.



Graph 3: Heat demand per guesthouse [kWh/m²] – building names also indicate the resp. year of construction and energy category. Data are for the year 2018.

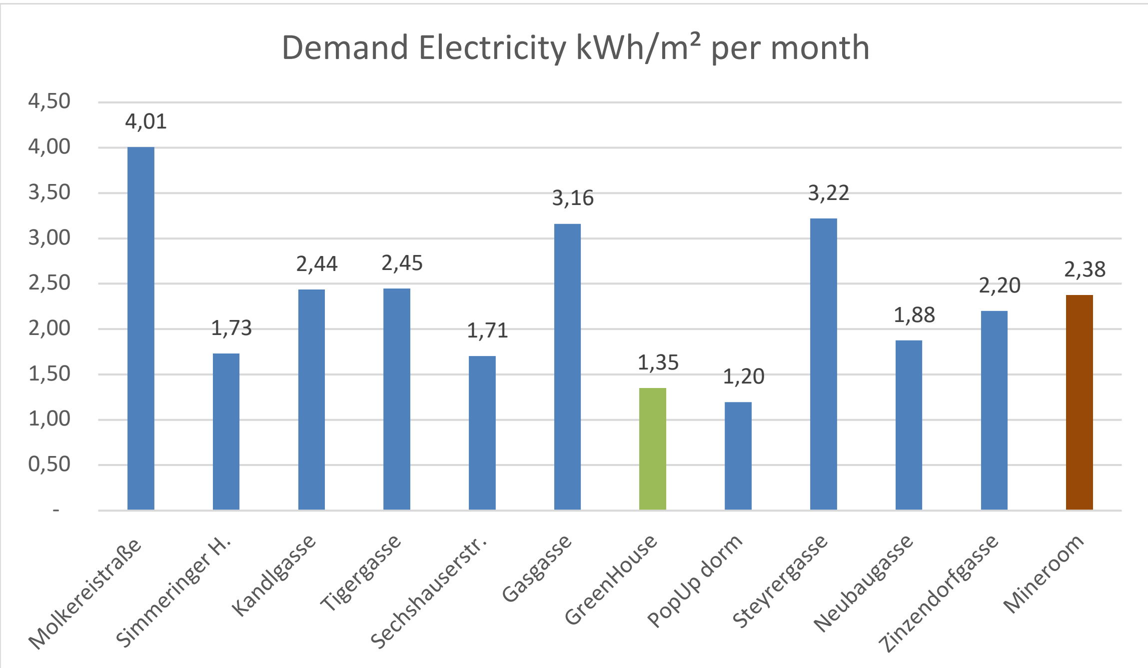
Surprisingly, for 2018, the electricity demand was higher in some of the passive houses than the other buildings (graph 4). This is in part due to some technical issue in the photovoltaic system of the guesthouse mineroom in 2018 – in line with that, the data shows a significantly lower electricity demand for 2017 (92.367 kWh). A further explanation probably lies in the behavior of the residents.

The electricity demand per m² and month (2018) was lowest in the passive houses, as is shown in graph 5.



Graph 4: Demand of electricity per guesthouse [kWh] – data for the year 2018

*PopUp dorms: Removable construction, size optimized for transportation. 250 m² common room as atrium – not conditioned, kitchen and laundrette in an oversea container.



Graph 5: Demand of electricity per guesthouse [kWh/m² per month] – data for the year 2018

4. Passive houses – active satisfaction

Striving towards reaching the highest possible standard of living with the lowest environmental impact, the contentment of OeAD-guesthouse residents is assessed once in a year via feedback questionnaires, which evaluate the overall satisfaction by looking at the different factors of room size, room quality and equipment. Residents rank the different buildings using grades ranging from 1 (very satisfying) to 4 (very unsatisfying). A system of 4 grades is used in order to put special emphasis on positive as well as negative critique.

The evaluation for 2018 shows an overall good ranking of OeAD-guesthouses within a range of 1.48 to 2.03, with the passive house-buildings GreenHouse (1.48) and Mineroom (1.52) providing the most satisfaction for residents. Also in 2017, GreenHouse and Mineroom were ranked best in contentment.

5. Sharing the knowledge with the world

Population growth, overuse of resources and environmental degradation are just a few of the big global challenges that we already face today. Too often, these developments are reigned by view that there is no alternative. However, there are many alternatives with some being already successfully implemented on a local scale. With the goal in mind to raise awareness, the OeAD-Housing Office initiated 2 summer universities: "Alternative Economic and Monetary Systems" (AEMS) in 2013 and "Green. Building. Solutions." (GBS) in 2011.

Both programmes attract highly qualified students and professionals from all around the globe and diverse backgrounds. In order to further foster diversity, there is also a system of scholarship support for those, who otherwise would not be able to cover the participation fee by themselves. This way 103 people from 50 nations and 5 continents could participate in AEMS and GBS in 2018.

5.1. The beginning of AEMS

11 years after the stock market crash, the world has not seen any substantial systemic changes. Neither economic textbooks nor incentives for financial actors to make one-sided bets have changed. The design of the financial and economic system basically remains the same, as does its inherent instability. There is overwhelming evidence that the current economic model based on everlasting economic growth is destroying the ecosystem of our planet, and thus the basis for the existence of humanity. However, dominant recipes for overcoming the current economic crisis still focus on restoring economic growth. AEMS sheds light on approaches and reforms that can make a difference.

The main intention behind the creation of the AEMS was to use a positive approach applied to the field of economic alternatives, asking if this apparently inherent economic instability might be reduced or avoided, and to show students chances for reforms. A great variety of possible approaches to economic reform has been proposed over the years proving that high demand for a new economic system exists.

A number of successful and promising concepts are presented to the students ranging from individual actions all the way up to fundamental reforms of global structures and institutions. This enables them to have a level-headed discussion of economic reform. The monetary system has its own intricate feedback loop with the economy; further emphasis on monetary reform is a natural choice.

AEMS offers room for critical thinking and the possibility to openly discuss and deconstruct ideas and concepts with distinguished experts from various scientific fields. The participants are able to move beyond the widespread limitations of higher education that lacks extensive exchange between scientific disciplines.

2018 saw the 5th installment of the summer school with 61 participants from 34 different countries.

5.2. Take care of your future

It is the aim of the OeAD-Housing Office to convey knowledge about eco-friendly building to future generations on the one hand, and to offer the highest possible standard of living with the lowest environmental impact on the other hand. To our minds, working sustainably does not only mean realizing eco-friendly projects, it also means creating awareness and knowledge, because nothing in this world is more sustainable than knowledge.

The GBS graduate-level summer program took place from July 21 to August 12, 2018 for the 8th time and 42 international students and professionals successfully completed the course. The GBS students primarily study architecture, urban planning, and engineering sciences; however, they worked alongside professionals and students from all faculties relating to the built environment.

The GBS takes up the central ecological, economic, technical, and social themes of sustainable design and construction to offer students the unique opportunity to study content focused on sustainable construction within an interdisciplinary framework, and also to experience the practical applications of sustainable concepts. The GBS provides knowledge that sharpens and deepens the students' competencies and understanding of sustainable planning, design, and construction. The participants belong to the generation that bears the brunt of the change from a postmodern industrial society to a circular-economy-oriented society. The participants therefore form a central target group that are sensitized to the environmentally conscious and responsible use of natural resources and need to be equipped with the appropriate knowledge to take action. The importance of the GBS Summer University is reinforced by ever-present evidence of more extreme climate change. The associated urgency to quickly reduce greenhouse gas emissions and resource consumption shows that the construction and building sectors are responsible for an enormous share of greenhouse gas emissions worldwide. The circular economy, urban mining, and the reduction of energy consumption in urban metropolises are indispensable measures which must be considered for sustainability in future urban planning, architecture, and construction sectors. Renewable energy production by new technologies and innovative ecological and sustainable building concepts and materials should therefore contribute to natural resource conservation and reducing greenhouse gas emissions.

Since 2018, both summer universities are supported by the Club of Rome.

6. Hard work pays off

All our efforts for an active ecologic contribution were honored with numerous awards (Table 3).

In November 2013 the OeAD-Housing Office was awarded with the Climate Protection Prize at the ORF climate protection awards in the category "Climate Protection in Companies". With more than 30,000 votes from the audience, the OeAD-Housing Office was chosen among 230 submissions.

The OeAD-Guesthouse mineroom in Leoben won the 2018 Blue & Green Award and the Styrian wood construction prize in the category large residential buildings in the year 2017.

In October 2018 the OeAD-Guesthouse PopUp dorms were awarded with the FIABCI Prix d' Excellence. It is an unique award given to real estate projects that embody innovation and economic sustainability. The OeAD-Guesthouse mineroom appeared as runner-up.

The OeAD-Guesthouse PopUp dorms was nominated for the climate protection award in 2016 and it was also awarded with the Green & Blue Building Award in 2015. Moreover the PopUp dorms were nominated for the 2018 City of Vienna Environmental Prize.

The OeAD-Guesthouse GreenHouse is the first award-winning Net-Positive Energy student residence in the world, winning the 2015 City of Vienna Environment Prize, with 1000 of 1000 points certified as a klima:aktiv gold building.

AEMS has won the "Bildung für nachhaltige Entwicklung - Best of Austria"-Award (Education for sustainable development – Best of Austria) in the category "political support" in 2016, while GBS was chosen by UNESCO Commission as UN Decade Project for Sustainable Education in 2013 and received the Green & Blue Building Award 2014 in the category Products / Services.

The OeAD-Housing Office and the University of Natural Resources and Life Sciences Vienna were runners-up for the Austrian TRIGOS Award 2015 in the category best partnership - for GBS and AEMS.

Table 3. List of awards and nominations

Nominee	Award	Year
OeAD-Guesthouse Gasgasse	state prize for architecture and sustainability	2012
OeAD-Guesthouse GreenHouse	winner klima:aktiv	2016
OeAD-Guesthouse mineroom	Green & Blue Building Award	2018
OeAD-Guesthouse mineroom	timber frame construction prize Styria	2017
OeAD-Guesthouse PopUp dorms	Green & Blue Building Award	2015
OeAD-Guesthouse PopUp dorms	winner FIABCI Prix d'Excellence	2018
OeAD-Housing Office	award Sustainable Development Goals	2018
OeAD-Housing Office	winner climate protection award	2013
OeAD-Housing Office	winner Austria's Leading Companies	2014
OeAD-Housing Office	winner innovative buildings	2016

In conclusion, the OeAD-Housing Office emphasizes Austria's leading role in relation to eco-friendly building and seeks to share knowledge with their international students and thus wants to carry the basic ideas of eco-friendly building out into the world. Moreover, our residents will always associate the comfort of their experience with eco-friendly building with Austria and will gladly return to the country - be it as tourists, university graduates or future business partners. Even if only a handful of our residents will be inspired by their positive experience with passive houses to build their own homes according to eco-friendly standards, or even launch an initiative similar to this one in their home countries, our goal of educating and inspiring people will have been reached and we will have contributed to a more responsible and intelligent use of resources.

Regarding the overall efficiency of the passive house buildings, it can be seen that the heat demand is significantly lower than in other guesthouses, while the picture for the electricity demand is not always as clear, since it is probably also influenced by other factors.

Visual tool to integrate LCA and LCC in the early design stage of housing

Miyamoto A, Allacker K, De Troyer F

KU Leuven, Faculty of Engineering Science, Department of Architecture
Kasteelpark Arenberg 1 Bus-2431, 3001 Leuven, Belgium

ayu.miyamoto@kuleuven.be

Abstract. Over their whole life cycle, buildings are responsible for high environmental impacts and require critical financial resources. Decisions in the early design phase have a significant impact on both. This study aims to develop a visual decision support tool for architects in order to integrate an environmental and economic life cycle approach for dwellings. To evaluate the environmental impacts of the building design, the tool uses the Belgian LCA method, 'Environmental Profile of Building Elements'. This method translates 17 environmental indicators in environmental costs by considering the cost to avoid, reduce or compensate the effects to a level that is bearable. The tool allows to combine these life-cycle environmental costs (LCEC) with Life Cycle financial Cost (LCFC). To estimate the operational energy use of the building, the "dynamic Equivalent Heating Degree Day (dEHDD)" method is used. This method allows for fast and relatively accurate heating energy estimations in the early phase, based on a limited number of input data. The tool visualises the results in a graphical way which can be easily understood by architects. Even more, visualisation is seen as a powerful communication tool to share information and ideas with all stakeholders.

1. Introduction

As the built environment has been well-known as a crucial contributor to climate change [1,2], the 2010 European Directive on the Energy Performance of Buildings Directive (EPBD) requires EU Member States to improve the energy efficiency of new buildings to achieve the target of nearly Zero Energy Buildings (nZEBs) by 2020 [3]. In the same line, in November 2015, 174 countries signed an agreement to plan a drastic reduction in greenhouse gas (GHG) emission at the UN Conference on Climate Change in Paris. Design decisions in the early design stage significantly determine a building's life-cycle environmental and economic impacts [4,5]. However, due to the complexity of life-cycle cost (LCC) and life-cycle assessment (LCA) and the time constraints to consider those aspects in the early design phase, including those aspects, has remained a challenge especially for small scale project like dwellings [6]. As architects play a crucial role to reach the target, they must be better equipped to estimate influences of their decision on the impacts. In the constant feedback loop of designedly thinking, architects use mainly visual tools [7,8]. This paper proposes a visual design support tool for architects to design a sustainable dwelling based on LCA and LCC approaches. This paper is structured into five sections. The framework of the research is described in section 2. The calculation method is presented in section 3. The data visualisation in the tool is demonstrated in section 4. Results and discussion are described in section 5. Finally, conclusions are provided in section 6.

2. Framework for the approach

2.1. Goal

The objective of this study is to develop an approach to integrate life-cycle environmental and economic performance assessment in the early design stage to support architects when making their design decisions for a sustainable dwelling. The major hurdles for architects to integrate LCA and LCC in the early design stage are: time constraints, complexity of input and integration of dataset/results of the simulation. To overcome these difficulties, this study includes the following features:

- User-friendly input (no additional time and effort for input)
- Quick calculation method for estimating the heating energy in winter
- Graphical representation of results

In this study, the environmental impacts are monetised into a life-cycle environmental cost (LCEC). This monetisation enables to compare LCA and LCC in the same unit and to aggregate into a single figure. In addition, monetisation allows environmental taxation which is high on the EU political agenda [9] and has many advantages as highlighted by the organisation for economic co-operation and development (OECD) such as environmental effectiveness, economic efficiency, the ability to raise public revenue, transparency and addressing a wide range of issues [10]. As buildings have an effect on a wide range of issues such as energy, carbon, transport, waste, air and water pollution and resource through the life-cycle, LCEC can be used for the preparation of building life-cycle environmental taxes. The life-cycle total cost (LCTC) is defined as the sum of LCEC and life-cycle financial cost (LCFC). Both LCEC and LCFC can be divided into initial costs and in-use including the end of life costs (use+EOL) (Fig.1).

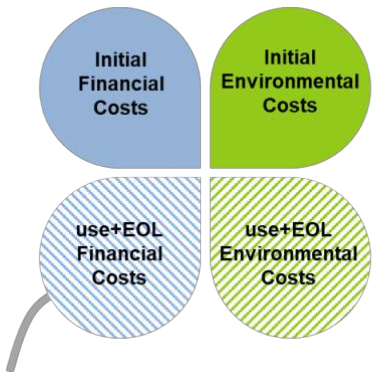

Figure 1: Four leaves clover diagram of LCTC

2.2. Workflow of the proposed approach

Figure 2 presents the hypothesis regarding the workflow of the design process considered in this research. The proposed tool, which is an Excel spreadsheet, consists of several input sheets, developed for each sub-stage: Brief-Form0, Form1 and Form2. Input parameters are classified into three categories: (1) geometry, (2) technical choices and (3) user behaviour. In the more advanced design stages, more detailed input parameters are required for each category. The user-friendly input and the calculation for estimating the heating energy in the tool are explained more details in [11]. Based on the input of these three categories, the tool provides a fast calculation of LCFC and LCEC. LCEC is based on 'Environmental Profile of Building Elements (MMG)'. Inputs of technical choice use a database of elements and materials from MMG. The database was extended with financial costs. The outputs are translated into two graphical representations: Sankey diagrams and parallel coordinate plots.

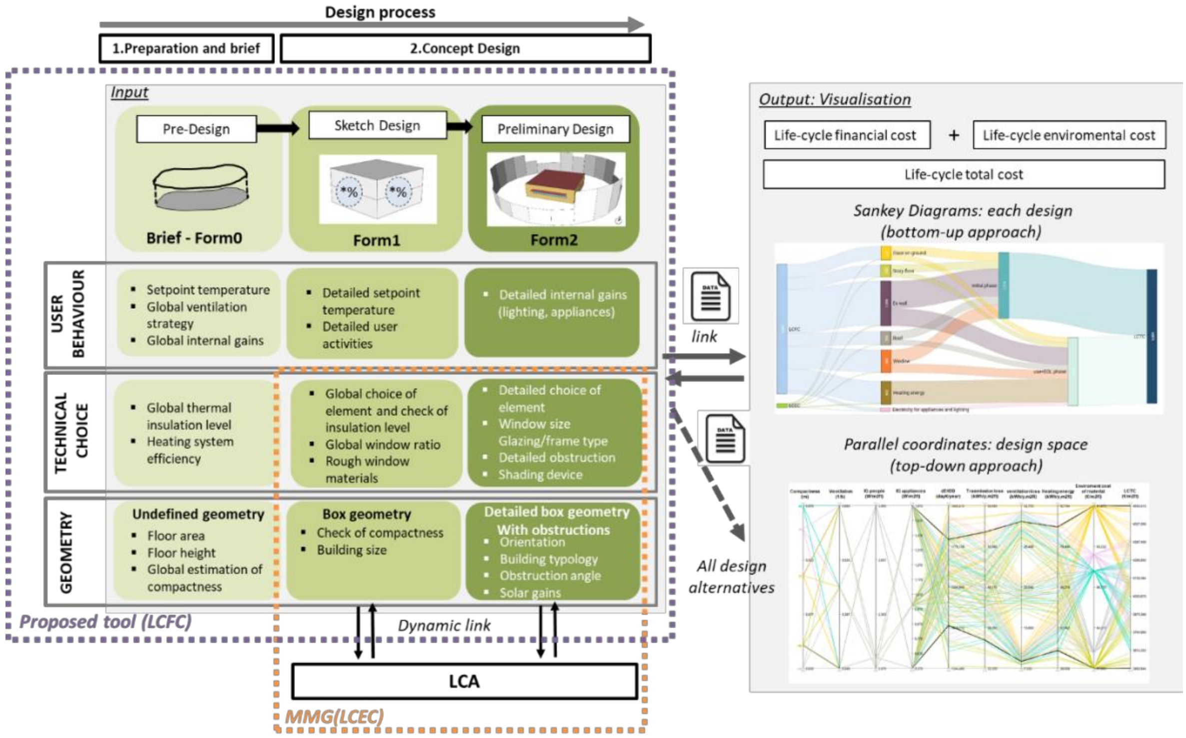

Figure 2: Considered workflow of the design process

3. Calculation method

3.1. Life-cycle financial costing (LCFC)

LCFC is based on the following formula [12]:

$$LCFC = IF + SPV(PF_0) + SPV(EOLF_0) \tag{1}$$

With:

- IF: initial financial cost (€)
- $SPV(PF_0)$: the sum of the present values of periodic financial cost (€)
- $SPV(EOLF_0)$: the sum of the present values of the EOL costs (€)

The present value of future costs is calculated as follows [12]:

$$PV[C_t] = C_0 \left(\frac{1+g/_{1+i}}{1+d/_{1+i}} \right)^t \tag{2}$$

With:

- $PV[C_t]$: present values of a cost (€)
- C_0: cost for a year of reference (€)
- g: nominal growth rate
- d: nominal discount rate
- i: inflation rate
- t: year of the cost (year)

In this study, the total financial cost is the sum of a construction cost, present values of future costs such as maintenance costs, heating costs, electricity cost for appliances and lighting and the EOL financial cost. A more detailed description can be found in [12].

3.2. Dynamic Equivalent Heating Degree Day (dEHDD) method to estimate operational heating energy

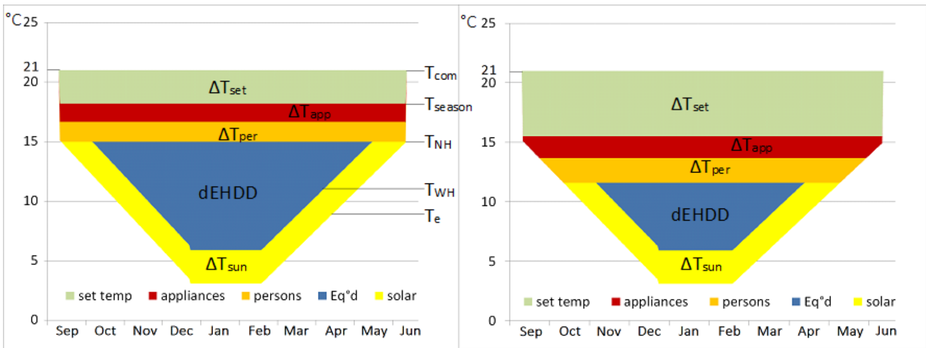

Figure 3: Representation of dEHDD for the temperate climate in Belgium and two different occupant behaviour profiles

The proposed tool uses a refinement of the Equivalent Heating Degree Days (EHDD) method to predict operational heating energy [13]. The Heating Degree Days (HDD) method predicts the yearly required energy for heating based on the number of days with a difference between the daily average outdoor and indoor temperature.

The EHDD takes into account the free solar and internal heat gains in a static way by a fixed reduction of the HDD [14]. In the dEHDD method, this reduction is calculated month by month for a better approximation of the solar gains and internal gains by occupant and appliances. The outdoor temperature (T_e) is obtained via linear regression of monthly temperature during autumn, winter and spring from Test Reference Years weather data (TRYs) [15]. The approach can be represented in a graphical way (Fig.3) with horizontally the number of days of the heating season and vertically the temperature. The number of dEHDDs is represented by the blue area in Fig.3. A more detailed description can be found in [13].

3.3. Life-cycle assessment (LCA) method: Environmental Profile of Building Elements (MMG)

In this study, the MMG method (the Belgian LCA method for buildings and elements developed for the Public Waste Agency of Flanders) is used to assess the life cycle environmental impacts and to monetise the environmental loads [16]. Seven environmental indicators “CEN” [17] in line with the European standard and ten additional environmental indicators “CEN+” from Belgian legislation [18] are taken into account. The method is described in more detail in [16]. This method monetises life cycle impacts as the cost to avoid, reduce and compensate environmental damage to a bearable level for the earth. The monetisation method in the MMG is described in [19].

4. Data visualisation in the tool

4.1. Sankey Diagram

Sankey Diagrams (SDs), initially developed by Riall Sankey to analyse the thermal efficiency of steam engines in 1898, are widely used to visualise quantitative flows in many fields of application. The width of the arrows is proportional to the size of flows. In this study, SDs are used to visualise the financial component of design decisions regarding elements. In the centre of Figure 4, the total cost for the different elements and costs for heating and electricity use by appliances and lighting are represented. The left flow (“flow (1)” in fig 4) visualises the relationship between elements and the sum total of LCFC and LCEC. The right flow (“flow (2)” in fig 4) visualises the relationship between elements and total initial cost and the cost during the use phase including the end of life (use+EOL). Several tools are available for SDs visualisation. “Sankey Diagram Generator v.1.2” [20] is used in this paper. Results of environmental cost are automatically collected from the MMG database to the proposed tool and the proposed tool automatically translates the dataset of LCFC and LCEC into a JavaScript code to visualise via the “Sankey Diagram Generator v.1.2”. Figure 4 and 5 show a representation of two design options. The useful feature for SDs is the possibility to visualise selected flows, e.g. in Fig.5 the inputs from the different elements of cost in “use+EOL phase”. SDs give architects insight into the impact of each design and help to evolve to a sustainable building.

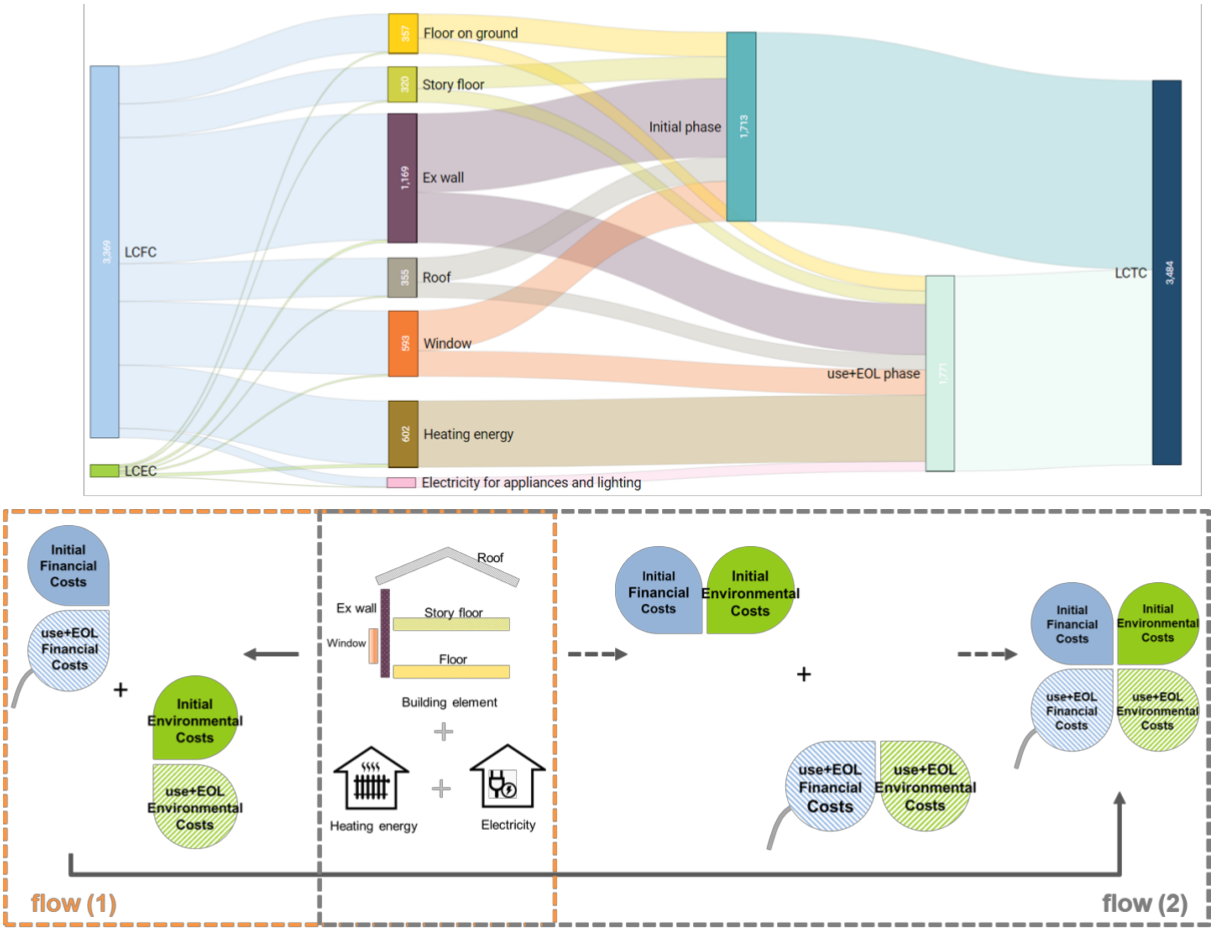

Figure 4: Representation of SDs for a design option (above) and diagram of flows (below)

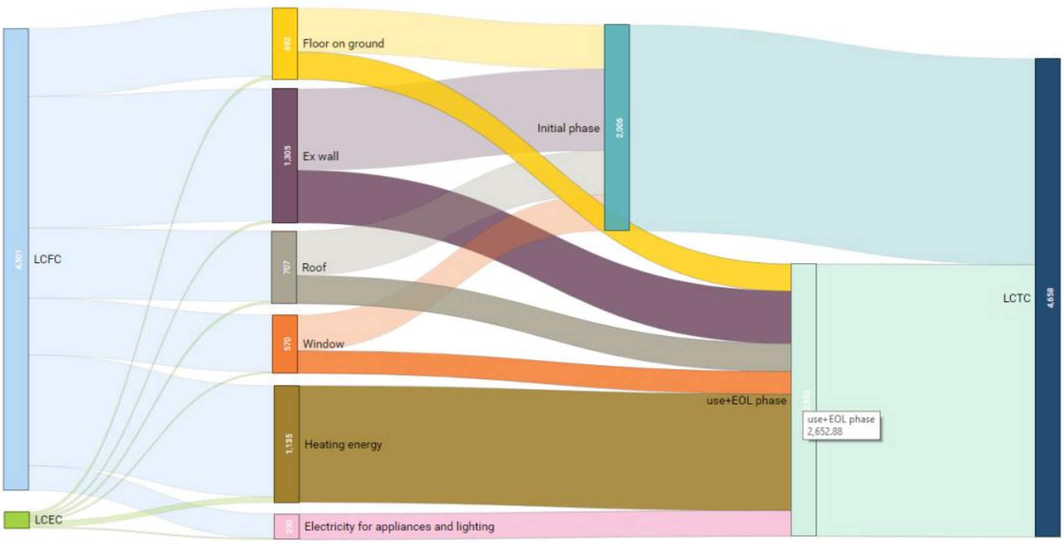

Figure 5: Representation for a design option and highlighting of “use+EOL phase” in SDs

4.2. Parallel coordinate plot for visualisation of design space

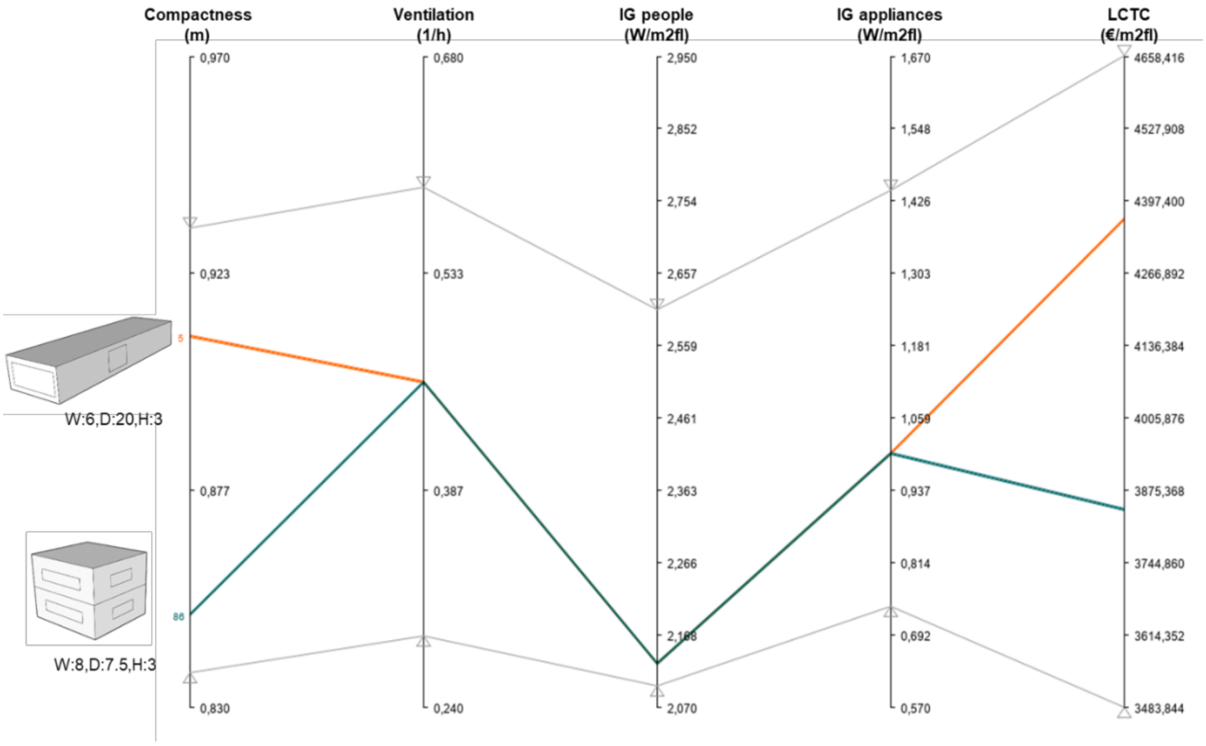

Figure 6: The representation of two design options (all axes with more extreme parameters then light grey being excluded)

Parallel coordinates are one of the most general techniques for representation and exploration of multidimensional problems. Parallel coordinate plots (PCPs) represent input and output parameters on parallel axes and all input and output values of one case are connected via lines. Hence, PCPs enable to represent an *n*-dimensional problem in a plane and allow to represent how a whole range of input parameters affect several outputs [21]. Several tools are available for visualisation via PCPs. For this paper “Xdat version 2.2” is used [22]. As highlighted by Siitola et al. [23], advantages of PCPs for architects in the early design phase are, firstly, an overview of the design space is easily grasped because PCPs itself is an overview. It enables architects via colouring and a selecting mechanism to understand the impacts of each parameter on the result quickly and to observe the relationship between parameters. Secondly, rearrangement operations such as changing the order of coordinate-lines, inverting the axis direction and so on, often give additional insights into the data set. Thirdly, architects can highlight the set of connections to facilitate comparisons between selected and non-selected lines. Fourthly, it is possible to display exact values per axis. It helps architects to discover design alternatives between certain limits, such as targets of LCTC and LCEC, investment cost, and so on. Figure 6 shows two design options (same total floor area but more or less compact buildings based on width, depth and number of floors) filtered so that only one value is considered for the ventilation rate, internal heat gains by people and appliances. The elaborated tool can automatically create a design space with user-defined parametric ranges and steps of each parameter. Figure 7 visualises the representation of a whole design space, applying different colours for each compactness and highlights design options of the smallest and the largest LCTC via a thick black line. It illustrates that the important feature of PCPs is its power to translate numerical data set into a visual representation and the ability to provide both an overview and detailed numeric values.

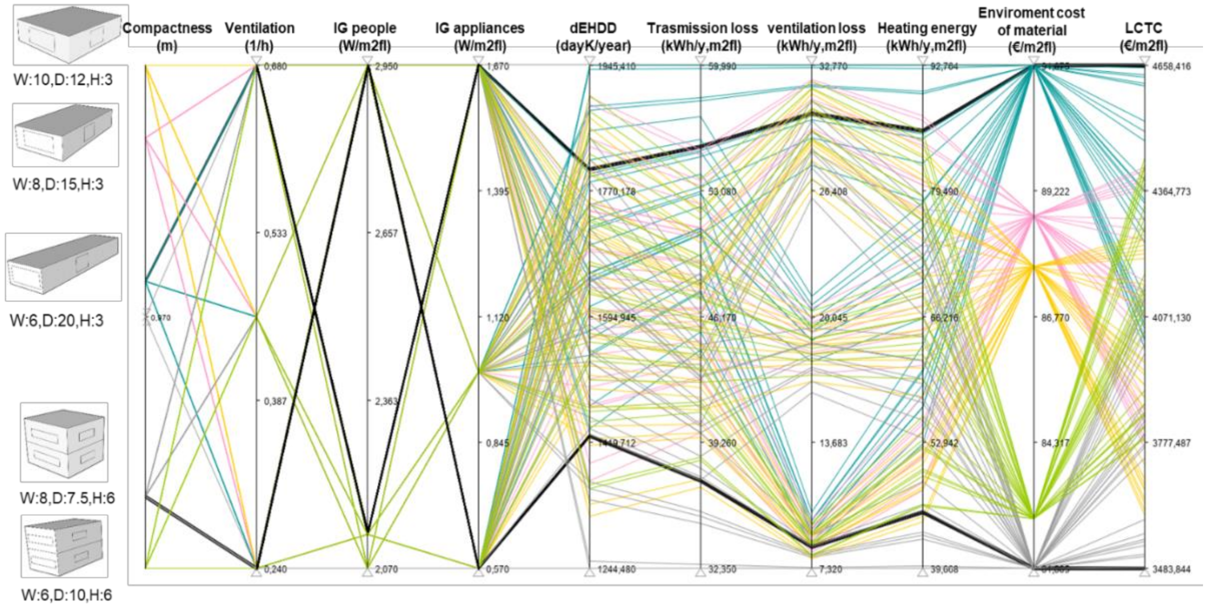

Figure 7: Representation of a design space and the lines representing highest and lowest LCTCs are highlighted in black

5. Discussion

This paper presents a tool to assess the life-cycle environmental and economic aspects for architects in an early design stage in order to support the design of sustainable dwellings. The tool proposed in this paper:

- Requires no additional effort to obtain LCFCs and LCECs of each design proposal than what architects already consider, such as orientation, location, geometry, materials, and so on. The proposed tool requires primary inputs categorised into (1) geometry, (2) technical choices and (3) user behaviour for energy estimation. A more detailed input can be provided along the design process if more detailed calculations are desired, typically evolving in level of detail from brief, sketch design and preliminary design.
- Enables fast and accurate estimations of the heating energy and electricity for appliances and lighting of each design option. This energy is translated into LCEC and LCFC. This quick estimation method enables architects to understand how their design decisions influence the environment and finance in a step by step process. As important design decisions are taken early in the design phase, this tool hence allows to assess the influence of these decisions at a crucial moment.
- Provides easily understandable output via monetisation of LCEC. Both environmental and economic impacts expressed in a single unit (€) and aggregated into a single figure enables to compare both easily.
- Demonstrates two types of visualisation of results: "Sankey Diagrams" (SDs) and "parallel coordinate plots" (PCPs) because architects often hesitate to deal with numerical datasets. SDs visualise the impacts of changing design parameters on LCEC and LCFC during a step by step design approach (bottom-up approach). PCPs generate an overview of the design space (top-down approach). However, since in the Sankey diagram the vertical scale is often adapted so that the sum of all costs of considered elements covers the whole screen vertically, the absolute differences between the design variants are not represented graphically but can only be read as a numerical value. To overcome this disadvantage, the tool allows to generate a design space by defining for each parameter a minimum value, a maximum value and a number of steps in between. This design space is visualised via parallel coordinates plots (PCPs). This plot can visualise the different costs on different axes. Analysing the effect of different design decisions becomes very graphical and allows an interactive iteration**.** Therefore, the combined use of these

two visualisation techniques enables architects to find better design solutions for sustainable buildings from an early design stage on. Even more, visualisation is a powerful communication tool for architects to share information and ideas with other architects, engineers, stakeholders and clients.

- Enables to use different climatic conditions with any Test Reference Years (TRYs) (also predicted future TRYs) for estimation of heating energy demands via dEHDD.

6. Conclusion

The advantages of the proposed approach are: (1) user-friendly limited inputs for the life-cycle financial cost (LCFC) and no extra effort to estimate in addition the life-cycle environmental cost (LCEC), (2) fast analysis of the importance of heating via LCEC and LCFC and (3) easy comprehensive visualisation. Via the tool, it is not a huge challenge anymore to integrate extra aspects (life-cycle environmental and economic) in the design processes as it does not require extra time and effort and it is easily interpretable via different graphical representations. This research is a starting point to assist architects in making decisions for sustainable nearly Zero Energy Buildings (nZEBs) from the sketch design stage onwards. Concerning further research, the usability test will be carried out by students and a workshop for architects will be organised to obtain feedback from practitioners. Furthermore, the tool will be extended to evaluate summer comfort/discomfort to avoid the need for active cooling.

patxi.hernandez@tecnalia.com

Abstract. This paper presents a comparative analysis of different space heating and hot water systems for a social housing project in Santurtzi, Spain. The building, comprising 32 apartment units and currently under construction, has been designed to minimize thermal energy demand, while ensuring comfort and quality of the internal environment for the social housing occupiers. The selection of the heating and hot water energy systems has been carried considering a life cycle perspective both for environmental and economic impacts. Different alternatives have been analysed which compare conventional gas boiler installation, which has been the norm for this type of social housing for the last decades, with various options based on heat pump technology. Life cycle analysis of the environmental effects of electrification of the thermal energy demand through heat pumps show a potential for reducing life cycle CO_2 emissions. The economic evaluation done through life cycle costing, comparing investment, maintenance, replacement and operational costs of gas boiler with aerothermal and geothermal heat pump solutions, have shown however that gas heating solutions are still the most competitive economically. Increasing the overall efficiency of those heating and hot water systems that include heat pump technology, while reducing their uncertainty in operation is a key element to ensure competitiveness of heat pumps in the current market.

1. Introduction

In the last decades heating and hot water for residential buildings, and in particular for social housing, has been increasingly supplied in the Basque Country by the use of natural gas. Current construction standards, with reduced thermal energy demand, provide the opportunity to explore solutions that move away from natural gas, for example by electrification of thermal supply through the use of heat pumps. With a vision for an electricity mix that will progressively reduce its environmental impacts by utilising a larger share of renewable generation, and the potential for on-site renewable electricity generation which is becoming very affordable (mainly through PV panels), use of heat pumps is expected to grow in the coming years.

This paper studies alternatives for electrification of thermal energy loads through heat pumps in a case study of a nearly-Zero Energy Building, with particular attention to the evaluation of life cycle environmental and economic performance of different design alternatives for the installations.

2. Case Study

Alternative technologies for heating and hot water are studied in a new residential building, for social renting use, being VISESA the building developer (Basque Country Public Housing Body). The building is situated in Santurtzi (Bizkaia, North of Spain), with a temperate climate (Köppen-Geiger climate classification Cfb) and 1,023 Heating Degree Days (15 degree base temperature). It comprises 32 apartments in four floors, with a total of 2885 m^2 of useful floor area, and a North-South orientation. Construction is expected to be finished within autumn 2019.

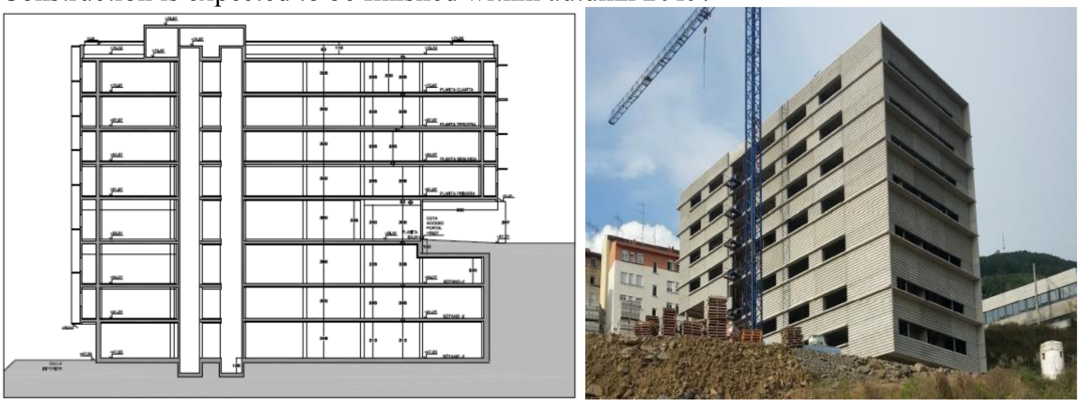

Figure 1. Section of the apartment building and current state of construction (December 2018).

The building has been designed to meet high energy – efficiency standards, beyond current building regulations in Spain, and even beyond future building regulations which are currently published as a draft, which is expected to require non-renewable primary energy use below 32 kWh/ m2·year, for new residential buildings in this location [1]. This is possible with a detailed design to reduce infiltration and thermal bridging, installation of mechanical ventilation with heat recovery, and the following thermal characteristics (transmittance U-values) for the building envelope:

- Windows: 1,20 W/m^2·K (Low emissivity, Argon filled, 4/16/3+3)
- Façade: 0,23 W/ m^2·K
- Roof: 0,21 W/ m^2·K

Calculated heating demand for a building of such characteristics in this climate is consequently very low, just 6 kWh/m^2*year, below the expected hot water demand which is 12 kWh/ m^2*year. No cooling systems are installed in residential buildings in this climate, as cooling demand is very low and natural ventilation, particularly night ventilation, is used to achieve comfort.

These low energy demands provide the opportunity to reconsider how energy supply is approached in buildings, as one of the main benefits of the gas supply, which is its ability to supply a large and instant power base, might not be longer needed for low energy buildings with correspondingly low peak power demands. Different options for utilization of heat pumps in this building have been therefore studied.

3. Different choices of energy systems for heating and DHW

Table 1 describes the different energy systems that have been considered for the building, which combine the use of the heat pump technology with different heat sources (air, ground, and mixed).

Table 1. Energy systems for heating and DHW considered in this study

	Installed Power	Efficiency
1- GAS + SOLAR (CENTRAL)	2 * 50 kW	102% (condensing boiler)
2- AIR-TO-WATER HEAT PUMP (CENTRAL)	2 * 47 kW	SCOP = 2,5

3- AIR TO WATER + GEOTHERMAL HEAT PUMPS (CENTRAL)	2 * 47 kW	SCOP = 3
4- GEOTHERMAL HEAT PUMPS (CENTRAL)	2 * 47 kW	SCOP = 4
5- AIR-TO-WATER HEAT PUMPS (INDIVIDUAL)	32 * 7 kW	SCOP = 2,5

Detailed design was carried for each of the options, with installation detail and budgeting as shown in Figure 2 as an example. Options 1, 2, 3 and 4 are centralized installations where heat is centrally generated and distributed to the 32 apartments. Option 5 refers to individual installations in each apartment.

The option 1 with gas, includes a solar thermal installation with 14 panels of 2.52 m^2 each, which covers 32% of the annual hot water demand, as this is requisite from the building regulations to comply with a minimum renewable energy contribution. Option 2 is an air to water heat pump, and option 4 a geothermal heat pump. Option 3 is a mixed solution which can combine both geothermal and air source heat pumps, depending on the temperature of the heat source (external air or ground). For all the heat pump cases, and with the estimated seasonal coefficients of performance (SCOPs) shown in Table 1, the requirements for contribution of renewable energy from current building regulations in Spain are fulfilled, as renewable energy from heat pumps is accounted as set out in the Renewable Energy Directive [2]. However, it is important to note that these SCOP values have a relatively large degree of uncertainty. The performance of the heat pump will depend on the performance of the actual installation, which includes various storage and buffer tanks (see figure 2), numerous pumps and heat exchangers, and a control logic that will be programmed. Real efficiency in operation will depend on the variations of both the heat source temperature (external air or ground) and the heating and hot water demands. Values for the seasonal performance of the heat pumps, which are provided by the manufacturers according to standard testing procedures such as EN 14825 [3], need therefore to be adjusted to real performance within this specific installation and expected demands. The values shown in Table 1 depart from the calculations made with the Spanish HULC energy certification tool [4], further adjusted for particularities which the software is not able to model, for example the losses through the different distribution and storage systems.

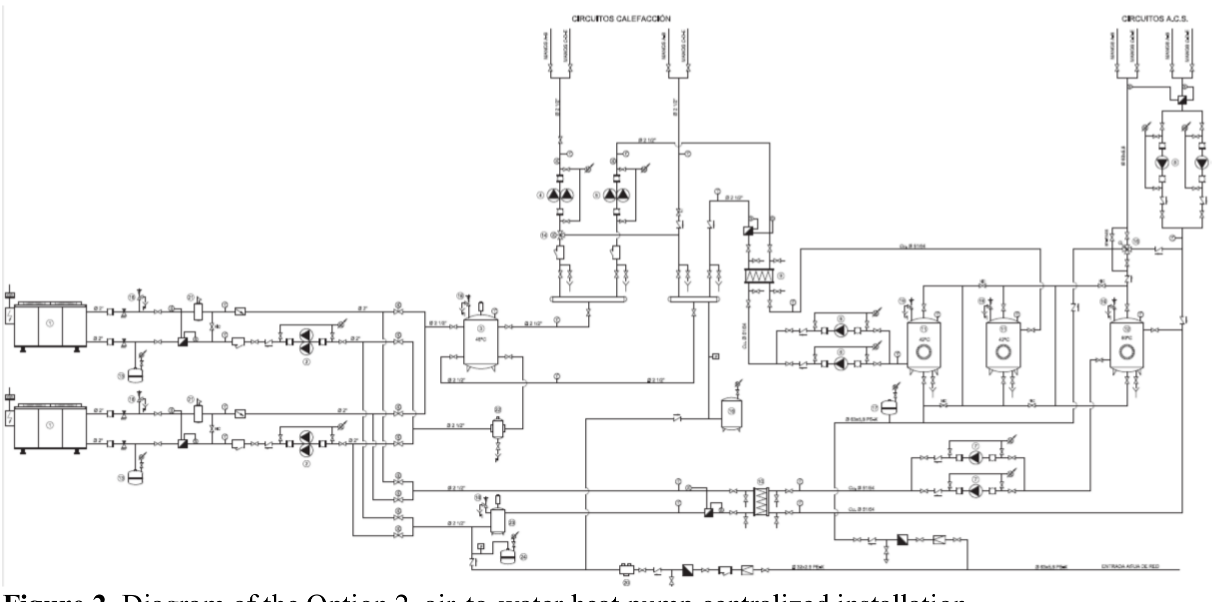

Figure 2. Diagram of the Option 2, air-to-water heat pump centralized installation

From these estimations about the energy performance of the different energy systems, heating and hot water final energy use for the building has been calculated and is presented in Table 2. This table does not add auxiliary energy use, which is very similar as core distribution system, which is quite standard in this type of buildings, has been maintained for all options.

Once the energy use of the different options has been calculated, an in order to assess economic and environmental performance of the heating and hot water system from a life cycle perspective, these results should be combined with the data on environmental and cost evaluation of other life cycle phases, such as the product manufacturing and installation, and the maintenance phases.

Table 2. Energy use for space heating and DHW for the different technologies.

	Gas [kWh/year]	Electricity [kWh/year]
1-GAS + SOLAR - CENTRAL	64701	0
2-AIR-TO-WATER HEAT PUMP - CENTRAL	0	36355
3-AIR TO WATER + GEOTHERMAL HEAT PUMPS – CENTRAL	0	30926
4-GEOTHERMAL HEAT PUMPS - CENTRAL	0	22722
5-AIR-TO-WATER HEAT PUMPS - INDIVIDUAL	0	30355

4. Results for life cycle environmental and economic performance evaluation

This study intends to serve as an example on how decisions on energy systems can take into account a life cycle perspective, and facilitate selection of options that have favorable economic performance over a period of study considering the whole life cycle cost, even if they correspond to different actors through that period (i.e.: building developer, building owner, building occupier/user).

Environmental and economic performance of the five technology options for heating and hot water supply have been evaluated from a life cycle perspective, following standard *'EN 15978:2011 – Sustainability of construction works – Assessment of environmental performance of buildings – Calculation methods for environmental evaluation' [5]*, and standard *'EN 16627:2015 – Sustainability of construction works – Assessment of economic performance of buildings – Calculation methods for the economic evaluation' [6]*. Evaluation considers the impacts of the products (manufacturing of the systems), on site installation processes, and the use stage (including operation and maintenance). End on life stage, as its impact is relatively very low for building energy installations, has been disregarded for this study. The study period for the assessment has been selected as 15 years, which is the expected service life for some of the key products in the analysis (such as the heat pumps).

The functional unit for the analysis has been selected as 1 kWh of heat delivered to the dwellings, for heating and domestic hot water. The environmental impacts and economic costs of delivering 1 kWh are quantified in the following sections.

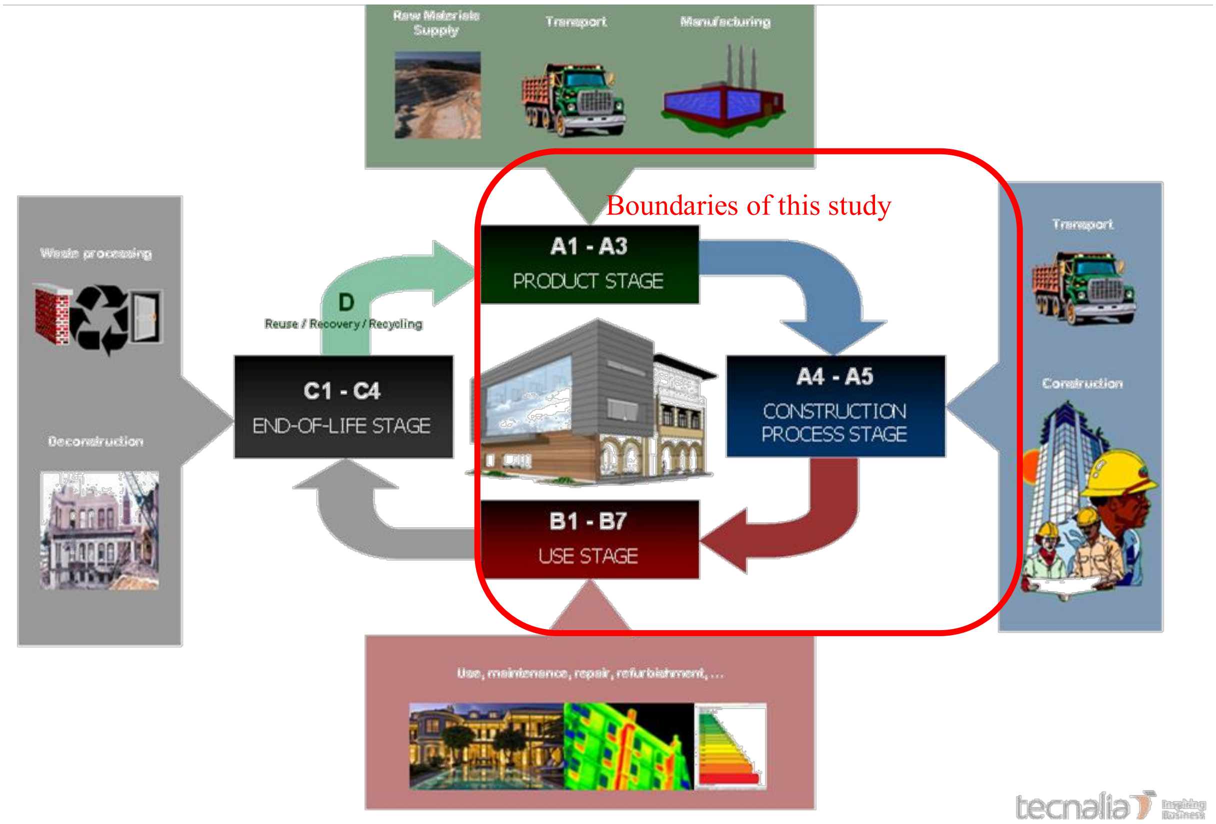

Figure 3. Description of the life cycle stages within EN 15978 and boundaries set for this study

4.1 Environmental performance evaluation

The Ecoinvent LCA database [7] has been used to attribute environmental impacts to the different products that conform the different installations, such as the gas boiler, solar panels, heat pumps, geothermal bore holes, storage tanks, etc.; as well as for the impacts related to electricity and gas usage. Different environmental indicators can be calculated according to EN 15978. Figure 4 shows the results for the global warming potential indicator.

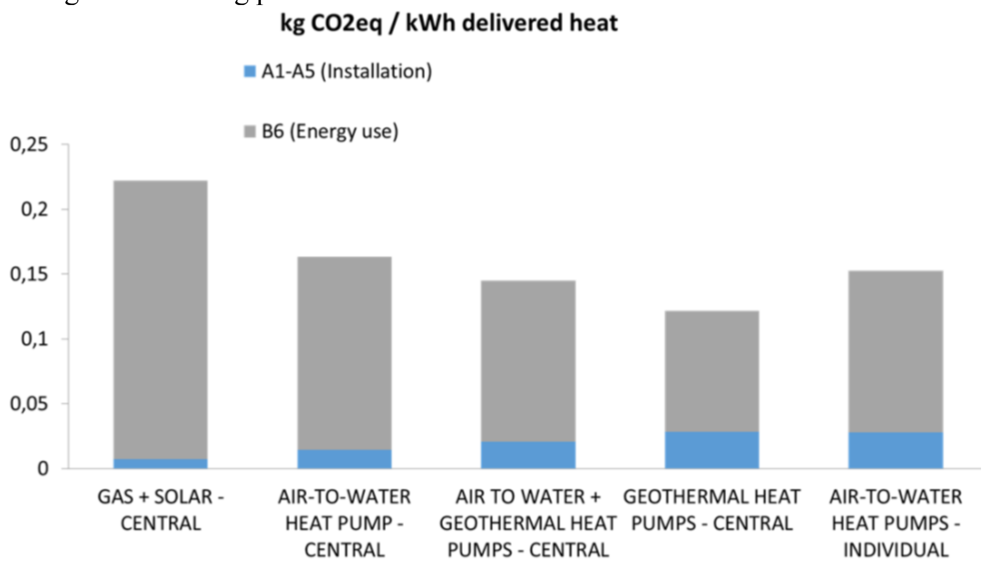

Figure 4. Global warming potential of delivered heat by the different energy systems

It can be observed that the main environmental impact is related, as it could be expected, to the actual energy usage in the operation stage (B6), and that the impact of the product stage (A1-A5) is relatively low. The solutions with heat pumps, even with the current electricity mix (which has been considered constant for the 15 years study period), are favorable to the heat pumps. Results range from 121 to 163 grams of CO_2eq per delivered kWh of heat delivered by the different solutions with heat pumps, compared to 222 grams of the conventional solution of gas boiler with solar water heating support.

4.2 Economic performance evaluation

To quantify the cost indicators over the study period, it is necessary to develop some scenarios and make certain assumptions on a few variables. This study considers a real discount rate of 3%, and conservative annual increases on prices of electricity of 0,5%, and 1% for gas. Costs of the different options are disaggregated and shown in table 3 (production and installations costs), and table 4 (maintenance costs).

Table 3. Cost of product and installation stages (A1-A5) for the different technologies

	1 -GAS + SOLAR	2- AEROT CENTRAL	3- GEOT+AEROT - CENTRAL	4- GEOT CENTRAL	5-AEROT – INDIVIDUAL
Total Generation + Distribución: Heating & DHW	**72.504,25 €**	**111.757,47 €**	**155.190,39 €**	**165.446,00 €**	**247.898,59 €**
Legal procedures	1.171,88 €	1.115,53 €	1.115,00 €	1.115,00 €	1.143,71 €
Generation and boiler room	27.453,93 €	69.347,62 €	71.866,81 €	70.089,00 €	237.920,00 €
Regulation and control	14.311,96 €	33.175,48 €	25.870,74 €	20.765,00 €	8.834,88 €
General distribution (not including internal for each apartment)	8.832,44 €	8.118,84 €	8.118,84 €	8.118,00 €	
Solar installation	20.734,04 €				
Bore holes			39.533,00 €	56.400,00 €	
Thermal Response Testing (TRT) & commissioning			8.686,00 €	8.959,00 €	

Table 4. Cost of maintenance stage (B2) for the different technologies

	Annual maintenance costs [kWh/year]
1-GAS + SOLAR - CENTRAL	1,700 €/year
2-AIR-TO-WATER HEAT PUMP - CENTRAL	1,700 €/year
3-AIR TO WATER + GEOTHERMAL HEAT PUMPS – CENTRAL	1,500 €/year
4-GEOTHERMAL HEAT PUMPS - CENTRAL	1,000 €/year
5-AIR-TO-WATER HEAT PUMPS - INDIVIDUAL	2,560 €/year

Operational energy costs are more complex to calculate. For centralized heat pump installations, the costs for contracting electricity power capacity for different time periods during the day need to be considered. For geothermal installations, lower contracted power is one of the economic advantages, as due to the more constant temperature of the ground used as heat source, a good coefficient of performance (COP) is maintained even in cold periods. On the contrary, air source heat pumps lower their efficiency during periods with low external temperatures, and therefore need to draw more power from electricity grid to deliver the necessary heat supply. Centralized installation with air to water heat pump need to contract an estimated power of 45kW for the peak power periods, compared to 25kW contracted power for centralized geothermal heat pump installations. As for individual heat pump installations, each apartment would need to contract additional power capacity, which has been estimated as additional 3kW, which largely increase the fixed costs of the operation for the users. Gas installations do have the advantage of very low fixed costs. Figure 4 shows results of the overall operational costs for the considered options, showing fixed costs and variable (energy) costs, for each delivered kWh of heat.

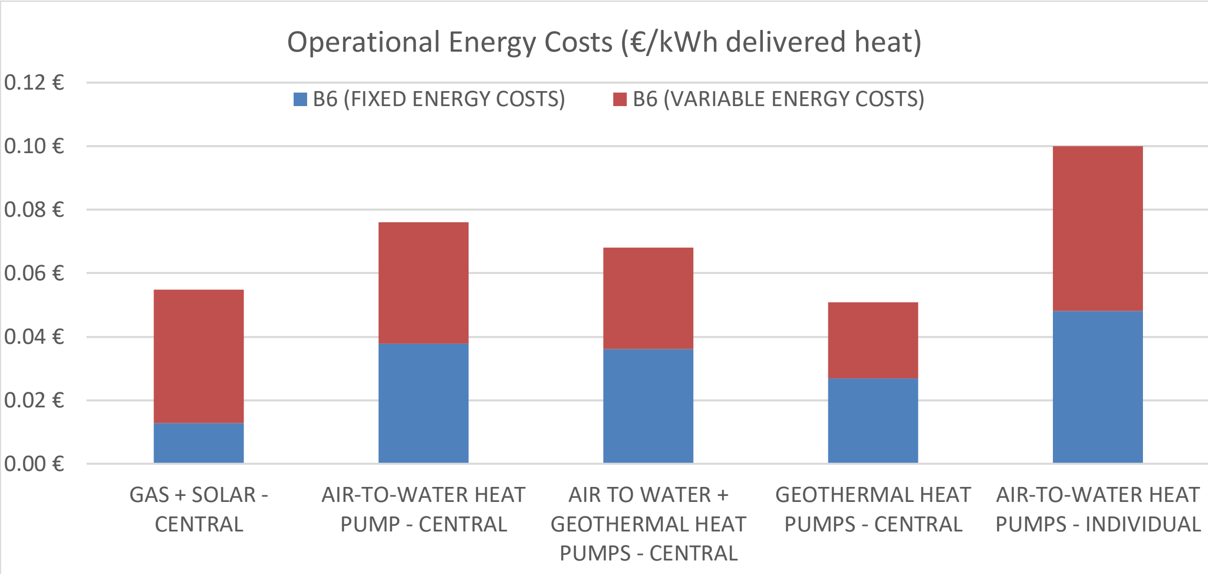

Figure 5. Operational energy costs for the different energy systems.

It can be observed that the low fixed costs of the gas installations make them a very interesting option from an operational energy cost perspective, only after the centralized geothermal installation. Individual heat pumps, due to both variable and fixed costs, are the most expensive solution in this case.

To be able to compare all the technologies for the selected study period of 15 years, costs of the other life cycle stages need to be added to the operational energy costs. Figure 6 shows the results of adding the initial costs for the installation and maintenance costs for the five technological options considered in this study.

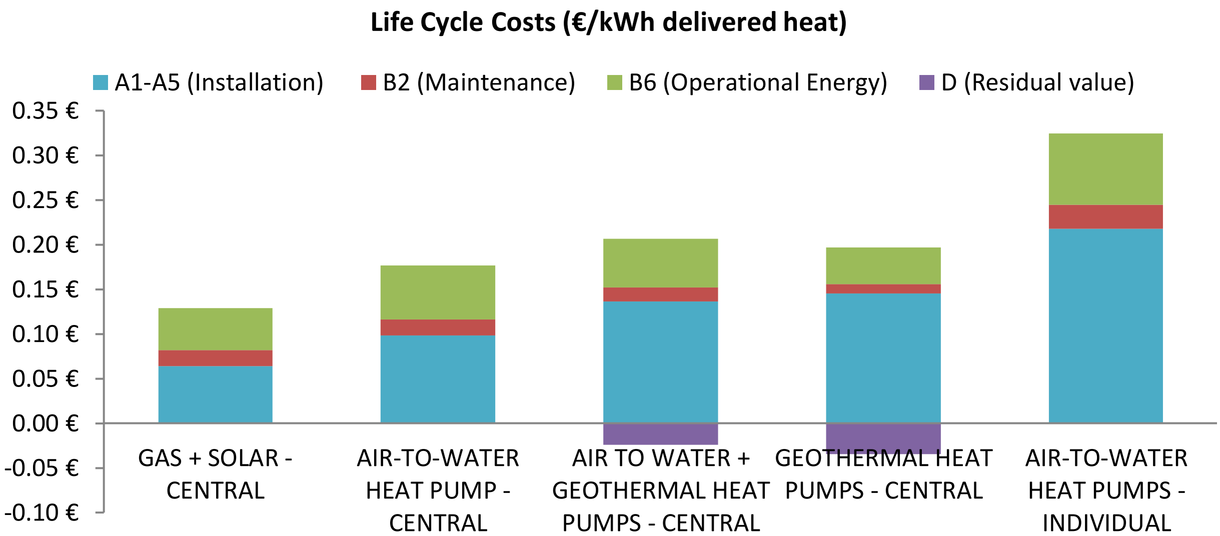

Figure 6. Life cycle costs for the different energy systems considered in the study. Residual value considering value of components (particularly geothermal borehole) after the 15 year study period.

Due to the lower initial investment and a competitive operational cost, gas installations backed with solar water heating systems are currently the most economically favourable solution for this case study building.

Geothermal installations offer the lowest operational costs in energy, and the lowest cost for the users considering also maintenance, but larger initial investment costs mean that overall life cycle costs are higher than both gas and air to water centralized installations. It must be noted that if we would consider the residual value of the borehole in geothermal installation, as will have an estimated service life of 50 years, much larger than the study period of 15 years, life cycle cost results would be similar to air to water centralized heat pump installations.

Air to water individual installations are the most expensive solution for this building within all cost categories (installation, maintenance, and operation).

5. Discussion and conclusions

The building sector is aiming for a progressive reduction of the energy use, and decarbonisation of the energy supply. A first step to achieve this goal is the drastic reduction of the energy needs for buildings, and a second step should be the study of the optimal technologies and energy systems to supply those energy needs.

This study has compared solutions for heat pump installations which could substitute the common gas installation, in a 32-apartment building designed for very low energy use for heating and hot water.

Most of the life cycle impacts of delivering heat to the building occur during the operation phase due to the energy use. Even for a building as the studied with very low energy use in operation, the manufacturing and installation of the actual heating energy systems represents a relatively small percentage of the total life cycle environmental impacts. Only for geothermal installations, where significant environmental impacts occur in the installation mostly due to the borehole drilling, and for the individual heat pump installations, the share of total life cycle CO2 emissions that can be attributed to the manufacturing and installation of the systems is above 10%.

Total life cycle CO2 emissions have shown that natural gas, which has been frequently cited as a ‘low-carbon’ and ‘transition’ fuel and is still the most common heating fuel in Spain, has larger CO2 emissions than alternative solutions based on heat pump technology, even with the current electricity mix.

Studying life cycle costs for the presented technology options, for a period of study of 15 years and including costs for investment, operation and maintenance, gives however a very different result. The gas installation, which is backed with a solar water heating system, is still the most cost-efficient option for providing heating and hot water to the case study building. The low initial investment, and operational energy costs only challenged by the most efficient geothermal heat pump solutions, means that solely in cost terms it is still difficult to compete with this standard solution. Comparing within the heat pumps, centralized air to water heat pumps is the most competitive, mainly because lower initial investment. If the period of study will be extended (e.g. 50 years), geothermal solutions could become competitive in cost terms, as their major investment cost (borehole heat exchanger) has a service life of 50 years. Individual heat pumps are the most expensive option, due to higher initial investment and higher operational costs, in part due to higher needs for contracting electricity power for the apartment occupiers.

As a final conclusion, heat pumps can be a good solution to reduce CO2 emissions, particularly as they offer the possibility of using increasingly renewable electricity, also from on-site renewable energy sources. Although economically they still have strong competition from the gas energy supply, overall life cycle costs are close and could be matched in the near future. Improving the overall performance of heat pump installations in operation will be of key importance to reduce life cycle costs of heat delivered by heat pumps. The large sources of uncertainty that were found when calculating seasonal performance of installations using heat pump technology, also highlighted the need for thorough commissioning, measurement and verification procedures for buildings including heat pump technology, procedures which have already been implemented in the described case study building.

Abstract. The environmental impact of human activities has been a concern for engineers and architects for centuries, from limitation of energy and raw materials to predicting future energy and resource demands. This review demonstrates how life cycle assessment (LCA) and life cycle costing (LCC) tools can be used to support design decisions in the building industry throughout the design process. The study is primarily based on DGNB certification projects in Denmark conducted by the engineering consultancy company Ramboll and focuses on how LCA and LCC tools can be used in the early design stages to quantify decision making and how tools are used in the final stages of a certification process to verify the building geometry with regard to life cycle costs and environmental impacts.

1. Introduction

In accordance with the Danish Construction Association only 4% of all building projects in 2018 were considered sustainable in Denmark, counting buildings with sustainability certifications, meet the voluntary Danish low energy class or additional sustainability measures exceeding the Danish building regulations [1]. In Ramboll Denmark approximately 6.5 % of the projects within the building industry are described as sustainable in the project database, half of these are certification projects like DGNB, LEED and BREEAM[1]. Looking at all Ramboll's projects within the building industry globally there has been an exponential growth in projects described as sustainable over the last 10 years.

The Danish building regulation has tightened the requirements to energy consumption of buildings over the last decades, but has yet to finalize the currently developing voluntary sustainability class, which will contain a requirement for LCA and LCC estimates for major building components. In the long term, specific requirements for a building's total energy and resource consumption over its life time may be implemented [2]. With lack of interest and demand for sustainable buildings and a lack in regulations it is crucial that engineers, architects, developers and contractors have entrepreneurial spirits when it comes to sustainable building design and informing the clients and developers of the possibilities and value propositions herein.

The aim of this paper is to increase awareness of design driven by life cycle methods through case studies in the engineering and design company Ramboll [3]. The case studies focus on different

[1] Deutsche Gesellshaft für Nachhaltiges Bauen (DGNB), Leadership in Energy and Environmental Design (LEED), Building Research Establishment Environmental Assessment Method (BREEAM)

methodologies utilising life cycle engineering[2] as a driver for design decisions and the paper will present the potentials and boundaries in both early design stages as well as detailed design stages.

2. Life Cycle Engineering Screening Approach

A common design constraint is limited time and budget for a project. To enhance informed decision making and promote sustainable solutions it is important to have tools which provide quick feedback to the designers and client. This section will explain the Ramboll sustainability screening methodology through theory and examples. This approach can be used both in early design stages as well as very late design stages and even during construction. The methodology has been developed to qualify the answer to one of the most common questions posed by clients; *what is the most sustainable material/product for a given function?*

2.1. Sustainability Screening of Building Materials and Products

To enhance informed decision making and promote sustainable solutions a screening tool as seen in figure 1 can be used. The screening tool can be used to compare functional equivalent products or materials which means the primary functions and services must be equivalent. They are compared on a variety of parameters which includes the life cycle and both social, economic and environmental qualities.

Functional equivalent product group		Sustainability Parameters		
		Social	Economic	Environmental
Life Cycle Stages	Production			
	Construction			
	Use			
	End of Life			

Figure 1. *Scheme for sustainability screening of building materials or products*

The use of this scheme will enable the designer to compare products over the entire life cycle of a building and on all three sustainability parameters; social, economic and environmental. This method can be adapted to all project phases. In the early design stages, it is possible to compare different materials, products or systems based on experience and generic data. Environmental data is accessible through the free online database *oekobau* [5], whereas costs can be found in the Danish cost tool *molio price data* [6]. Social data can be both descriptive and specific. A descriptive parameter could be aesthetic and cultural quality and a specific material property could be light reflectance which will influence the daylight in a room and thereby also the users, thus some parameters are easy to quantify whereas other are subjective.

The scheme can also be used to specify material qualities in a tender through requirements for e.g. enclosure of environmental data and building sustainability certifications. In a later design stage, the scheme can be used to compare specific building components or products against each other on a chosen set of parameters. The data will primarily be derived from the manufacturer's websites combined with generic data when needed e.g. for life span, maintenance and cleaning cost.

---

[2] *Life cycle engineering enables informed decision making by evaluating environmental, economic and social impacts of products, buildings or cities in a life cycle perspective. The Life Cycle Engineering methodology presents results clearly and enhance transparency to create a solid basis for decision makers* [4].

Table 1 gives an example of what parameters can be chosen when comparing different ceiling products on their sustainability in the early design stage. The method helps the practitioner identify comparable measures and can be used to ensure equal focus on both social, economic and environmental aspects in a life cycle perspective. In figure 2 the final visual presented to the client is seen. The purpose of the visual is to quickly enable the client to make a decision based on both social, economic and environmental data in a life cycle perspective.

Table 1. *Example of a sustainability screening for comparing different ceiling products*

Comparison of ceiling products		Sustainability Parameters		
		Social	**Economic**	**Environmental**
Life Cycle Stages	Production (A1-A3)	FSC Certification & Cradle2Cradle	Building Component Cost [EUR/m2]	Global Warming Potential (kg CO2e/kg) & Recycled content
	Use (B1-B7)	Aesthetic, Light reflectance & Off-gassing	Maintenance [EUR/m2/year] Life Span (years)	Maintenance and cleaning Life Span (years)
	End of Life (C1-C4)	-	-	Global Warming Potential (kg CO2e/kg) Cradle2Cradle

Acoustic ceiling panels	Environmental Impact [kg CO2 eq]	Lifetime [years]	Price [kr/m2]	Maintenance friendly	Recycled Material Content [%]	Toxicity and degassing [mg/m3]	Product Certification	Aesthetics
Ceiling Panel 1	0,43 kg CO2 eq	50 years	130 kr/m2	**Yes** Possible de- and remounting for easy accessibility	0%	0,02mg/m3	FSC/ PEFC	The solution does **not** meet the requirement for a "uniform ceiling surface"
Ceiling Panel 2	1,87 kg CO2 eq	30 years	296 kr/m2	**Yes** Possible de- and remounting for easy accessibility	71%	<0,5mg/m3	C2C	The solution meets the requirement for a "uniform ceiling surface"
Ceiling Panel 3	1,20 kg CO2 eq	50 years	225 kr/m2	**Yes** Possible de- and remounting for easy accessibility	52%	0,01mg/m3	?	The solution meets the requirement for a "uniform ceiling surface"

Figure 2 Example of a sustainability screening of different ceiling products as it is visualised to the client

2.2. Potentials and barriers related to the simplified life cycle approach; Sustainability screening

The simplified life cycle approach has shown the potential to enhance designers and clients to make more informed and thereby more sustainable design decisions. The method can be tailored to the specific client needs and context, but is also vulnerable as it depends on the consultant's competences and experience. This method requires the practitioner to have a basic understanding of the functional unit of environmental impact data to ensure data comparability and knowledge of product certifications.

Even though this simplified method is faster than conducting environmental and economic life cycle assessments it has shown to be time consuming in data gathering. The data needed can be found in various databases and from manufacturers directly, but currently no common database that can create this overview exists. A database requires continuous maintenance in securing accurate and updated data, hence the manufacturers should see the benefit of reporting and updating their data.

A potential flaw to this method is the risk of making comparisons based on too few parameters and thereby neglecting important issues which might lead to taking wrong decisions. As both qualitative and quantitative data can be used to describe materials or products it can result in a subjective weighting of the variants. A common understanding in the industry of the minimum requirements for a comparison is important in order to not neglect important issues or parameters.

A common barrier for the specific product comparison is the lack of data on the manufacturers' websites and the lack of specific environmental product declarations in Denmark. The lack of data limits the design space and may result in the same few products being used repeatedly. Some manufacturers do not disclose their product content online which could make the designer choose another brand where the data is easy to access. This might leave new and innovative products out of the comparison, as they often have not declared their product through environmental declarations (EPD) or have certifications and labels like *Cradle to Cradle* or the Danish indoor climate label etc. This approach could then make it even harder for new and potentially more sustainable products to penetrate the market.

3. LCA and LCC comparison studies of building elements

This section describes the process of conducting LCA and LCC comparison studies during a design phase. What building components or design solutions should be compared will depend on the specific context and should thus always be evaluated to ensure that design solutions with substantial impact are chosen.

3.1. LCA and LCC comparison studies of building elements

Often various solutions are explored and discussed and poses questions like; *which solution is more sustainable, solution A or solution B?* In this case it is possible for the sustainability consultant to utilize the Danish LCA and LCC tools; LCAByg [7] and LCCByg [8] developed by the Danish Building Research Institute to visualize the environmental and economic impacts over the life span of the given building to enhance transparency of environmental and economical sustainability impact. Comparison studies requires a stringent methodology and a common understanding on how to define prerequisites and set up assumptions. To conduct LCAs and LCCs the right data needs to be at hand, an overview of the different data needed can be seen in **Table 2**.

Table 2. *Data Requirements for calculation LCA and LCC*

	Data Requirements	**Where do we get the data from?**
Life cycle stages	Quantities	Estimates, 2D or 3D design models e.g. Sketch Up, Revit
Production (A1-A3)	Cost	Estimates, Molio cost database, Contractor's *list of products*
	Environmental impact	Oekobau, EPDs or Proxy data
Use phase (B1-B7)	Energy consumption	Be18 calculation
	Maintenance & Cleaning	Molio cost database, Danish Facility Management (office), The Danish social housing sector (social housing), Manufacturers maintenance & cleaning guidelines
End-of-life (C1-C4)	Life Span	Oekobau, EPDs or Proxy data
	Environmental impact	SBI 2013:30 Industry Guidance on life span, Levetider.dk (A Danish database of building component life span)

Financing data like inflation and discount rate is already implemented in the Danish *LCCByg* tool and national standards for CO_2 emissions related to energy production is already implemented in the Danish *LCAByg*. Figure 3 shows an example a comparison of the life cycle cost of three different possible solutions to a façade renovation. The different alternatives were discussed with the building owner, the project team and the facility manager and then modeled and compared via the Danish *LCCByg* tool. The price data for the different processes in the renovation solutions were found in the *Molio cost database*, where it is possible to find the related cost per area for pressure washing of the existing façade, repair and re-painting, etc. The three different renovation solutions over a 50 year life span are depicted in

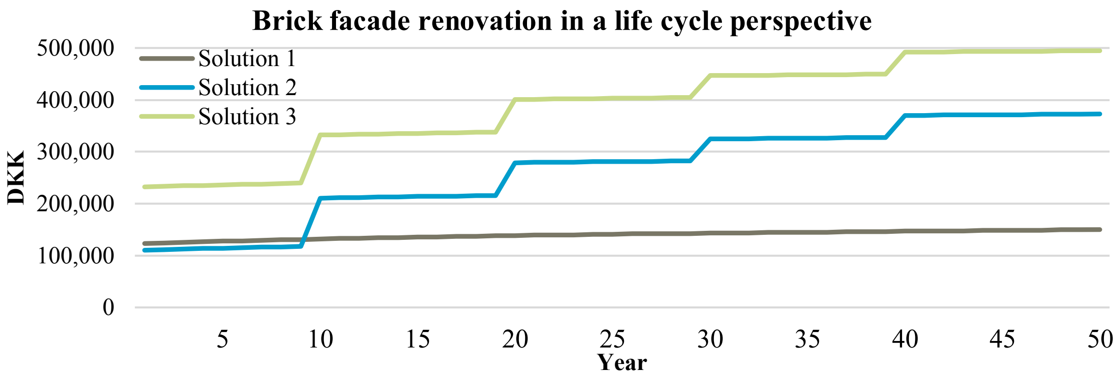

Figure 3.

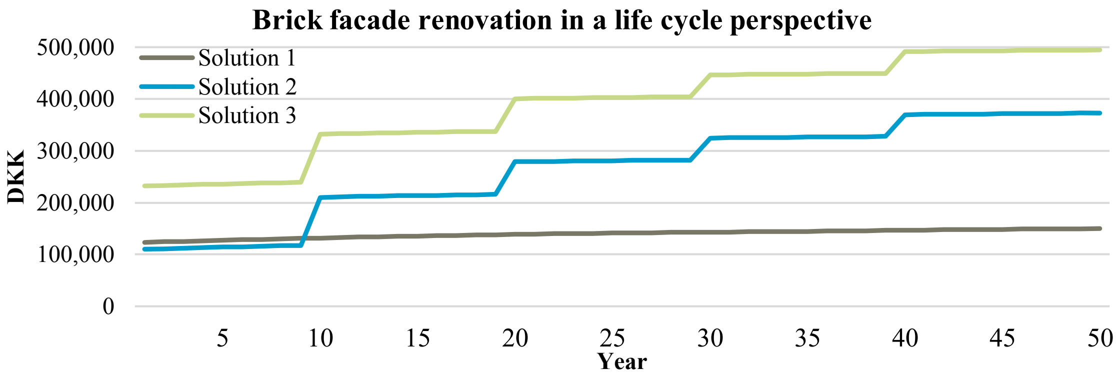

***Figure 3**. Life cycle cost of 3 brick wall renovation solutions. Solution 1: Revert to raw brick wall by cleansing the façade. Solution 2: Clean the façade, re-plaster and repaint. Solution 3: Repair the cracked façade with new plaster and repaint.*

3.2. LCA and LCC comparison studies including whole building simulations

LCA and LCC comparison studies can be integrated into engineers' and architects' design explorations. As an example, a client wanted to explore different solar shading systems and the related energy and daylight performance. The life cycle cost comparison of a fixed and a dynamic solar shading system can be seen in figure 4. Here the yearly energy consumption, daylight levels and heating and cooling demands are accounted for as well as the construction and maintenance cost. This life cycle cost assessment not only compares the performance of the two systems 1:1, but also sees the systems in the relation they are in, within the building. The energy and daylight simulation data were retrieved from a whole building simulation model by the indoor climate engineer and the cost data were provided by the contractor on the project as well as the specific product manufacturers. Maintenance and cleaning data were derived from the DGNB manual.

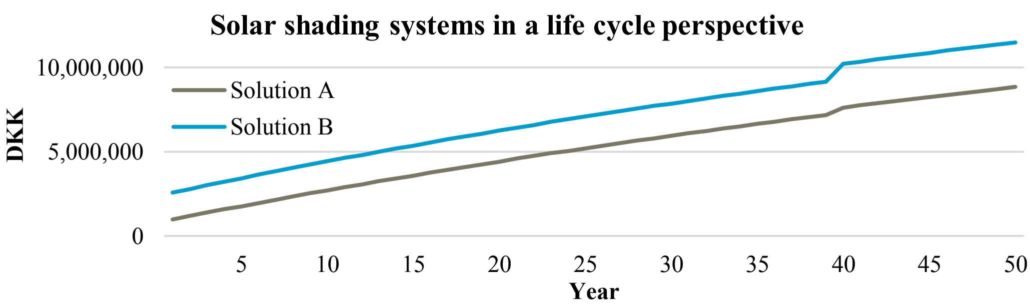

***Figure 4.** Life Cycle Cost of a fixed (solution A) and a dynamic (solution B) solar shading system*

3.3. Potentials and barriers related to the LCA and LCC comparison studies

The LCA and LCC comparison studies provide a quantified overview of consequences and is a useful tool in a decision-making process. Even stronger arguments and more holistic decision making would be obtainable by conducting LCAs and LCCs simultaneously. An integration possibility between the two tools would ensure consistency in data and enhance the use of both assessments.

Numerous barriers prevent the utilization of LCA and LCC as decision making tools e.g. limited time which is often related to limited knowledge and experience of the consultants or project managers. The building industry is rather conservative and tends to go on with a "business as usual" approach, thus not allowing time for comparative studies like the examples above. Other barriers can be the data gathering, and discussion on how simplified a comparison can be without leading to wrong decision making. This dilemma of LCA and LCC is related to the nature of the design process. Early design choices are responsible for a significant amount of the total environmental impacts and costs, but conducting LCAs and LCCs during this stage is based on assumptions and incomplete data [9].

Another limitation during the design process is the many different stakeholders that need to be involved to give input to the calculation. Often different companies need to be involved as well as facility managers and contractors, which often are not included in the early design stages. It is crucial to find the right balance between involving the needed stakeholders and not spending too much time.

As the data and information needed to perform the LCA and LCCs come from many different sources it is important to have standardized methods of e.g. modelling, to allow for easy quantity take offs and calculations.

4. Whole building LCA and LCC

Most of the whole building LCA and LCCs conducted in Ramboll has up until now been conducted at the end of the design process, during construction or even by the time of handover. This approach has mainly been due to the lack of experience within these early stage analyses in the market and the complexity and large amount of information required as well as due to time constraints. The reasoning has been to conduct the LCA as late as possible where the exact data is at hand and time can be saved as no design changes will occur. This approach will only be useful for benchmarking and help the client get a sustainability certification (DGNB) and does not utilize the potential of LCA and LCC as a design tool in the early stages to improve economic and environmental sustainability. The importance of life cycle calculations of both environmental and economic aspects is the ability to visualize the impact over the entire building life cycle for the client and not only the construction cost and impact. In current DGNB projects LCA and LCC studies are initiated during conceptual or schematic design on the largest building components and will be finalized during the construction stage with exact data from the contractor. **Figure 5** visualises the distribution of global warming potential (GWP) or carbon emissions between building components in a large office building in Denmark.

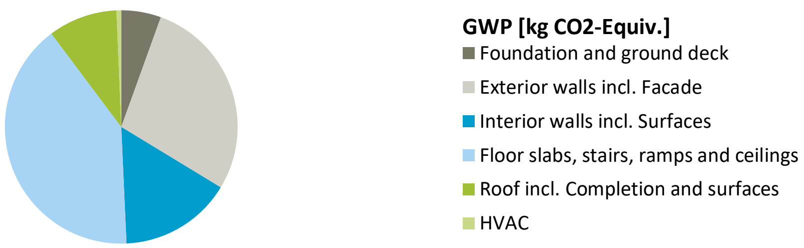

Figure 5. *Life Cycle Assessment result visualising the global warming potential (GWP) related to the building components for a large office building in Denmark.*

4.1. Potentials and barriers related to the whole building LCA and LCC

Even though the use of LCA and LCCs as design decision tools are not currently an integrated part of the design phase, the potential of it is being recognized. This has initiated an internal global development in the company. As seen in **Figure 5** the LCA can help the designer understand where the largest optimization possibilities are. Conducting a related LCC assessment will help visualize the business perspective and cost optimization possibilities.

LCA and LCC is currently not implemented in the early design, which may be due to the lack of BIM integrated tools [10]. The lack of integration between BIM and LCA/LCC tools means that design changes must be imported manually, re-calculated and exported back into the models. The manual work is time consuming and prone to human error. However, during the testing of several BIM integrated LCA tools in Ramboll the problem occurred to be the lack of standardization of the models, which can be difficult to change when collaborating with external stakeholders. Another lack within the BIM-integrated LCA and LCC tools were the fact that the 3D models may only be available at schematic or detailed design, when design changes become increasingly difficult to make. Utilizing LCA and LCC as drivers for the entire building design in the early design phases is currently difficult due to the vast design space of interrelated data and parameters to consider. On the other hand, LCA and LCC can no longer successfully be used as a decision-making tool in late design stages because proposed design changes likely will require large costs [9]. For certification purposes an as-built model with adequate detailing is necessary for the BIM integrated design tools to give the exact quantities. These models are, however often the responsibility of the contractor and are thus not as detailed as is needed for the certification purpose. An example is that the rebar in the reinforced concrete is not modelled in 3D and the actual amount will have to be retrieved from delivery notes from the building site. Another reason to why LCA and LCCs are not integrated design tools may be due to the lack of professionals and training courses within life cycle assessments and life cycle costing [11].

5. Conclusion

Life cycle calculations for buildings are receiving increased attention from national building regulations like the environmental ministry of Finland announcing that building LCA will become mandatory by law in 2025 at the latest [11]. Similarly, the number of DGNB certified buildings in Denmark is increasing and thus pushing the market. The increased experience with LCA and LCCs will impact the industry to develop methodologies adapted to the different design stages, but to see an even faster transition in the industry, legislation is needed. Since 2006 it has been mandatory to calculate the overall demand for primary energy in all new buildings in Denmark, with a continuously increasing threshold. This regulation has resulted in early design simulations as an integrated part of the design process today, whereas in the beginning the calculations were made at the end of the design or during construction only. Through regulation on LCA and LCC similar changes in the industry may occur. The industry needs access to comprehensive national databases with both product specific EPDs and generic country specific data as well as regulation pushing for LCA and LCC for new buildings.

Abstract. Bat-Eco 2 is a research project on building refurbishment life cyle assessment (LCA) and whole-life costing (WLC). The project's goal is to contribute to the development of a tool to help decision-making on refurbishment solutions, considering the environmental aspects along with the economic ones. This project has been split in four steps: (i) LCA of a standard single-family house refurbishment built in 1939 and located in Libercourt, Hauts-de-France; (ii) WLC of the same case study; (iii) crossing of LCA results with WLC ones; (iv) simplified tool specification in agreement with these results. This paper presents the WLC methodological choices and the corresponding WLC results. The WLC methodology complies with the ISO 15686-5. It details the refurbishment life cycle stages in compliance with the EN 15 978. The main choices are presented, i.e. system boundaries, economic rates, present costs for each life cycle stage, building residual value. Results enable to enumerate economic hotspots for the case study of this single-family house refurbishment. The whole-life costing is calculated using excel sheets, considering economic data from the social landlord Maison & Cités, house owner of the study case.

1. Introduction

The French building stock is composed of more than 65% of buildings constructed before 1975[1], hence following no thermal regulation. According to the recent plan of thermal refurbishment in France[2], 500 000 housings per year must be refurbished.

The refurbishments, basically, consider the investment costs in order to help decision makers[3]. However, this investment costs are not representative of the whole building life costing. Still, there are many studies considering economic sustainability[4–8], but without taking into account the whole-life costing (WLC) of a building (products, construction or refurbishment, services during lifetime and end-of-life). The whole-life costing is the sole methodology which considers all costs along the building lifetime, and thus it is more pertinent to represent the economic aspect of a building[9].

2. Goal and Scope

The current work uses specific methodological choices concerning indicators, economic parameters, system boundaries and rates. The goal of this paper is to present and to discuss the WLC results. A sensitivity analysis of the WLC assessment will supplement the analysis. This investigation was carried out on a typical single-family semi-detached house refurbishment located in the North of France.

This project takes into account the cost of financing the investment, as well as the externalities associated to (i) the tenant solvency and (ii) the vacancy rate. This corresponds to a WLC approach. The income is not considered in the study

This work is part of the Bat-Eco2 project, a regional project aiming at specifying a tool in order to support decision-making for different refurbishment choices, combining environmental and economic criteria.

3. Method

The economic assessment used in the present work is the WLC applied to a dwelling refurbishment. It takes into consideration all the costs of a building period of analysis. This methodology includes the life cycle costing (LCC) plus the externalities, the non-construction costs and the income. For a building, the LCC sums up the costs of construction, the operation costs, the maintenance costs and the end-of-life costs[3]. The methodology follows the standard ISO 15 686-5:2008[10] and the boundaries are represented in Fig. 1.

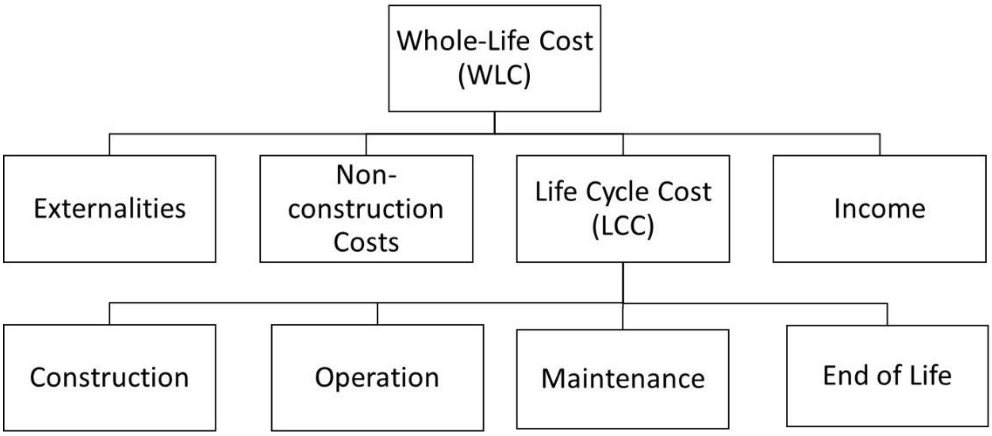

Figure 1: System Boundaries
Source: ISO 15 686-5

The "Construction" aspect corresponds here to the refurbishment and its initial investment. The operation consists of the rents, the insurances, the energy and water consumptions and the living taxes. The maintenance is composed of the replacements during the building period of analysis and the expected/planned maintenances. The end-of-life costs represent (i) demolition or deconstruction, (ii) waste transport; (iii) products and equipment treatment or disposal.

The WLC methodology is quite similar to that of life cycle assessment (LCA). After defining the goals and the system boundaries, an inventory is established with the detailed costs for each step as mentioned before. The results are then summed up.

The income is not considered in this analysis. Regarding the non-construction costs, only the cost of financing the investment is taken into account; and regarding the externalities, only the vacancy and unpaid rent rates are taken into account.

The environmental cost impacts are not taken into account on the operation step. This study focus only on the economic assessment, an environmental assessment has already been done. The interaction between environmental and economic assessments is under work.

4. Case Study and Methodological Choices

This paper presents the WLC of a refurbishment operation of a single-family house from 1939 located in Libercourt, North of France. The house is a semi-detached dwelling on a area of 300 square meters. The living area after refurbishment operation is 59 square meters.

The dwelling is composed of two bedrooms, one living room, one kitchen, one toilet, one bathroom and one small cellar.

The case study is part of the social landlord Maisons & Cités Soginorpa. It is one of their typical energy efficiency refurbishment.

This study is presented as part of the Bat-Eco2 research project, aiming at supporting decision-making on different refurbishment choices.

The partners of this project are Artois University, Lille 1 University, CD2E (Centre de Développement des Eco-Entreprises, a public agency), CIRAIG (Centre international de référence sur le cycle de vie des produits, procédés et services, a Canadian Research Center on Life Cycle Assessment), CROA (Conseil Régional de l'Ordre des Architectes), NJC Economie (a French firm dealing with economics in building) and the landlord Maisons & Cités Soginorpa.

The WLC methodological choices are presented hereafter.

4.1. Period of Analysis

The economic period of analysis depends on the profitable time of the building[3]. If the estimated period of analysis of the building during a life cycle assessment (LCA) is of 50 years, the one used in the WLCs is normally lower. The standard ISO 15 686-5 suggests not exceeding a 100-year period of analysis for WLC.

However, many studies consider a lower period: between 25 and 40 years[11], arguing that any future costs after year 40 are insignificant. Another explanation is the increasing uncertainty linked to the extension of a considered period.[12] The longer the considered period, the more uncertain the evolution of economic taxes and rates. As a matter of consequence, the reliability of economic results decreases as the considered period of analysis increases. For this case study, the considered French building period of analysis is usually 50 years nowadays. Taking into account this duration, the period of analysis is also of 50 years for the present WLC. This complies with the requirement given by the standard, i.e. less than 100 years.

4.2. Real versus Nominal Value

In economic terms, the values can be expressed in two different ways, due to the existence of a monetary value fluctuation in time due to the inflation rate. Thus the economic assessment results can be expressed in real or nominal values. The real one presents the values without inflation effects. The nominal one considers inflation effects and stands for the current value of products.

Considering real or nominal values, it is fundamental to define a reference year in order to calculate the present value according to the future values using real or nominal discount rates, respectively. For this case study, the real value has been chosen in order not to take into account the fluctuations in product costs.

4.3. Inflation Rate

The inflation rate indicates the variation in product prices. This rate is normally computed from observed variations of previous years. However, price fluctuation of previous years is not necessarily helpful to predict the future ones. Thus, the results obtained for the inflation rate can be highly debatable.

In terms of economic assessments, it must be defined whether one chooses to express the results in real value or in nominal one. According to the choice, the inflation rate is not taken into account.

4.4. Discount Rate

The discount rate is the expression of present value preference instead of future value. This discount rate can be drawn, as the inflation rate, from previous year variations.

In order to lower the uncertainties of this study, a set of different real discount rates were allocated such as replacements discount rate, maintenance discount rate and living tax discount rates.

4.5. Economic Data
The economic data related to the construction products and equipment, as well as the data regarding the energy and water prices, maintenance and replacements, end-of-life must be considered in the whole-life costing approach.

These data can be generic ones, possessing a degree of uncertainty, but, if available, they are specific data. In the French context, there is a generic economic database named Batiprix [13]. It is updated each year and contains data related to prices of each construction product and of each equipment, as well as prices of implementation.

For this case study, specific data were collected from the project team social landlord.

4.6. System Boundaries
The analysis considered the externalities, non-construction costs and the LCC, according to the standard ISO 15686-5 [10]. The LCC phases have been fully considered. However, no cost spent by the tenant is computed, meaning no energy and no water consumption costs during the use phase. Indeed, this case study is analysed in order to produce data to help the decision-making before refurbishment operation.

The costs included in this WLC are rent; externalities due to unpaid rent and vacancy rates; initial investment; cost of financing; planned replacements; planned maintenances; property taxes and end-of-life.

4.7. Economic Indicators
The standard ISO 15686-5 proposes the use of the net present value (NPV) or net present cost (NPC). This net present value represents the sum of all costs discounted for a reference year. The equation of NPV is presented below.

$$X_{NPV} = \sum_{n=1}^{p} \frac{C_n}{(1+d)^n}$$

Where
C is the cost of year n, q is the discount rate, d is the real discount rate per year, n is the number of years between the reference year and the occurrence of the cost, and p is the period of analysis.

Many studies consider the NPV as the economic indicator [5–7,14,15], but there is also some dealing with the future value [11,16].

The economic indicator used in this WLC is the NPV and the discounted payback time.

The discounted payback time is the time to recover the costs of investment in present values. In this paper, the payback time is calculated as the ratio between the initial investment and the net cash flow per period.

5. Results
The economic results computed from the case study details and methodology are shown in Fig. 2.

The values presented in Fig. 2 are relative values, for the sake of the landlord economic data confidentiality. The percentages are calculated considering the total rent as 100% and the corresponding percentage debts for initial investment, replacement, maintenance, property tax and end-of-life.

The whole-life costing includes the entire costs during the building period of analysis. Thus, some important economic hotspots are highlighted, such as, the maintenance and replacements costs, which represent 17% of the expenses altogether.

The costs associated with the end-of-life are very low, thus not clearly visible in Fig. 2. These costs regroup the aspects of demolition, transport and waste disposal at the end of the period of analysis, i.e. 50 years.

In order to complete the current analysis, a sensitivity analysis has been carried out and is presented hereafter.

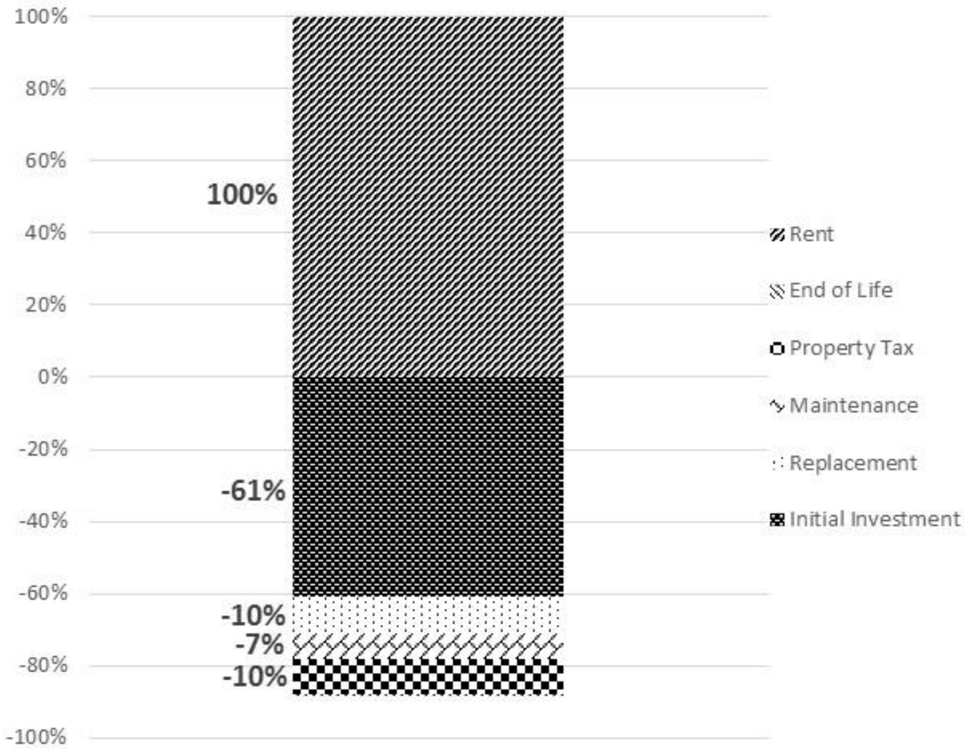

Figure 2: Relative Net Present Value according to different steps on the case study lifecycle (relative results are presented from top to bottom according to the legend)

6. Sensitivity Analysis

6.1. Period of Analysis

The building period of analysis for this case study is 50 years. In order to analyse the sensitivity of the results to this information, two other periods were considered: 30 and 80 years. All maintenances and replacements were then taken into account. No other extended new refurbishment was considered for the longer period. The results of this analysis are shown in Table 1. The relative values are all given in relation to the reference scenario (50-year-period).

Table 1. Analysis Results according to building period of analysis (reference period of 50 years)

Period of analysis (years)	NPV (%)	Discounted Payback time
30	-53 %	-
50	100%	41
80	180%	41

The 2nd result is as the reference and the others were calculated in accordance. The NPV of 30 years building period is negative and thus, the percentage is equal to (-) 53% of the reference scenario with 50 years building period of analysis.

The payback time is of 41 years for both 50 and 80 years periods. This 41 years payback-time is out of reach when the period of analysis is of 30 years.

6.2. Loan period

The variation of the loan period does not give very different NPV as can be seen from Table 2. The payback time varies from 35 to 45 years, depending on the loan period.

Table 2. Analysis Results according to Loan Period

Loan Period	NPV (%)	Discounted Payback time
15	137 %	35
20	100 %	41
25	61 %	45

6.3. Discount Rates
Discount rates estimations are drawn from past values. These rates are one of the keys to the assessment reliability. The sensitivity analysis considers variations of the following rates: loan, maintenance, replacement, property tax and rent. The results are shown in Table 3.

Table 3. Analysis Results according to Discount Rates

Discount Rate Values	NPV	Discounted Payback time
Loan Discount Rate		
2%	175 %	33
4.10%	100 %	41
6%	25 %	48
Maintenance Discount Rate		
0.5%	76 %	43
1.6%	100 %	41
3%	121 %	37
Replacement Discount Rate		
0.5%	54 %	45
1.8%	100 %	41
3.1%	131 %	37
Property Tax Discount Rate		
1.2%	79 %	43
2.2%	100 %	41
3.2%	116 %	37
Rent Discount Rate		
1%	329 %	31
2%	100 %	41
3%	-68 %	-

6.4. Rental vacancy and unpaid rent rates
For this case study, a rental vacancy rate and an unpaid rent rate of respectively 1.1% and 0.9% are considered. These rates are related to the attractiveness of the houses and the capacity to pay the rent. The house used in this case study is part of the stock of Maisons & Cités, which is composed of social houses and are occupied by modest families. The thermal refurbishments in the entire house stock are of importance to reduce the energy costs as much as possible. Indeed, the energy and water consumption costs are essential to determine these two rates

The results of these taxes variations are given in Table 4. A variation of +/- 0.5% gives a difference of +/-5% of NPV, but the payback time is almost identical.

Table 4. Analysis Results according to Rental vacancy and unpaid rent rates

Rate	NPV	ROI time
	Rental Vacancy	
0.6%	105 %	41
1.1%	100 %	41
1.6%	95 %	42
	Unpaid Rent	
0.4%	105 %	41
0.9%	100 %	41
1.4%	95 %	42

7. Discussion

One can notice the economic importance of the initial investment in this WLC. If initial investment was only considered as a matter of expense in the WLC, the social landlord will obtain almost 40% of the benefits from this operation. Contrariwise, if the whole-life costs are to be taken into account, this refurbishment operation project provides a benefit of about 13% of the rents in NPV.

The degree of uncertainty is higher for longer periods of analysis. Hence, the chosen period for economic assessment is not usually beyond 50 years. It could be observed that the discounted payback time is very important in this analysis, showing a beneficial situation or a non-beneficial one depending on the considered period of analysis. Considering 30-year-period, the building does not reach any payback on investment. On the contrary, for an 80-year-period, the payback time is equal to the one of 50-year-period. However, the NPV reaches 180%. The graph of cumulated NPV is presented in Fig. 3.

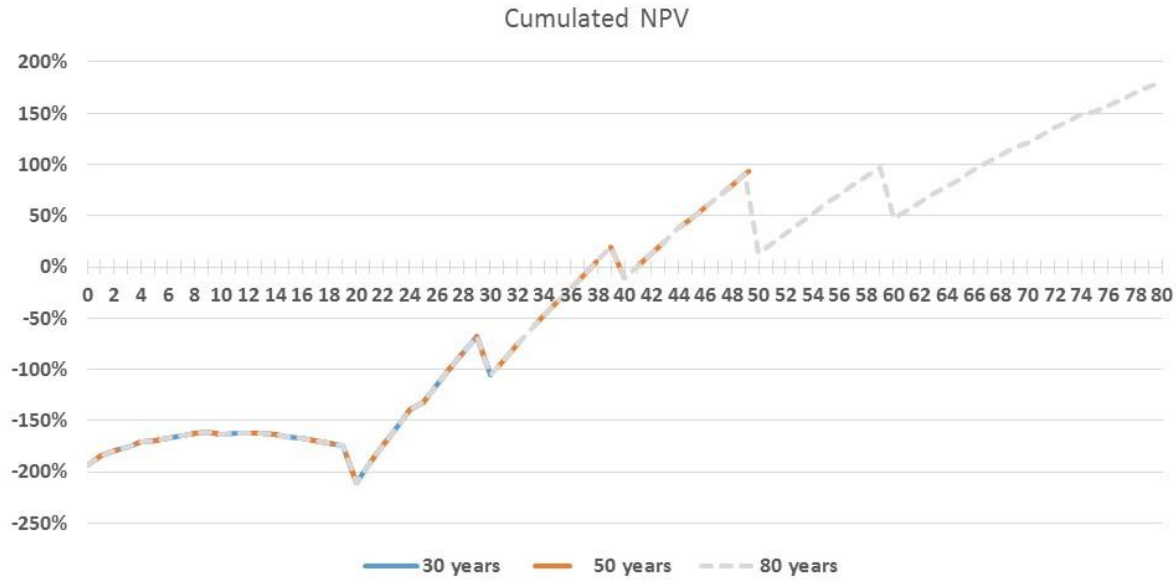

Figure 3: Cumulated NPV for 30, 50 and 80 years of period of analysis

The cumulated NPV presented in Fig. 3 is calculated as a percentage of 50 years cumulated NPV. Thus, for 50 years cumulated NPV it reaches 100% and for 30 and 80 years, the cumulated NPV is obtained according to the reference value.

Interestingly, it is more profitable for the social landlord to consider either a period of 50 years or a period much longer than 66 years. Indeed, the cumulated NPV after a period of 66 years equals the one reached after a period of 50 years. This is related to the planned replacements.

The sensitivity analysis highlights the importance of the rent discount rate. A decrease of 1% can result in + 200% of NPV results. On the contrary, an increase of 1% can result in no return on investment at all. Another important discount rate is the loan one. The fluctuation of this rate can result in a variation of + 75 % or - 75% of the NPV. The payback time varies accordingly. Hence those different rates must be chosen very knowingly.

8. Conclusion

This study discusses some methodological choices for building whole-life costing. It presents economic results of a typical refurbishment operation. It compares the results of WLC with the initial investment. Furthermore, it analyses the sensitivity of these economic results.

The corresponding results show the importance of considering the building whole-life costing instead of just the initial investment. While considering only the initial investment would give a very profitable operation, a whole-life costing presents lower returns on investment.

According to the sensitivity assessment, the dominating discount rate is the rent one. Its chosen value has the greater influence on the operation profit. The loan discount rate is important too. The results variation reached +/- 75%.

Attention must be paid to the choices of the different discount rates, as well as of loan period and lifetime period.

Next step of this project is investigating the case study eco-efficiency, based on those WLC results along with the corresponding LCA results.

A survey of private landlords in Karlsruhe and their perception of deep energy retrofit

Naber E[1], Lützkendorf T[2], Volk R[1], Schultmann F[1]

elias.naber@kit.edu

Abstract. Energy use related to buildings accounts for 35.3% of Germany's final energy consumption and nearly a third of greenhouse gas emissions. Thus, deep energy retrofit (DER) has a substantial role in the German energy efficiency strategy. Although many DER measures are economically viable, the pace of DER is below expectations and target value. A few studies investigated this phenomenon and conducted surveys mostly among owner-occupiers. However, 54% of the 40.5 million apartments in Germany are rented and a total of 15 million are let by private (not professional) landlords. Therefore, this investigation focuses on private landlords to find out what drives or constrains them to do deep energy retrofitting. A survey was conducted in a quarter of Karlsruhe, a large city in Germany with an above-average demand-driven real estate market. In this quarter, 83.2% or 8464 apartments are rented. 85 private landlords who own 10% of the rented residential buildings in the quarter responded and gave insight into their perception of DER. The results show that the buildings of the respondents originate from a construction period with large saving potential. Main strategies for investments in DERs are conservation of economic value of the property and the compliance with legal requirements. The main trigger is required maintenance. Despite an eco-friendly attitude, ecological criteria have a minor part in the DER decision. Finally, policy recommendations are made.

1. Introduction

In the strategic plans of the German government, the national building stock has a major role in achieving the goals of the German energy transition [1, 2]. These plans include several national milestones until 2050. Main goal for the national building stock is to reach nearly climate neutrality in 2050, which means a reduction of its primary energy demand by at least 80% compared to 2008 [2]. Currently, the energy use in the building stock is responsible for 35.3% of Germany's final energy consumption and most of the consumption originates from residential buildings (22.1% of Germany's final energy consumption) [3]. The latest monitoring report of the German energy transition, published mid-2018, states that the weather-adjusted final energy consumption in buildings increased by 4.3% from 2015 to 2016 [4]. However, since 2008 it has decreased by an average of 0.8% p.a. In order to meet the reduction targets, it needs to decrease much faster in the remaining years. Hence, further efforts are required in order to achieve the energy transition targets as quickly as possible [4]. The main challenge is the transformation of the existing building stock, as most of the residential buildings were constructed before first thermal requirements came into force in 1977/1978. Moreover, the pace of deep energy retrofit (DER) is below expectations and target value. Latter can be explained, as private owners have decision-making sovereignty over the majority of the building stock and many of them do not invest into deep energy retrofitting, despite many retrofit measures are technically feasible, increase comfort, can be economically profitable, contribute to other tangible and intangible factors positively [5, 6]. In order to tackle the challenge, generating knowledge about the perceptions, preferences and the respective decision-making processes is of high importance. These findings support policy makers in determining strategies to increase the DER rate. However, owners can have multiple roles at the same time (see section 2). For owner-occupiers many studies about the perception of DER exist (see section 3). Therefore, this study aims to relate the perception of DER to a given role. The focus group of this investigation of the perception of DER are private ("amateur") landlords. This focus distinguishes this study from others and forms the original contribution of this paper.

Furthermore, in the *Urban transition lab 131* research project (*www.iip.kit.edu/english/1064_2827.php*) the citizens of the Oststadt quarter of the German city Karlsruhe demanded an investigation of their building stock, its owners and tenants. Subsequently, several surveys and field studies were carried out in this quarter. A survey of private landlords forms the basis of this paper.

2. Brief overview of ownership structure and deep energy retrofit in Germany

Owners pursue multiple aims concerning their properties and have different capabilities. Furthermore, they can be owner-occupier and/or landlords of a property. Then, landlords can be subdivided into professionals and "amateurs" [7]. The importance of considering roles is illustrated for Germany in the following. According to census data from 2011, the ownership structure and the type of use of apartments in Germany is shown in figure 1 [8]. A closer look into the statistics discloses that about 54% of a total of 40.55 million apartments in the German residential building stock are rented. Thereof, 15 million are let by private ("amateur") landlords (for comparison in the EU about 30% of the apartments are rented [9]). Furthermore, the results of EU-SILC survey [10] indicate that the household ownership rate has a slightly decreasing trend or seems to remain static in Germany (e.g. the EU household ownership rate was at about 70% in 2017 [10]). Another investigation predicts an increase of ownership rate from about 45% to 50% by 2030 for Germany [11]. However, on a granular level the German statistics show considerable regional differences. Besides ownership structure, the apartment age or building construction period is of high interest for the analysis of DER [12, 13]. A comparison of the frequency distribution of construction periods of residential buildings and apartments shows little discrepancies [14, 15]. In the period 1949-1978 the average number of apartments per building is higher than in other periods [14, 15]. Which indicates that more and bigger multifamily houses were built in that period. The micro census of 2014 reveals that rented apartments are on average older than owner-occupied apartments [16], e.g. in Baden-Württemberg (the state of the investigation area) rented apartments are on average 4.5 years older than owner-occupied apartments and about 74% of the rented residential building stock was built before thermal and heating system regulations came into force (1978). That is about 10% more than owner-occupied apartments. These figures show the significance of considering the roles and for the case of Germany the importance to conduct private landlord focused research.

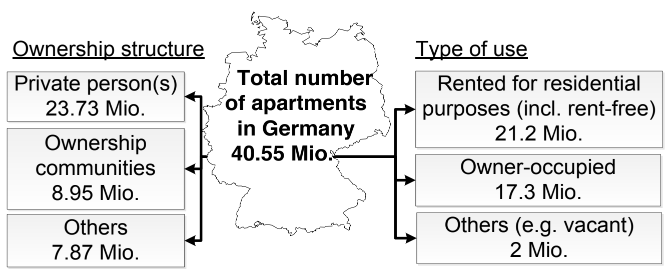

Figure 1 Ownership structure and the type of use of apartments in Germany (according to [8])

For assessing the progress in deep energy retrofitting, the respective annual rate is determined. The determination of this rate is complex, and approaches differ from each other. For Germany, the most cited studies compute insulation rate between 0.99% and 1.43% p.a. for the past 15 years for the building cohort built until 1978 and replacement rate of heating systems between 3.1% and 3.27% p.a. for the past 15 years for the same cohort [14, 15]. Nevertheless, the retrofit activity is limping behind the target values, which are twice as high. Besides favorable circumstances such as low interest rates and current real estate market conditions, other stimuli are set by the government to promote DER in the entire building stock. For new buildings, high requirements towards thermal insulation and heating systems are in force. For existing buildings, DER of certain building parts are mandatory and financial incentives are offered, as well as legal frameworks to mitigate burdens and drawbacks. Additionally, the replacement of heating systems with renewable heating sources is promoted via subsidies and requirements. Furthermore, informational instruments such as energy performance certificates (EPC) are used to raise awareness.

3. Brief literature review of decision-making of deep energy retrofit

The decision-making process and perception of DER has been investigated in several studies. Among others Friege & Chappin [17], Stengel [7] and Steinbach [18] present comprehensive reviews on modeling decisions of retrofit of buildings in the context of energy efficiency. Friege & Chappin [17] conducted a review using bibliometrics. Stengel [7] and Steinbach [18] reviewed relevant literature as part of their dissertation. These authors show that the parent topics are: technical options, modeling/simulation, policy/incentive instruments and understanding decisions. The following subsections briefly summarize three areas of interest, which partly complement the mentioned reviews.

3.1. Survey based studies of deep energy retrofit

More than 50 scientific survey-based publications can be found, which are related to energy efficiency measures in residential buildings and were published after the year 2000 (found via analyzing the Scopus query which yielded more than 620 results: TITLE-ABS-KEY(("Homeowner*" OR "Landlord* "OR "House Owner*" OR "Building Owner*" OR "Dwelling Owner*" OR "Apartment Owner*") AND ("Renovation*" OR "Retrofit*" OR "Refurbishment*" OR "Renovating" OR "Retrofitting*" OR "Refurbishing"))). The surveys have diverse approaches to study the subject matter. Some use official panel and survey data. However, due to limited consideration of items and attributes concerning retrofit, renovation or refurbishment of homes, many conducted own surveys. Most of them focus on owner-occupiers. Many of the reviewed surveys use convenience or random samples, which show a high heterogeneity of socio-demographic characteristics among the owner-occupiers and private landlords. For more insight please refer to [7, 17, 18] and to the query. As communality, most studies conclude that economic aspects are very important but not sole driver of DER decisions. The observed depth of DER activity is mainly based on economic trade-offs. For Germany, Albrecht et al. [19] created persona types of owner occupiers which are well established, often used and modified. More recent studies aim at combining survey results with agent-based models [20, 21].

3.2. Deep energy retrofit and landlords

Landlords are much less addressed than owner-occupiers. A reason could lay in the assumption of economic rational behavior, which seems likely. Another reason related to this void could be the challenge of surveying them. Official data about landlords is rare. Then, reaching them is not trivial and neither framing the survey. Many landlords do not reside in the rented building or in the vicinity of it. Therefore, questionnaires can fail to reach them. Additionally, the surveys need to isolate the behavior towards the building used by a third party. Otherwise, they can end up merging the general attitude with the specific attitude towards the rented object. Hence, generic surveys have pitfalls when considering multiple roles. Schätz et al. [22] conducted a survey among 1,354 landlords in Germany (2005-2006). According to them, the level of professionality can be determined by the quantity of owned apartments. They assume that landlords with more than 15 apartments are professional, who then act more rationally and economically effective (a similar differentiation is made by [23] for so called “micro”-landlords who own up to 20 apartments). Interestingly, 73% of their sample manage their apartments themselves or with the help of family members [22]. The most prominent motive for apartment acquisition is retirement provision and asset formation. In a subsample with landlords of buildings older than 1990, more than half of them rate their assets as in excellent condition (without any renovation needs). However, only half of the respondents are aware of energy efficiency requirements and nearly 70% will only make investments if absolutely necessary. In 2015 Renz & Hacke [24] interviewed 18 private landlords in order to verify several hypotheses and combinations of motives. Among others, a significant barrier to implement DER is the principal-agent dilemma. Concerning this dilemma, the legally permitted modernization allocation is regarded as a not realizable option. Another interview of 18 private landlords in Germany [25] provides insight in the investment behavior in DER in the context of low demand housing markets. The interviewees show a lack of knowledge concerning energy efficiency of buildings and have limited access to good-practice examples. In contrast they were well acquainted with negative reporting of DER. Investments are made to fix small problems/maintenance and can be triggered, if an increase of finding new tenants or keeping long-standing tenants happy can be expected. Accordingly, the interviewees stated that investments are driven by social responsibility and by an emotional relationship with the building or the neighborhood, rather than due to increasing profit. However, energy efficiency is not regarded are an essential asset or benefit [25]. A survey of >2,000 private landlords and members of a German homeowner association conducted by the association itself in 2017 states that the top four barriers for investments in their assets are: rent cap, tax burden, lack of subsidies and bureaucracy [26]. In contrast to the other surveys, this survey was not analyzed scientifically by its authors. However, it is the only one which covers private landlords which are part of an organized network. The variety of surveys show some commonalties, especially the lack of knowledge about DER and the principal-agent dilemma seems to be a main issue for landlords both in low demand housing markets or in well-organized landlord associations.

3.3. Principal-agent dilemma and deep energy retrofit

The principal-agent dilemma is a problem, which occurs when agents make decisions and take actions based on their interests, which impacts principals with contrary interests. For the real estate rental market this dilemma is called landlord-tenant dilemma. It can occur in several situations. Only the DER triggered problem will be presented. This problem forms a major difference between owner-occupiers and landlords and forms a main economic barrier for the latter. Alike other countries, in Germany tenants pay for their energy consumption. The energy consumption for space heating and cooling is dependent on the composition and quality of the building. Therefore, landlords have little incentive to invest into DER as they do not profit from lower energy bills, unless they raise the rent level which is not in the interest of the tenant. This makes it plausible that investments are mainly dedicated for value conservation or maintenance. In theory, there are many possibilities to overcome this problem [27, 28]. In practice, landlords in Germany profit from financial subsidies such as low interest loans and grants to mitigate the financial burden and the landlord-tenant dilemma. Then, rental laws allow for modernization allocations, which enable landlords to increase rents after DER. An important influence on the dilemma are the real estate market conditions. The profitability of an investment depends on the enforceable rent increase and low rent levels represent an obstacle. However despite currently expectable profitability, retrofit activities appear to be stagnating and only a moderate increase is expected [29]. Survey results show that private landlords are not familiar in solving this problem. For example, they do not bail out the legal possibilities of rent increase as professionals do and are not acquainted with DER [24, 30, 31]. Testorf et al. [31] conducted a survey (2009-2010) among owners who received support from subsidy programs and had a total of 5,797 respondents. 251 of them were enterprises and about 13.2% of the remaining private owners were landlords. In their study, they compared landlords’ rent level increase after DER. Professional landlords increased the rent on average by 27% whereas private landlords increased it by 10%. With respect to the specific investment per m^2, the increase is again considerably different between professionals (median is 18%) and amateurs (median is 2.5%). As causes for the discrepancies Testorf et al. identified legal uncertainties and market conditions [31].

4. Survey design and data

A series of paper-based, online questionnaires and experiments was conducted in the quarter of the "urban transition lab 131". The investigation area has a population of about 21,000 who live in 10,173 apartments (83.2% or 8,464 apartments are rented). The quarter features an above-average demand-driven real estate market, mixed use areas and mixed construction periods, but most buildings are built before 1978 (85%). For this paper, the main questionnaire of private ("amateur") landlords is presented. This questionnaire had two forms: paper-based and online. Depending on the number of assets in the quarter the questionnaire was designed to be completed in 30-60 minutes. For the purpose of this study, the share of private landlords in the sample is maximized. Hence, a variant of snowball and convenience sampling as nonprobability sampling strategy was chosen in order to acquire an adequate sample. Requirement for participants was being a landlord with at least one asset in the investigation area rented by a third party. Therefore, the largest local homeowner association was approached in order to ask for referrals to private landlords in their network. Finally, the questionnaire was distributed by mail to 655 private landlords who met the criteria and were members of the association. The questionnaire was scheduled from 20th May 2016 to 25th July 2016. 20 questionnaires were undeliverable. Additionally, 34 responded in order to inform that they did not match the criteria. A reconsideration of the sample by the association assumed that about 120-230 of the 655 private landlords would not match the criteria as they suspect an error in address pre-processing. Therefore, population size is assumed to be 450.

5. Results

The analyzed sample contains 85 fully complete responses of landlords. The online survey yielded 11 complete and 34 uncomplete questionnaires which can be interpreted as a quit rate of about 77%. The number of uncompleted paper-based questionnaires which were handed in is 11. Two of them commented on the uncomplete questionnaire (rough translation): "…that local agencies and politics are to blame for the unattractiveness of DER…" and "…that landlords are discriminated by the legal framework... ". 20 landlords have assets which they partly occupy themselves and rent out the rest. The remaining 65 completely rent out their apartments/buildings. The 85 landlords own 419 apartments in 93 buildings in the investigation area. 54 of the buildings are solely owned by the respective landlords. The remaining belong to an ownership community. The residence of about one third of respondents lays in the investigation area, about one third in the city Karlsruhe and about one third elsewhere.

5.1. Age, asset management and identification of basic environmental perception

70% of the sample are older than 55 and 37% are at least 66 years old. Gender is mixed. Concerning the responsibility for asset management, 63% manage their apartments themselves, 32% hand the management over to third parties and 5% hand it over to friends or extended relatives. A cluster of Likert scale questions concerning attitudes and other questions about ecologic commitments (such as donations and other ecology related activities) aimed at identifying the basic environmental perception. In a comparative analysis, milieus and lifestyles are assigned according to the range of observations in the sample. This analysis is based on the official environmental awareness survey of 2010 [32]. On the social scale of Sinus-Milieus the landlords in the sample range between mid and upper class. On the fundamental orientation scale the landlords range across all three classes (traditional, modern/ individualized and reoriented)[32]. A more granular analysis shows a good degree of conformity to several items in three Sinus-Milieus/lifestyles (Traditional, Social Ecological, Intellectual Milieu)[32].

5.2. Funding and investment planning

For maintenance and repairs, 54% of the landlords allocate funds in sinking funds or other similar dedicated reserves. The others fund maintenance and repairs from their general savings or with loans. 60% of the respondents do not dedicate any funds for DER related investments. The remainder dedicate savings in some extent, but only 11 consult experts for determining the amount. A hierarchical cluster analysis of the responses reveals a group of 25 landlords who do not use any particular financial performance indicator for evaluating investments in their property. The remaining 60 landlords form 16 clusters which can be assigned to two main groups. The first group focuses on tax-based evaluation of investments and the other on amortization assessment/recapitalization.

5.3. Motives, occasions, barriers
A total of 19 motives gathered from literature and interviews of landlords were tested in a Likert scale. Similarly, 14 occasions and causes for DER and 20 barriers were tested. Figure 2 summarizes the results of the three areas. For each area, results with the three highest and three lowest approvals are presented. For challenging the perception, some items were compared to objective data, e.g. energy performance certificate (EPC) values were compared to the perception of the energy performance of their building. In this case, the landlords highly overestimated the performance of their property.

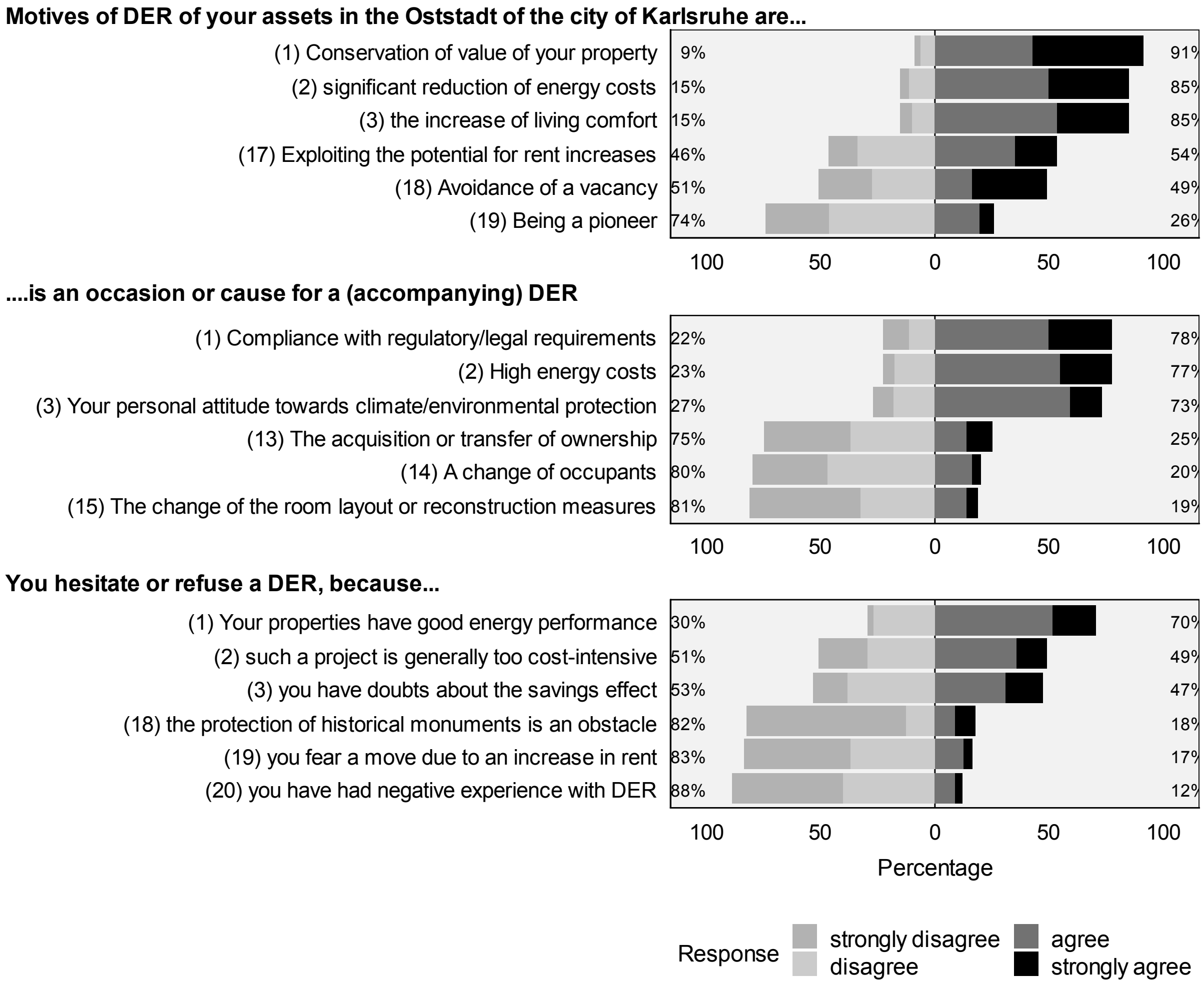

Figure 2 Approval of motives, occasions, barriers. Respectively, the items with the three highest and three lowest approvals are presented. N=85; top: motives; middle: occasions; bottom: barriers.

5.4. Experience with previous deep energy retrofit
More than half of the landlords made some experiences in the context of DER. The experience was assessed with four values: no experience, positive, negative and neutral. Figure 3 summarizes the results.

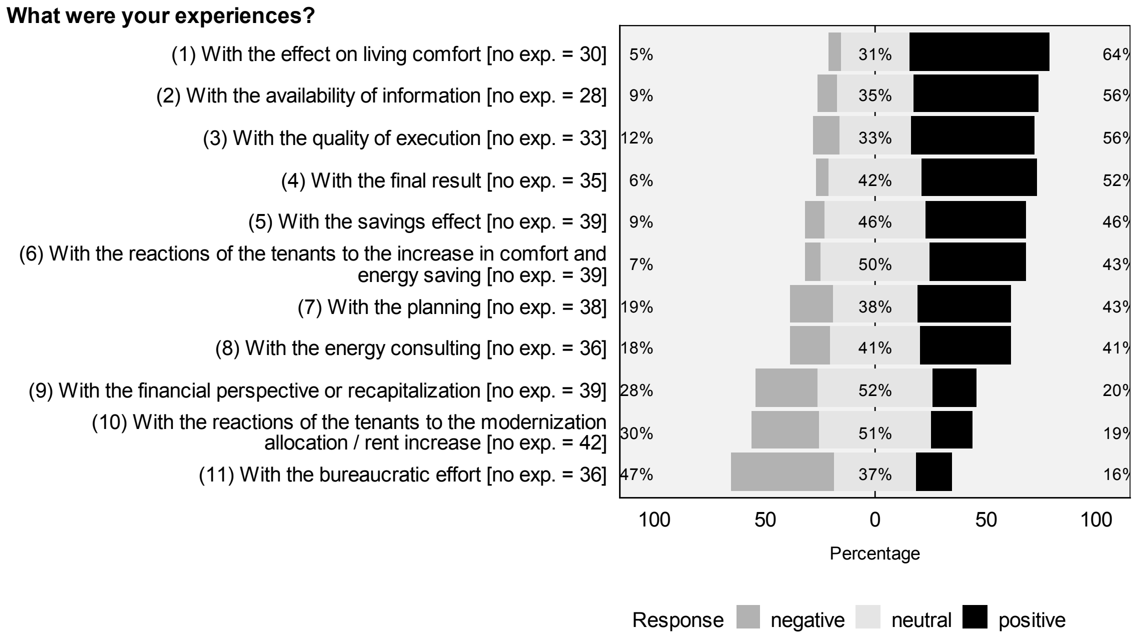

Figure 3 Experience with DER. N=85; no exp.= number of respondents without experience.

5.5. Channels of advice and information

The participants were asked who they seek advice from concerning their property on legal, financial issues and DER. They could choose multiple sources from a total of 25 predefined options. Figure 4 shows the sources with 30 and more mentions. Concerning legal advice, most of the respondents consult their homeowner association (who are professional lawyers). For financial advice, most landlords approach banks. For DER, no clear main information channel is used. The most frequently chosen channel is technical press. Internet sources and DER consultants are second. Real estate agents, neighbors and consumer advice centers belong to the least considered sources for advice.

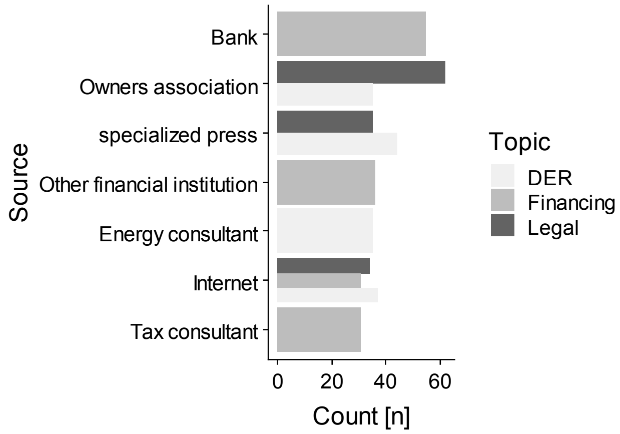

Figure 4 Sources of advice and information for the three topics of DER, financing and legal. The bars present and groupe different topics if a source has 30 and more mentions of the respective topic.

6. Discussion of the results

Despite the bias created by the sampling method, the interpretation of the results has some generic elements. Additionally, the design yields some specific findings about organized private landlords in demand-driven rental markets. A cluster-based analysis of presented and other results yielded six profiles. The communalities are aggregated to form a generic profile (cf. section 7). Concerning the demographics of the sample, the age spread and distribution is in accordance with other studies (e.g. [22]). Acceptable correlation between age and DER was not found, which is in accordance to Kastner

& Stern [33], who did not discover a clear pattern of correlation across several studies. In general, the sample has a positive attitude towards environment and climate protection. However, the identified milieus/lifestyles (personal attitudes) seem to have limited transferability to decision making behavior of DER of not self-occupied buildings, as ecological criteria have a minor part in the decision (cf. 5.1.-5.3.). The share of self-managed properties is comparable to the share determined in other surveys [22]. Those who transfer the management to professionals have a clear link between finance planning and maintenance-dedicated funds. This can be explained by the condominium act, which regulates administration and forming funds. In comparison to the survey on low demand rental markets [30], the motives and barriers shift as expected (figure 2), which emphasize the importance of considering the market conditions. The barriers for DER are mainly related to doubts about DER effectivity and to overestimation of the buildings' energy performance (figure 3). However, landlords should be sufficiently informed due to the mandatory generation of EPC. This indicates that EPC fail to achieve the informative purpose. The motive to exploit rent level increase potential by DER has one of the lowest approvals, which is in accordance with the observations of rent level increase after DER made by Testorf et al. [31]. This can be coupled to the legal framework, e.g. rent caps and uncertainty of enforceability, or to social responsibility or low familiarity and utilization of financial indicators (cf. 5.2-5.3). Noteworthy are the mainly positive and non-economic experiences after DER (figure 3 items 1, 3, 4, 6). The experiences made in preparation phase of DER (figure 3 items 2, 7, 8) show a split field. Landlord specific experiences which relate to the relationship to the tenants and the economic aspects show a considerably less positive experience. Overall, the experiences are mainly neutral or positive, which promises a potential to invalidate some barriers related to DER. The survey revealed a considerable deficit related to the information sources/access. For legal and financial issues, the information channels have a distinct expertise and the majority uses these as main sources. Specialists on DER are much less approached and most information on DER are compiled from technical press and the internet. This causes considerable issues concerning the perception of DER and energy performance, as two of the three most utilized channels for DER can be characterized as passive and not individualized.

7. Conclusion and policy implications

For reaching climate neutrality in the building stock, the importance of considering private landlords is evident. Despite good circumstances, DER implementation is behind expectations. The conducted survey revealed insights into private landlords in an above average demand rental market. In general, private landlords are characterized by their interest in climate and environment topics. They are motivated to save energy and convinced of the ecological advantages of DER. However, they doubt the promised energy savings. The main strategy for investments is conservation of property value and compliance with legal requirements. The main trigger for DER is maintenance. The building performance is often overestimated. Despite an ecofriendly attitude, ecological criteria have a minor part in the DER decision. Financial subsidies are the preferred type of financial incentives. In summary, four areas of policy improvement can be identified: economic incentives, markets, enforcement, lack of knowledge and awareness. For economic incentives, private landlords prefer grants more than subsidized loans. A large part of them focuses on tax-based economic evaluation. Even though tax deductibility of DER is possible, a combination with other economic incentives is not. Then, real estate markets are not reflecting the energy performance sufficiently. EPC fail their informative purpose and DER has no strong association with property value conservation. Adequate access to data about prices, rent levels and energy performance could improve this. Some DER measures are mandatory. However, these requirements are merely enforced. A stricter enforcement would raise awareness, responsibility and place DER higher on the agenda of legal and financial advice. In parts, simplifying bureaucracy could solve some issues of applying for subsidies or receiving professional advice. Concerning the lack of knowledge and awareness, better access to good-practice and DER roadmaps/EPC information could yield significant improvements, as well as the enhancement of public contact points and sources of information with dedicated DER experts. Finally, a higher focus of campaigns on landlords' and tenants' perspectives could raise awareness and mitigate the landlord-tenant dilemma.

New business models to support sustainable development: The case of energy-efficiency measures in buildings

Honold A[1], Lützkendorf T[2]
[1] Institute of Information Systems and Marketing, Karlsruhe Institute of Technology
[2] Centre for Real Estate, Karlsruhe Institute of Technology

anika.honold@kit.edu

Abstract. The German government has set ambitious climate-protection targets to limit global warming. The aim is to achieve an energy-efficient and almost climate-neutral building stock by 2050. This applies particularly to buildings, responsible for more than 20% of CO_2 emissions. The aim is to reduce the primary energy demand of buildings by 80% by the end of 2050. Achieving a nearly climate-neutral building stock requires targeted modernization measures that contribute to increasing energy efficiency. Barriers confronting the implementation of energy-efficient measures include lack of knowledge due to inadequate provision of information, lack of trust, and problems regarding financing possibilities. Therefore, solutions are needed for holistic concepts that make energy-efficient building and modernization more attractive. In addition to traditional business models (BM), measures that accelerate the implementation of energy-efficiency and BM that support the sustainable development of potential customers are sought. Expert knowledge must be shared to close information gaps; savings guarantees must be considered to build trust, and finally, financing possibilities must be available to support implementing sustainable measures. The research focuses on a modification of BM under the aspect of increasing energy efficiency in buildings for customers. This approach considers specific functions, effects, and benefits of BM. The aim of this extension is to create a basis for systematizing existing BM on the one hand, and on the other, to extend the proposed methodology. Finally, the developed guide supports startups designing new BM.

1. Introduction

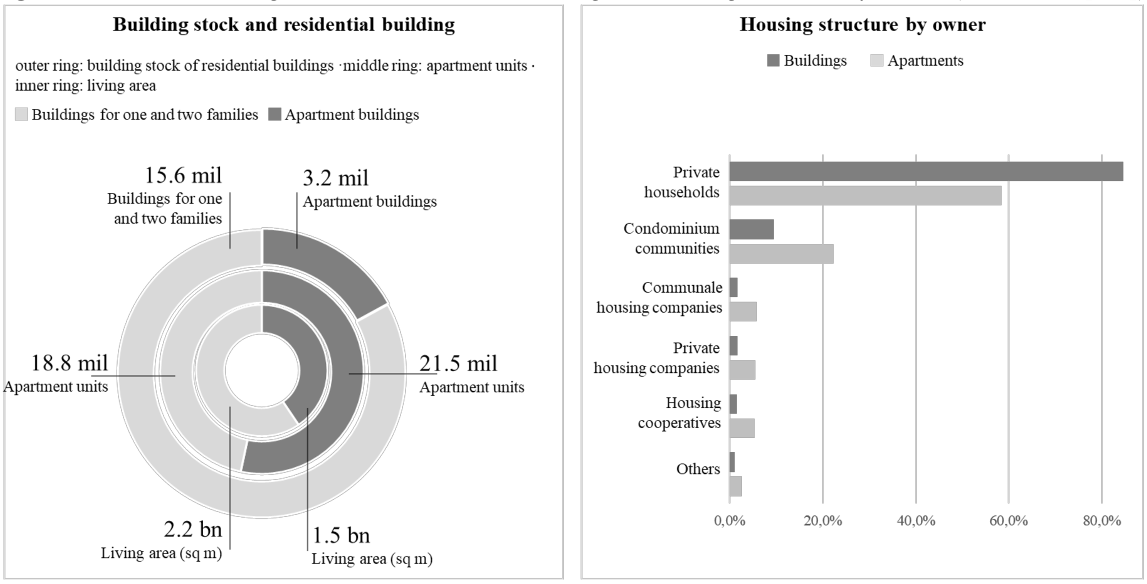
Today, the development of strategies for sustainable development is based on generally accepted goals, specifically, the Sustainable Development Goals (SDGs) [1]. One essential goal is the protection of the climate in ways that contribute to the conservation of natural livelihoods (SDG 13). With the goal of influencing production and consumption patterns (SDG 12), a solution applicable in the area of construction and urban development (SDG 11) is presented. Several countries are currently developing national strategies to improve climate protection. In 2016, Germany presented the Climate Action Plan 2050 [2]. It establishes the principles and targets for conserving resources by saving primary energy and reducing greenhouse-gas (GHG) emissions. Proposed solutions include reducing energy demand, improving efficiency, increasing the use of renewable energy, optimizing operations, using new products and technologies, improving methods and tools for design, and questioning demand (sufficiency). In addition to identifying areas of action—Energy Sector, Transport, Industry, and Agriculture—the plan formulates reduction targets for GHG emissions particularly for the area of action designated as Buildings. By 2030, GHG emissions in buildings are to be reduced from 1990 levels by 67%. For this action area, a budget of 70 million metric tons of CO_2-equivalent will be available in 2030. For the year 2050, Germany is targeting an almost climate-neutral building stock [2]. In order to achieve these medium- and long-term goals, the energy performance of existing buildings must be improved. Although an annual renovation rate of 2% is targeted, recent IPCC publications show that an average renovation rate of up to 5% is required to achieve the goal of limiting global warming to below 1.5 degrees [3]. In Germany, an annual renovation rate of less than 1% is currently being achieved in the field of energy-efficient modernization of residential buildings [4]. However, such data are controversial; clear definitions and survey methods for refurbishment and modernization rates are missing. Modernization rates for individual building components or parts of buildings are available in the literature [5]. It appears that current efforts are not sufficient to achieve the defined objectives, so possibilities must be sought to identify and overcome existing barriers to significantly improving energy efficiency in buildings. Private and institutional building owners currently do not have sufficient scope or willingness to take action that will speed up the modernization of existing buildings to improve energy efficiency. This raises the question of whether and to what extent additional incentives and/or complementary approaches should be pursued. One possible approach is the establishment and extension of new business models to improve energy efficiency in buildings. The authors of this contribution have undertaken a research project to investigate the potential for new business models, focusing on the following questions: (1) What is the condition of existing buildings in Germany with regard to their energy quality, and what is their ownership structure? (2) What barriers can be identified and assigned to actor groups? (3) What business model requirements can be formulated, and what approach to the systematization of business models can be derived from this (best needed)? (4) Which business models already exist, and how can their approaches be generalized or reused (best available)? Which hints and recommendations should business startups receive when they would like to contribute to the improvement of energy efficiency in the building sector with new business models? How can achievable economic effects be estimated? This article presents the first preliminary results in answer to these questions. Section 3 discusses major barriers; sections 4 and 5 present approaches for a typology and analyze existing BM. Section 6 provides information for startups. The basis for the article is a literature review, the authors' professional experience, and the results of discussions with experts.

2. Overview of the building stock of residential buildings and ownership structure in Germany

In Germany, the building stock is divided into 18.8 million residential buildings and 2.7 million nonresidential buildings (excluding industry). Nonresidential buildings account for 37 percent of total building energy consumption, while residential buildings account for the remainder. Figure 1 (left) shows the building stock of residential buildings. Those built before 1979, when the 1st Thermal Insulation Ordinance came into force, are of special interest. In fact, this applies to 62 percent of residential buildings and 66 percent of residential units, whose share of final energy consumption is 68 percent [6]. The energy requirements of new and renovated residential buildings are significantly lower. The legal requirements for building construction before 1979 were significantly lower than after 1979. In addition, the current energy consumption of these buildings cannot be determined exactly, due to partial, complete, and multiple modernizations in the meantime. While the members of the organization *Bundesverband der Deutschen Wohnungs- Immobiliengesellschaften* refurbished two-thirds of its building stock (28.9% partially, 37.3% completely) in terms of energy efficiency, the documentation of modernization measures for the private housing stock is fragmentary [7]. The progress in energetic retrofitting of individual building components also varies considerably [5], substantially complicating the analysis of the energy consumption of these buildings.

The “Destatis report” of the Federal Office of Statistics in Germany on the stock of buildings and apartments shows that the supply of housing in 2011 is predominantly in private ownership (Figure 1). More precisely, private households possess 84.6 percent of residential buildings and 58.4 percent of apartments [8]. Private households are grouped as *owner-occupiers,* who use their residential property for their own needs, and *private landlords* (also known in Germany as “amateurs”). The share of homeowners is the proportion of owner-occupied residential units to all residential units. In 2014, this share was around 46 percent in Germany. Conversely, 54 percent of private households own apartments that they do not occupy, assigning this proportion to the group of private landlords. The second most common form of ownership is condominium communities (9.5 percent of buildings, 22.4 percent of apartments). These are owner-occupied properties and apartments eligible for allocation to the rental-housing market. Together, condominiums account for almost a quarter of the total housing stock. The remaining parts of the residential space fall into three forms of ownership: communal and private-sector housing companies and housing cooperatives (building share < 2 percent, residential share between 5 and 6 percent [4]).

Figure 1. German building stock and residential building and housing structure by owner (based on [6], [8]).



3. Overview of the barriers related to energy retrofit

Barriers are unwanted factors that slow down, hinder, or block a decision-making process. Various studies have already investigated the circumstances of the matter, subjecting influencing factors to refurbishment decisions and removing barriers that arise during energy-related refurbishment (cf. [9-17]). Table 1 shows the identified barriers (see lines A-K), whereas columns 3-10 check whether a barrier could be confirmed in the literature [10-17]. The most frequently occurring obstructions are explained as examples here. Often, financial factors (barrier type A) prevent an energetic refurbishment. For example, those affected by an alleged refurbishment measure may encounter limited financial possibilities [9], insufficient financial support, or an uneconomical refurbishment [10]. Limited financial possibilities imply a postponement of measures to improve energy efficiency [11,12]. Insufficient knowledge (barrier type B) results in those affected, on the one hand, not knowing about the need for renovation of their property [9,13]; and, on the other hand, being insufficiently informed about possible savings (e.g., heating costs, energy, CO_2) after a refurbishment. This is usually due to a lack of consciousness with regard to the issue of environmental protection, which often has the consequence that other aspects (e.g., economic efficiency, aesthetics, living area) have a greater impact on refurbishment design than energy-related aspects [13]. Time-related factors (barrier type E) also have an influence, whether because of the long period of un-inhabitability of the property [14] or the complexity and associated strain of various time aspects on the design and coordination effort [15]. The principle of the landlord/tenant dilemma (barrier type K) describes the interest of landlords in protecting their investments over the long term, but possible unwillingness to finance short-term costs. In addition, the tenant is reluctant to bear short-term costs, despite benefiting directly from the refurbishment and lower energy costs [11,12,18]. However, the investor could levy a modernization charge and a rent increase after an energetic retrofit, a potential disadvantage for the tenant if a disproportionate increase in rental costs to offset the additional expenditure is significantly higher than the energy costs saved.

Different strategies for select appropriate solutions to address the barriers may include government incentives, counseling programs, and regulations, as well as new technologies, which can be used to overcome them. Another approach is either existing or newly developed business models. This research paper examines business models as a solution to identified problems. Prospective business models could possibly contribute to achieving a modernization rate of more than 2 percent per year.

Table 1. Barriers confirmed in literature.

Barriers	confirmed in literature							
	Friedrich et al. (2007)	Jakob (2007)	Kesternich (2010)	Stieß et al. (2010)	Beilan et al. (2011)	Meyer et al. (2014)	Renz/Hack e (2014)	Vögele et al. (2017)
A Financing problems (e.g. no money, no monetary incentives, uneconomical)	✓	✓	✓	✓			✓	✓
B Insufficient knowledge (e.g. about possible savings and energetic condition)	✓	✓	✓	✓	✓	✓	✓	✓
C No discussion of the topic of energetic refurbishment (e.g. lack of knowledge about possible solutions)			✓	✓	✓	✓	✓	✓
D Lack of knowledge in the operating phase and operational optimization (lack of problem awareness, no need to refurbish)	✓	✓		✓	✓		✓	
E Time factors (uninhabitability of the apartment, lack of time for planning and coordination, etc.)	✓	✓	✓	✓	✓		✓	✓
F Underestimation or doubt of savings potential	✓						✓	
G Missing technical and satisfactory solution (e.g. loss of comfort, no holistic solution)							✓	
H Missing planning tools								
I Lack of reason for renovation (e.g. low price level of fossil energies)		✓		✓			✓	✓
J Architectural and constructional reasons (e.g. restriction by monument protection and other technical factors)		✓	✓	✓			✓	
K Investor-user-dilemma	✓	✓	✓	✓		✓	✓	✓

It is now possible to apply this table to the identified actors in the housing sector (see section 2). Then the question can be answered: which stakeholders are affected by which barriers? In essence, private households (amateur landlords, owner-occupiers) and communities of homeowners provide the most reasons for a lack of modernization measures and have major deficits in knowledge, financing, and trust.

4. Business Model—Basics, trends and typology

4.1. Basics and scientific trends of business models

The term "business model" is not clearly defined in literature. Where Osterwalder and Pigneur [19] describe a business model as the "rationale of how an organization creates, delivers, and captures values," Margretta [20] combines business models with the fundamental questions of a company (i.e., how a company can earn money with its business). Bieger and Reinhold [21] see a business model as the result of an analysis of existing and new combinations of business-model elements. Network-centric approaches to business models aim to link different types of stakeholders into a coherent system. This includes all types of stakeholders (e. g., customers, investors, employees, suppliers, partners) and, in particular, society and the environment [22,23].

Companies still have some uncertainties with regard to environmentally friendly strategies. However, research shows that the sustainability factor implies technological and organizational innovations that positively influence sales and profits [24]. In addition, there are positive side effects, such as environmentally friendly production, less use of resources, less CO_2 emissions, and more innovations [25]. The current literature contains numerous papers dealing with business models in the context of sustainable development [25-37]. An excerpt from that discussion can be found in Nidumolu et al. (2009), who describe the path to business models that support sustainable development. They outline in five steps the challenges a company faces on the way to a holistic sustainable strategy. Sustainable business models are the result of exploring new paths that can include ecological services, but also the restructuring of established paths that require modernization [25-27]. Concretely, concepts such as *Green Economy* or *Green Growth* emphasize the sustainable use of resources [28]. A similar aspect is taken up by the *Green* [29,30] or *Sustainability Business Model* [22,31]. Such models include the establishment of lower environmental impacts and a promising platform for innovation. Their focal point is a change of core business strategy (e.g., from selling products to selling service systems containing the product). Somewhat less specific but still relevant are general recommendations for business models on redesigning systems (e.g., minimizing consumption, maximizing the society's benefits, and avoiding waste, cf. [32]). These aspects are considered and classified into so-called archetypes. Different archetypes include different approaches (e.g., maximizing material/energy efficiency; adding value from waste; replacing renewable energy and natural processes; and providing functionality instead of ownership. Detailed descriptions can be found in [29,30,33,34]).

Economically successful technological innovation requires business-model design and implementation combined with careful strategic analysis [26]. Canvas—a business model by Osterwalder and Pigneur [19]—takes this aspect into account. It provides every business with a simple tool to describe and think through its processes. This architecture of business models typically contains and connects different dimensions—for example, in relation to customers, benefits, added value, partners, and finances. While previous research has generated concepts that include the ecological aspect in Canvas (e.g. [30] or *Value Mapping Tool* [34]), the *Triple Layered Business Model Canvas* (TLBMC) is a specific tool that is an extension of Canvas, combining topics such as innovation of business models, as well as sustainable and green business models [33, 35-37]. This extension adds an ecological and a social dimension to the model, the ecological extension of the TLBMC based on a life-cycle perspective on environmental impacts and benefits of products and services. Environmental impacts contain ecological costs based on performance indicators (e.g., GHG emission). Environmental benefits extend the aspect of value creation. Essentially, innovations are sought that reduce (increase) negative (positive) environmental and social impacts [30,33,37].

Although the current literature aims to integrate sustainable development into business models, it is essentially focused on the optimization of internal and organizational processes. Therefore, an approach is sought that aims to optimize customers' processes in order to create added value for customers, ecology, and welfare. A first approach links the sustainable business model to user-driven innovation. The development of a sustainable value proposition constitutes the core of a sustainable business model [38]. However, to this aspect, the externality of the business models can be added. The research approach in this paper follows one that defines business models in the context of supporting sustainable development (in this specific case, an energy-efficiency strategy) for the customer.

4.2. Functions, effects, benefits of business models to improve energy efficiency in buildings (EEiB)

The main function of an EEiB-business model (as defined by the authors) is to increase the energy efficiency of a building. Hence, in order to eliminate barriers that arise during energetic refurbishment, a business model requires certain functions that imply effects and benefits for the customer and for society. Table 2 shows the identified functions (A), effects (B), and benefits (C).

Functions of business models represent their basis. This could be the provision of innovative products and services, but also the development of concepts for the design and implementation of renovation measures, or approaches for the optimization of existing HVAC systems. The effect describes the result a business model can produce. With regard to a potential refurbishment investment, this characteristic represents the time-related advantage of an investment, the identification of savings potentials or guarantees, or the provision of knowledge. The benefit of a business model refers to ecological circumstances that the business model causes (e.g., saving GHG emissions or primary energy and the associated costs). The benefits essentially reflect environmental circumstances. The conceptual step that follows is the development of benefits around social and economic aspects (e.g., reduction of externalities, creation of jobs and partnerships, or integration of companies with different interest groups). Thus, a business model can be evaluated from environmental, social, and economic points of view. Together, these components represent the future value proposition of a company's range of products and services to its customers.

4.3. Introduction of specific business models

The range of business models that contribute to the improvement of energy efficiency in the housing and real-estate sector is constantly increasing. In fact, a recent evaluation of the accompanying research "Energiewendebauen" commissioned by Project Management Jülich indicates that the number of projects (PRJs) dealing with business models has more than doubled from 2018 to 2019. Accompanying research includes projects on contracting (28 PRJs), prosumer models (16 PRJs), and leasing (8 PRJs), but also on approaches such as crowdfunding or sharing economy (in total, 9 PRJs). In Table 2, five business models (partly based on the mentioned projects) are presented.

The selected examples show the approaches to complementary research mentioned above and set different priorities. While in Case 1, the EEiB business model focuses on a financing concept, other business models are based on product service systems or prosumer approaches. Finally, these business models are classified according to the systematization described in Chapter 4.2.

Table 2. Examples of EEiB business models

Case 1 EPC [39]: Energy performance contracting is based on a contract between an owner of a building and a service provider, which contains a guaranteed savings goal in relation to energy consumption or energy costs before the contract is concluded. The service provider receives a regular payment that the client can often finance from the saved energy costs. The contractor controls, optimizes, and maintains the systems with regard to the highest possible energy efficiency. Planning and operational optimization for lighting, cooling, ventilation, and/or heating installations remain in the contractor's hands.
Case 2 RRA [40]: The leasing of roof areas with simultaneous roof renovation is an example of sharing concepts. This model enables a refurbishment measure with a significant increase in the value of the property. The operator of the photovoltaic system receives possible subsidies and the current feed-in tariff by feeding the generated electricity into the grid of the local grid operator. In exchange, the owner of the roof area receives the agreed-upon payment from the operator. The amount of the payment for the roof is determined individually. In addition, a complete renovation of the roof is carried out for owners of large roof areas, such as large production halls and warehouses, commercial enterprises, and public facilities.
Case 3 SW [41,42]: The leasing of software includes the aspect that the supplier often retains ownership of the physical product. This is a subscription-based service that, depending on the rate, offers services in addition to basic applications. Software for operating and building technology may enable energy management of buildings. Efficiency potentials in highly complex building operation can be identified, and energy-saving measures can be implemented and controlled. Corresponding software service packages also provide online diagnostics, updates, cloud applications, or maintenance.
Case 4 FSM [43]: Full-service renovation packages include consulting, design, energy testing, renovation, quality control, commissioning, and financing. The concept of serial modernization of buildings differs fundamentally from previous refurbishment offers, in terms of lower costs, short refurbishment duration, attractive design, and functional and savings guarantees. This is implemented with elements such as 3D scans of the building, pre-assembly of all components, and quality control to achieve the Net-Zero standard.
Case 5 MS [44]: The decentralized generation of electricity from renewable sources or in a combined heat and power plant, often in combination with a tenantable-electricity approach (*Mieterstrom)*, is based on a prosumer approach (i.e., an energy consumer like a building also acts as an energy producer). Energy is preferably fed into the house network of the building and either directly covers the current energy consumption of the tenants living in it or charges a battery store. Only when the energy produced on site cannot be consumed is the excess electricity fed into the public grid. For owners of apartment buildings, these models offer the opportunity to reduce ancillary costs, become less dependent on electricity price trends, increase property value, and generate additional revenue. Tenant savings of energy costs is another advantage.

5. Classification and analysis

The classification and analysis aims to identify business models that increase energy efficiency in the construction sector and contribute to the reduction of greenhouse-gas emissions. The developed systematization refers to the identified barriers. The evaluation in Table 3 regarding functions, effects, and ecological benefits is based on the personal assessment of the authors. Development of the systematization with regard to further functions, effects, and benefits shown in Table 3 is possible. In the future, the list should be extended in both horizontal and vertical directions, with the aim of clustering similar models and uncovering future potential for new business models.

Table 3. Systematization of business models

	1) EPC	2) RRA	3) SW	4) FSM	5) MS	Addressed barriers*
A) Function	✓	✓		✓	✓	B, C, E, F
A1 Building inspection and energy audit	✓	✓		✓	✓	B, C, E, F
A2 Approvals from local authorities and applications for grants and subsidies		✓		✓	✓	A, B, J
A3 Analysis and diagnosis (energetic analysis)	✓	✓	✓	✓	✓	B, C, H, I, F
A4 Consulting, development, and selection of solutions and energy concepts			✓	✓		B, G, I, J
A5 Economic efficiency calculations	✓			✓	✓	A, B, F, K
A6 Financing concepts and aids	✓	✓		✓	✓	A, B
A7 Project planning				✓	✓	E, J
A7 Project implementation and renovation work	✓		✓	✓	✓	E, J
A8 Project management				✓	✓	E, J
A9 Quality control	✓		✓	✓	✓	B, D, F
A10 Operating the plant/facilities	✓	✓	✓		✓	B, D
B) Effect						
B1 Energy saving potentials	✓	✓	✓	✓	✓	
B2 Savings guarantees	✓		✓	✓	✓	
B4 Investment priority	✓	✓		✓	✓	
B4 Provision of information	✓	✓	✓	✓	✓	
C) Ecological benefits						
C1 Primary energy saving	✓	✓	✓	✓	✓	
C2 Reduction of greenhouse gas emissions	✓	✓	✓	✓	✓	
C3 Comfort gains for customers		✓		✓		
C4 Cost saving for customers	✓	✓	✓	✓	✓	
C5 Reduction of resource consumption	✓	✓	✓	✓	✓	
C6 Motivation to deal with the life cycle of a product/service	✓	✓			✓	
C7 Improved longevity and durability of products (upgradeability and repairability)	✓		✓			
C8 Recycling of materials						
C9 Change in consumer behaviour			✓			
C10 Active development and maintenance of existing value creation networks				✓		
C11 Promotion of efficiency	✓		✓	✓	✓	

*Barriers: A) Financing problem, B) Insufficient knowledge, C) No discussion of the topic of energetic refurbishment, D) Lack of knowledge in the operating phase and operational optimization, E) Time factors, F) Underestimation or doubt of savings potential, G) Missing technical solution, H) Missing planning tools, I) Lack of reason for renovation, J) Architectural and constructional reasons, K) Effort without direct benefit

6. Guide for Startups: Turning an Idea into a Business Model

If the development of business models seems complicated and ambiguous at first sight, a guide serves to develop and help in business-model selection. The path from an idea to a business model that improves the customer's sustainable process includes the key points summarized in Table 4. Ideally, when searching for and selecting a suitable business model, startups must consider four steps. In step 1, ecological, technological, and social developments result from the named techniques. These trends call for business models that support the energetic-refurbishment measures. Step 2 analyses the market and its participants. The focus includes identification of a suitable target group. For example, using the building and ownership structure from Chapter 2 for this study enables identifying the target group of private landlords. Subsequently, assessing for the focal target group the barriers confronting customers becomes possible (cf. chap. 3). Essentially, private landlords and owner-occupiers show considerable deficits in terms of knowledge, financing, and trust (e.g., [11]). A potential business model must take this into account. After designing a business model with the tools of Canvas or TLBMC, the business model must be specified (step 3). In addition, the functions, effects, and benefits of business models (see chapter 5) must be considered in order to counteract the barriers identified in Step 2. After identifying potential business opportunities, the business model with the greatest potential for overcoming the barriers must be selected. Finally, further steps (such as the preparation of a business plan and its implementation) must be initiated [45].

Table 4. Turning an Idea into a Business Model.

	To do	In detail
1	Have an idea or search for upcoming trends	Generate ideas using creativity techniques (e.g. brainstorming, mindmapping) and trend analyses regarding current developments in society, culture, state, law, politics, economy, technology, and ecology
2	Analyze all conditions and elaborate the idea	Analysis regarding market, competition, market potential, market trends; customers as well as their needs and barriers; strength-weakness analysis of all market participants
3	Identify potential business models	Model a business model using Canvas and TLBMC; take into account the functions, effects and benefits of business model
4	Select business models	Select a suitable business model and initiate the next steps (business plan, implementation, controlling, monitoring, and, if necessary, adaptation of the business model)

7. Discussion and outlook

Through the proposed systematization of business models, this paper offers an approach to linking the theoretical concept of (sustainable) business models with the problem of the barriers that arise during the energetic refurbishment. In addition, the identified functions, effects, and benefits have the potential to represent future value-proposition formulations for the customer. Companies and startups can use combinations of the identified systematization to design their own business model. A guideline for startups is also provided, to help startups on their way from an idea to an economical and ecological business model. Business models that focus on sustainable process improvement for the customer contribute to improving the energy efficiency of existing buildings. In addition, supporting overall solutions (e.g., a combination of consulting, design, and financing concepts) instead of individual solutions ensures a holistic approach to the barriers that homeowners face. The proposed systematization has its limits in terms of completeness. Therefore, carrying out studies that identify barriers by type of building owner and building (chap. 2-3) can extend this conceptual research. It is also important to broaden the systematization in chapter 5 to find patterns and gaps in business models. Future research may also address broad changes in political, social, environmental, and economic aspects. In addition, the aspect of potential conflicts of objectives that may arise among initiators must be examined. Intellectual property is protected knowledge and is only available to society at high cost. For example, to integrate analytical and diagnostic software into building services as a standard would require government intervention. With the help of patent races (e.g., an award system), the government has the opportunity to announce project goals, winners of these competitions receive a reward, and at the same time, the innovation becomes a public good. Furthermore, the state can offer training programs for startups. The systematization and guideline developed in this paper can inspire and help prospective companies to develop new sustainable business-model ideas.

Acknowledgement

This research has been supported by the Research College EnEff.Gebäude.2050, which is part of the project “EnEff.2050.Begleit” (FKZ 03EGB0006B) and financed by the Federal Ministry for Economic Affairs and Energy (BMWi). The authors would like to thank all members of the research college and Project Management Jülich for the support, and the BMWi for the encouragement. Additional thanks to Ingo Halbauer for his support.

Social housing energy retrofitting: Business Model and supporting tools for public administration

paola.penna@fraunhofer.it

Abstract. High refurbishment costs and uncertainty of the investment payback period account as the main reasons of low rate of energy retrofit of the European building stock. Moreover, assessing energy and economic benefits of energy retrofitting may result difficult e.g. due to the unpredictability of users' behaviour which may alter the effectiveness of energy refurbishment intervention. This paper deals with the question whether approaches exist, aimed at securing the profitability of energy retrofitting and at creating the market condition to incentivize the energy refurbishment on a large scale. The paper presents the operational tools, developed to support the public administrations along the entire retrofit process, and the Business Model (BM), structured to financially support the refurbishments by the energy cost savings. This tools and the BM has been developed for the South Tyrolean context, to promote the energy retrofit of the social housing building stock of the Autonomous Province of Bolzano. The results presented in this paper are part of the ongoing research project "KlimaKit", founded by operational programme European Fund for Regional Development of the Autonomous Province of Bolzano EFRD 2014-2020 – Investments in Growth and Employment.

1. Introduction

The European Commission [1], as well as the Intergovernmental Panel on Climate Change [2], identify the construction sector as the one with the highest potential in reducing energy consumptions and environmental pollution. According to the European Commission the CO_2 emissions of the residential sector should be reduced about 90% by 2050 [3]. Considering that the annual growth rates of new constructions is around 1.0–3.0% per annum [4,5], it means that existing building stock represents the main opportunity to save energy. For reducing the CO_2 emissions, the political measures of the 28 EU countries set to 2,5% the energy retrofit rate of existing building stock by 2020 and 5%-5.5% by 2030 [6]. Despite this, the renovation rates of residential buildings still remain relatively low, about 1% per year in most of the EU countries [5, 6]. In South Tyrol the trend is similar to Europe: more than 50% of the residential buildings were built before 1970 (Table 1) and the retrofit rate is about 1% (550 buildings per year) [7]. For this reason, at regional level, the objective for 2020 is increasing the overall amount of renovated buildings to 1,500 per year, namely equal to 2.5% of the existing housing stock. Some of the main barriers in investing in energy refurbishment are the high investment costs, the lack of information [8], the uncertainty related to payback time [9], lack of collaboration of stakeholders involved in retrofit process [10] and the wide variety of possibilities offered by the market [11]. For changing the dynamics of the market, a figure of a frontrunner is essential.

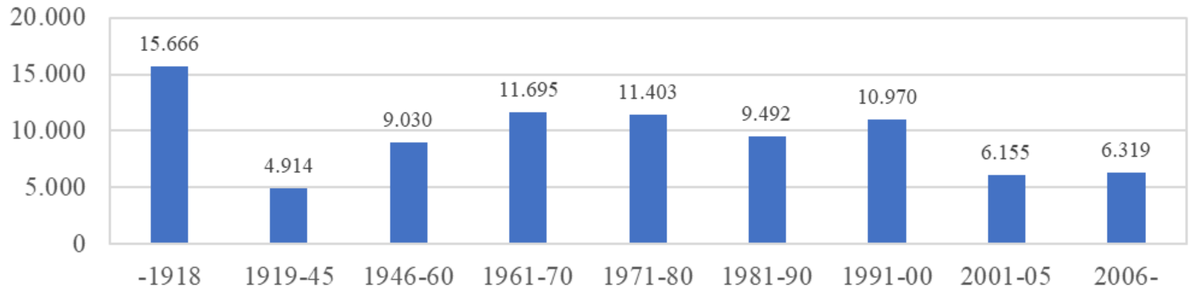

Figure 1 - Number of residential buildings by construction period (Source: ASTAT).

Social housing associations have a key role in mobilizing the refurbishment market, becoming an inspiring example for the private sectors. Once technical solutions and business models have been developed and tested on the social housing stock, it is much easier to penetrate the private housing market [12]. For this reason several studies [13, 14, 15, 16] and European projects [17, 18, 19, 20, 21, 22] deals with energy refurbishment of social housing. A promising strategy to promote the energy refurbishment seems to be the development of standardized retrofit solutions [23, 24], especially since social housing buildings are characterized by a typological and technological homogeneity [13, 14]. The definition of integrated packages of Energy Efficiency Measures (EEMs), developed based on representative building, allows take advantage of synergies between EEMs [8, 25] and improve the collaboration among stakeholders of building and energy sector. The idea of moving from one-off project towards standardized refurbishment packages with defined energy performance underpins the Dutch program Energiesprong [12, 26, 27]. By linking up home owners, skilled builders, financing institutions, housing associations, researchers and local government, it was possible to transform more than 100’000 home into net zero energy buildings. The basic concepts are the realization of the retrofitting works within 10 days and a 40-year energy performance warranty from the builder [28]. This retrofit concepts are combined with a Business Model (BM), which allows the financing of the refurbishments by the energy cost savings. The success of the BM is a key driver for shifting the model to large scale [29, 30, 31].

The paper presents the operational tools developed to support the renovation of the building stock of the social housing association of the Autonomous Province of Bolzano (IPES - Istituto Per l´Edilizia Sociale) and the BM defined to drive the changes of energy refurbishment market in South Tyrol. IPES is rather sensible to the topic of energy refurbishment and it is already involved in some important renovation processes, such as the European Sinfonia Project [17], which aims at testing urban-scale strategies for improving the energy efficiency of social housing stock [32, 33]. However, the major part of the social housing stock has not been renovated and still presents high energy consumptions. Section 2 presents the methodology used to develop the supporting tools and the BM. Section 3 reports the results of the analysis carried out to define the main critical issues of the energy retrofitting supply chain and the existing retrofit process. The supporting tools and the proposed BM are presented in Section 4. Section 5 identifies the limitations and the opportunities of the proposed solutions. Conclusions with the main recommendations and future development of the work are reported in Section 6.

2. Methods

The methodology used to develop the supporting tools and the BM for energy retrofit of social housing includes two distinct steps. The first step entail the systematic analysis of the management of energy retrofit process by the local social housing department. To this aim, the Director of the technical services Division and the Director of the west technical Office of IPES attended semi-structured interviews (approximately 60 minutes based on predefined open questions). The experts interviewed contributed to define the specific characteristics of the process, the main organizational challenges emerging along the entire energy retrofit supply chain and the different actors involved in each phase. The second step consists in a series of workshop, reported in Table 2, carried out to discuss the proposed solutions. The series of workshop was conceived as an iterative process where the experts validate progressively the results of the project, enabling the research team continuing the development and finetuning of the most promising concepts. The different stakeholders were not involved at the same time during the workshops, but they took part at the meetings where they are directly involved in the decision making process, in order to preserve high commitment into the project.

Table 1. Structure of the workshops

Workshop	Objective	Participants
Concept	Description of organisational structure First draft of the Business Model	Social housing department
Implementation	Benefit and role of actors Team requirements	Social housing department Energy service provider
Simulation	Market and legal scenarios Risk management plan	Social housing department Public procurement agency Tenants association
Validation	Supporting tools Business Model	Social housing department Energy service provider Public procurement agency Tenants association Companies

In the first workshop, a draft of the BM concept, formulated according to the information collected during the interviews, was presented to the social housing department. The BM has been compared with other national and international similar experiences. Through the second workshop, the implementation of the supporting tools has been proposed and discussed. Specific solutions and the stakeholders role were defined for each phase of the retrofit process. The third workshop provided concrete scenarios supporting the introduction of the energy retrofit model in the market. The legal aspects along the entire renovation process were also considered and discussed with the local public tender agency. During the final workshop the supporting tools and the validated BM were presented to the stakeholders involved in the energy retrofit supply chain, including different companies and suppliers. The different workshops, conducted between November 2017 and December 2018, consisted of presentation of preliminary results and open discussion moderated by research team, composed by researchers of Fraunhofer Italia and the Institute of Renewable Energy of Bolzano.

3. Findings of the Analysis

The systematic analysis of the existing energy retrofit process allows to identify the most critical aspects of the energy retrofit supply chain and the existing structure of an energy refurbishment project carried out by the social housing association. The main findings are reported in the following sessions.

3.1. Critical aspects of the energy retrofit supply chain

For each phase of the energy retrofit supply chain the most common problems have been identified.

- *Preliminary design.* During the preliminary design the requirements of the retrofit project are defined. In this phase, the most critical aspect is related to the choice among several option offered by the refurbishment market.
- *Designing.* The design project is entrusted to external professionals through a public tender. The choice of the reliable partners appears to be the most critical step because of the tendering process that it is not structured in a proper way.
- *Building Construction works.* In this phase it is noted a poor control over quality of building works. This aspect generates uncertainties in costs, timing and architectural quality.

- *Operational Phase.* In the current process, energy savings assessment and planning of maintenance of the building system are not scheduled. This lack generates uncertainty on the retrofit benefits and the malfunctions of the technical system are not prevent.

3.2. Existing retrofit process

Besides the critical aspects of the supply chain, according to the existing retrofit process a real BM for encouraging the retrofit process on a large scale is not present and all the incurred costs are faced just by the social housing association. As shown in figure 2, before the retrofitting, the tenants pay a fix rent to the IPES, calculated based on family income. The comfort conditions, as well as the condition of the building, are not taken into account for the rent calculation. An average estimation of this cost is about to 200€. In addition, the tenants has to pay for the energy supply of the utilities. This cost changes on a monthly base and it is managed and debited to the tenant by IPES, which acts as an intermediary between the tenants itself and the energy supplier. For exemplifying purpose, a cost of 150€ for the overall energy supply has been estimated. A total expense of 350€ per month for each apartment is collected by IPES from tenants. On the other hand, the social housing association takes care of the maintenance of the building and the heating system during the operational phase (estimated about 40 € per month). In this framework, since there is not a real planning of the management and maintenance of the building, the costs tend to be higher than it should be. Once the building has to be retrofitted (Figure 3), the retrofit is not structured to take advantages of synergies between different EEMs, but it often involves just some individual measures. The design phase and the realization work are entrusted respectively to external professionals and construction companies by means of a public tender. All the construction activities are supervised by the IPES technicians, which have to guarantee the achievement of specific standard of architectural quality. Based on IPES experience, a total cost for the energy retrofit of about 30.000€/flat has been estimated. This cost is entirely financed by IPES. According to this process, the only stakeholder that benefits of the energy refurbishment is the tenant, who pays less for energy supply and enhances indoor comfort conditions. The monitoring and the assessment of energy performances after retrofit are not planned and no guarantee of performance is due. This process is characterized by a fragmented supply chain, resulting in many difficulties in communication, planning and coordination.

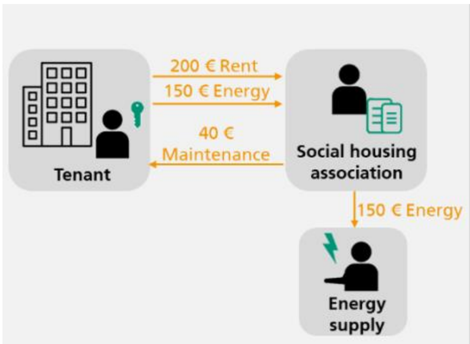

Figure 2 – Costs before the retrofit.

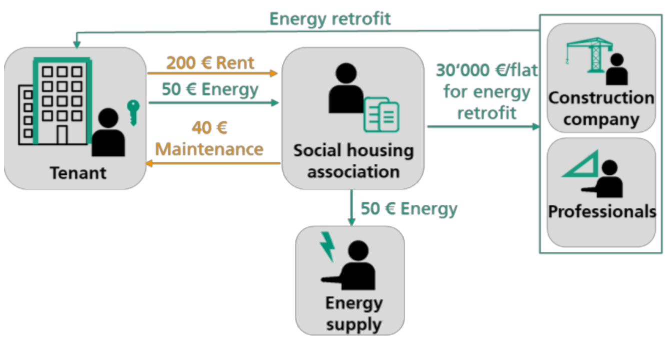

Figure *3* – Existing retrofit process of the social housing association IPES

4. Results

The series of workshop allows to define and validate the identified solutions to the critical aspects of the energy retrofit supply chain. During the workshop the BM has been developed based on the South Tyrolean context and according to the social housing association requirements and needs.

4.1. Supporting tools for public administration

To support the public administration and IPES during the refurbishment process, the following operational tools have been developed:

- *Building Analysis*: during the preliminary design a decision support tool can help in choosing among different EEMs, improving the awareness of decision makers. To develop this tool, the social housing stock of Merano has been analysed [34] and five reference buildings, representative of the building heritage, were selected. Based on the these buildings, five standardized retrofit packages with heterogeneous levels of certified energy saving performances, have been defined. By answering a set of questions, related to an existing building belonging to the South Tyrolean housing stock, the tool identifies the most similar reference building and, according to a series of drivers, recommends one of the standardised retrofit packages. Beyond the recommendations of the technological solutions, the tool provides a reliable range of information regarding the expected energy savings, the reduction of CO_2 equivalent emissions, the retrofit costs for the envelope and for the technical system and an estimation of the payback time of the intervention. The process development of the tool is presented in [35].
- *Soft Criteria:* The introduction of soft criteria into a public tender is a practical input to support the public administration in choosing reliable partners during the designing phase. Soft criteria should not be compulsory, but they should award professionals and building companies that include the following aspects into their offer. The first criterion is the warranty of building energy performances. In particular, the public tender participants should specify the method used to calculate the energy savings and the time-frame within this performance should be guaranteed. The second criterion is the application of a monitoring system for checking the indoor thermal conditions and the energy consumptions post retrofit. Especially in case energy savings are lower than the expected ones, it is important to define whether the responsibility belongs to the construction company or to the user behaviour. The planning of management and maintenance of the building and the building system is the third soft criteria. Planning these aspects is particularly important to prevent malfunctions and to avoid deteriorations of the system.
- *Building Information Modelling (BIM) Methodology*: In a retrofit project the use of BIM methodology leads to several benefits. First of all, during the realization phase, by improving the management of the building site, it increases the control on the quality of the realization. BIM allows also to create a database with all the information related to the retrofit project, for example the specification of construction materials applied to the building, the characteristics of the glazing or heating system, etc. This information can be integrated in a facility management system and can improve the management and maintenance process. Moreover, coupling BIM with the data coming from the monitoring system allows to easily visualize comfort conditions within the building and to detect malfunctions of the building energy system.
- *Contracts*: The relationship between the stakeholders involved into the BM has to be defined by contracts. It is particularly important for the application of the BM to regulate the relations between the social housing association and the energy supplier, as well as the relationship with the tenants. At this purpose, the guide line, for supporting both the realization of the building retrofit project and the following phase of monitoring and management, has been defined. By means of the consultancy of the Faculty of Law of the University of Trient, the regulatory framework, the main structure of the contract and the contractual elements, that has to be integrated into the contract, such as obligations, compensation, legal protection or duration, have been specified.

4.2. Business Model (BM)

The developed supporting tools facilitate the application of the BM. The idea behind the BM is similar to the one proposed by Energiesprong [12, 25] and used as a model by Energy Service Companies (ESCOs): integrating the energy bills of the tenants into an energy plan. This allows the social housing association to recover part of the retrofit investment cost by means of energy savings. The proposed BM is summarized in the schema below (Figure 4). The social housing association applies one of the standardized retrofit packages, able to optimize synergies among different EEMs. The investment cost related to each retrofit packages changes according to the package itself and to the level of energy performance, defined in each package. It varies from 15’000 €/flat to 40’000€/flat. Also the energy savings changes according to the package and the level of performance (from 50% until about 90%). For exemplifying purpose, an investment cost of 30’000€/flat and an energy reduction of about 80% have been considered. The soft criteria allow the selection of reliable partners for the designing and the realization phase. The entrusted professionals and construction companies apply the retrofit packages and a monitoring system, giving the warranty of energy performance and architectural quality of the realization.

After the refurbishment, the tenants continue to pay a fixed renting rate and a service fee. These costs are equal to the sum of the rent and the energy bills paid before the retrofit (350€ per month). The service fee (150€/month), paid as a fixed monthly fee, guarantees the thermal energy supply, for maintaining an indoor temperature of 20°C, domestic hot water and an electricity bundle for electric utilities. If tenants exceed that agreed amount of energy performance, they pay the additional energy consumption. In this way, since the energy costs are reduced, the energy savings allow IPES to recover some of the investment costs. The monitoring system provides information to tenants about their energy consumption and if the performances are not consistent with the estimated ones it provides the cause, whether it is behavioral or technical. On the other hand, also the social housing association pays a service fee to the energy supplier, for the management and maintenance costs for the building energy system. A regular maintenance of the system improves the system efficiency and permits costs reduction. This BM presents several benefits:

- It allows social housing association to recover part of the investment costs for retrofit that can be one more time invest in other refurbishment project, spreading the refurbishment on a large scale;
- It protects the tenants to future energy prices;
- It defines a long-term customer loyalty between energy supplier and social housing association;
- It improves the collaboration among stakeholders, that should collaborate to create integrated solutions with warranty of energy performance.

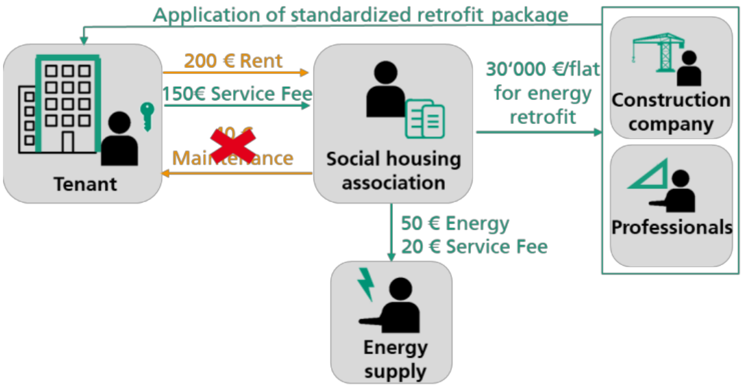

Figure *4* – The proposed Business Model

5. Discussion

The success of the BM is a key driver for shifting energy retrofitting of the existing building to large scale. In this paper some operational tools for supporting the application of the BM on the South Tyrolean context have been presented. The application of this BM has to face several difficulties, first of all, the agreement with tenants that normally benefits of the retrofit interventions without being charged of any renovation costs. In fact, IPES is not allowed by provincial legislation to increase the monthly rent after the refurbishment and this could compromise the feasibility of this BM. In this framework, the communication strategies pays a crucial role to make the tenants aware of the importance

of reducing the energy consumptions and to make them understand that even if they do not have an immediate reduction of the energy costs, they can benefit of enhanced indoor comfort conditions.
It is important to highlight that the identified supporting tools, combined with the BM, have been developed for the social housing association of the Autonomous Province of Bolzano, therefore, to extend the results on a national or European level, both tools and BM need some changes.

6. Conclusion

The paper presents some of the main outcomes of the KlimaKit project. In particular, it presents the methodology used to develop the supporting tools and the BM for supporting the social housing association of the Autonomous Province of Bolzano in promoting energy refurbishment in South Tyrol. A systematic analysis allows to identify how the process of energy refurbishment is carried out by IPES and the most critical aspects of the existing retrofit supply chain. By means of a series of workshop, the supporting tools and the BM have been discussed and validated by the main stakeholders. The idea behind the proposed BM is to integrate the energy bills of the tenants into an energy plan. This enables the social housing association to recover part of the investment costs for retrofit and to invest more in other refurbishment project. The application of an efficient BM is crucial in energy refurbishment project, because it allows to start a virtuous circle able to scale up the refurbishment on a large scale.

Effects of the tenants electricity law on energy system layout and landlord-tenant relationship in a multi-family building in Germany

Braeuer F, Kleinebrahm M and Naber E

Karlsruhe Institute of Technology, Institute for Industrial Production

fritz.braeuer@kit.edu

Abstract. Multi-family buildings (MFB) accommodate 53% of the German apartment stock. Although PV-systems on single-family buildings are widely implemented, the PV-potential on MFBs has barely been touched. Therefore, the German government introduced the *Mieterstromgesetz*, the tenants electricity law (TEL), in 2016. This law exempts electricity directly produced and consumed in a building from certain charges and taxes. Within the TEL framework, the landlord acts as the local electricity provider and can profit from selling electricity to the tenants and tenants can save electricity costs. This paper analyses the techno-economic effects of the TEL on the energy system layout of a MFB in Germany. Furthermore, it gives implications on how the TEL affects the tenant-landlord relationship. In this analyses, a MILP model is used to maximize the net present value (NPV) and determines the optimal layout and dispatch of the energy system. The model can choose to invest in PV, CHP and a battery storage system. Additionally, one to six electric vehicles (EVs) are integrated into the model. The novelty of this paper is the model-based analysis of the German *Mieterstromgesetz* considering EVs. The results show that the combination of PV and CHP is the most profitable system layout with NPVs up to 31.9k€. An optimized charging strategy increases the self-consumption rate and the NPV substantially compared to a fast-charging-strategy. Thus, the TEL can create a symbiotic relationship between landlords and tenants.

1. Introduction

The building sector accounts for a big share of the German energy consumption, which is mainly related to space heating and cooling. Thus, it is mainly regarded as an energy sink. Nonetheless, recent development in the sector of single family buildings (SFB) has proven that as a prosumer home owners can actively contribute to the energy transition process. By installing a photo voltaic (PV) system on their roof or integrating a combined heat and power (CHP) unit, they become an additional energy source. Nevertheless, this development is mostly restricted to single-family buildings. Although 53% [1] of German household units are set in multi-family buildings (MFBs), this potential energy source remains mostly untapped. To foster this potential, in 2016, the German government amended the *Mieterstromgesetz*, the tenants electricity law (TEL), which is regulated in the renewable energy act (EEG)[2] and the combined heat and power act (KWKG)[3]. The main goal of the TEL is to create a legal framework to increase the amount of locally produced and consumed electricity from renewable energy sources. Doing so, the law regulates and incentivizes landlords of MFBs to invest in PV-systems and CHP-units in their buildings and to operate as electricity provider for the tenants in a tenant electricity model (TEM). In this TEM tenants can voluntarily participate and directly consume the self-produced electricity in their building and can reduce their spending for electricity. According to TEL, landlords operating a TEM have to offer electricity to participating tenants at least 10% cheaper than the retail prices of the local basic electricity provider (BEP). As 52.4% of the German apartment stock is rented and about 80% of these are located in MFBs [1], TEMs might have a substantial effect on the future electricity mix in Germany. This paper evaluates the energy system of a MFB within the special framework of the TEL. It computes the maximum net present value (NPV) of the energy system from the landlord's point of view considering PV, CHP, energy storage technologies, a varying number of electrical vehicles (EVs) and the current legal framework. For applying the constructed model a MFB in Karlsruhe, Germany, built in 1978 and with 10 apartments is used. The results of this paper address the following questions:

(i) How does the TEL influence the optimal sizing and operation of an energy system in a MFB?

(ii) How do EVs and different charging strategies influence the profitability of a TEM and the layout of an energy system?

(iii) How does the TEL influence the tenant-landlord relationship?

To answer these questions, a mixed-integer optimization model (MILP) is implemented. The model maximizes the NPV of a landlord's investment and determines the optimal sizing and dispatch of the electricity generation and storage units. The analysis varies the number of EVs, charging strategy and the tenants' electricity price. Rent levels and building operation costs are not considered.

In the following, section 2 gives a short overview of the TEL and its economic framework as well as a summary of recent studies on energy systems modeling in MFB and landlord's investment decision processes. In section 3, the methodological approach and the optimization model are presented. Then, section 4 presents the model results and section 5 discusses these results and gives a critical reflection on the methodology. Finally, section 6 gives concluding remarks and an outlook on topics of future research.

2. State of the art

The TEL regulates that, if landlords operate the PV-system or CHP-unit, they act as an energy provider for the tenants. Landlords must provide electricity to a fixed price either directly-produced or coming from the grid. The electricity contract has a maximum run-time of one year and has to be renewed thereafter. Additionally, participation cannot be linked to the rental agreement, thus, participation in a TEM is voluntarily. The following requirements need to be fulfilled in order for a TEM to conform to the TEL.

- Self-produced electricity must be consumed in immediate geographical proximity.
- The public grid must not be utilized for the transmission of self-produced electricity for direct consumption.
- Electricity prices for tenants must be less than 90% of the price of the BEP

Conformance to these requirements enables to profit from the following subsidies:

- Exemption from grid fees, levies and taxes on directly-consumed electricity except the EEG-surcharges.
- A tenant electricity premium (TEP) is paid to the PV-operator for directly consumed PV-electricity. A similar premium is paid for direct consumption of CHP-electricity.

In scientific literature the TEL is investigated by the following authors. [4] and [5] give a compact overview of the TEL for PV-self-consumption. [6] present possible business cases and discuss the socio-cultural hurdles of implementing a TEM with PV-generation. [7] present the legal and economic framework for a CHP-use case. [8] present a comprehensive collection of studies on the TEL. Among the different articles, [9] elaborate on the political background of the TEL and discuss future developments. [10] analyses the profitability of a TEM utilizing a PV- and CHP-generator with a fiscal focus. A variety of scientific publications focuses on a model-based approach to study PV-self-consumption and CHP integration in buildings. A comprehensive number of studies analyzes the self-consumption of PV-energy in buildings. While most studies focus on SFBs, considerably fewer optimize the energy system in MFBs. [11] simulate the energy system for four different building types considering the PV- and heating installations. They focus on the increase in self-consumption and found out that the installation of PV on a large-residential building can yield higher returns on investment than smaller buildings due to higher self-consumption rates. [12] investigate the cost-optimal energy system of a new MFB in Germany. They apply a MILP-Model to identify the cost-optimal investment and operation of the system. They conclude that the installation of a CHP-unit and a PV-system is optimal as they complement each other. The high heat demand in winter and the resulting high electricity output of the CHP-unit correlates with low energy production of the PV-system, vice-versa in summer. Similarly, [13] formulate a MILP to determine the optimal size and operation of an energy system for heat and electricity supply. They model the German market and legal framework accurately but do not consider EVs nor a TEM.

[14] is identified as the only peer-reviewed publication mentioning the TEL. [14] study the electricity self-supply of a MFB with non-subsidized PV-electricity with and without an energy storage in Austria and Germany. The authors use a multi-objective MILP approach to minimize electricity cost and maximize self-consumption. Furthermore, they investigate the tenant-landlord relationship for different values of the weighted average cost of Capital (WACC). The WACC considers increase in operational cost and rent. While [14] raise an interesting research question, they do not apply their model to the specifics of the German TEL TEL. Neither do they consider heating nor electric mobility. [15] present a comprehensive Excel-tool for a detailed description of the TEL regulations. With only minor flaws, the tool is suited to obtain a quick assessment of the profitability of individual technology combinations, while EVs are not taken into account. Nonetheless, one can observe deficiencies in scientific publications that properly asses the energy system of MFBs. Especially the influence of the TEL and EVs has rarely been studied.

Investment decisions in building service equipment such as PV, CHP, batteries with a service life of more than 15 years are considered long-term investments. These decisions are based on diverse economic objectives or management strategies and are set depending on individual preferences and building future prospects[16]. Apart of the economic expectations related to personal attitude or enterprise philosophy, other tangible and intangible criteria such as comfort, eco-friendliness and reputation can be decisive criteria[17]. However, actuarial return, payback assessment, NPV and visualization of financial implications are the methods of choice in building related investments decision-making[18]. From both perspectives of owner-occupier and landlords, an optimization of the NPV is regarded as adequate[18]. Despite the appropriateness of a NPV based approach, most of the identified studies do not maximize it.

Before encountering the decision-making situation, awareness and acquaintance with the TEL are perquisites. Then, motives and barriers trigger the decision making process. These can vary across landlords. For more details on motives and barriers in retrofit and for investments into building service equipment refer to [19, 20, 17, 21, 22, 23].

3. Methodology/Model

The model used to determine the energy system of the MFB is based on [24]. They developed an MILP model to identify optimal design and operation of the energy supply system of a residential building. The model calculates the energy flows in the system in an hourly resolution to match the households' energy demand for one representative year. For determining the optimal system layout and operation *NPV* maximization is set as objective and calculated over a time period of 20 years. The decision variables are energy flow, the size of the technological units and the binary variables for the operation of the CHP-unit as well as the differentiation between different remuneration levels. A schematic overview of the modelled energy system is given in figure 1. The model is implemented in Matlab and solved with the CPLEX solver.

For this paper, multiple EVs are implemented in the model and modelled according to [25]. The *NPV*

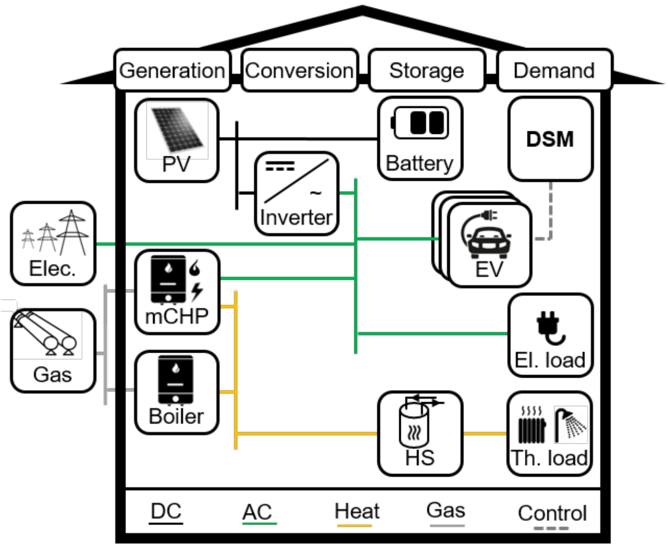

Figure 1. The modelled energy supply system (Elec:electrolysis, FC: fuel cell, el: electrical, th: thermal)

(equation 1) is the difference between the discounted investment (C^l_{inv}) and the discounted annual cash flow (acf). The investment for each technology l in equation 2 consists of an initial investment in the year $a = 0$, a discounted reinvestment after the calendar lifetime (clt) of technology l is reached and a discounted residual value after the considered investment period A. The annual cash flow is represented in equation 3. It includes a term for operation and maintenance, which is a percentage of the installed capacity (cap^l). Hourly electricity flows (P^t) are differentiated between electricity directly consumed ($P^{t,l}_{direct}$) and fed into the grid ($P^{t,l}_{feedin}$) for every technology l. The technologies considered are PV, CHP, a battery storage system and electricity from the grid. Therefore, the cost for directly consumed electricity $c^{l,a}_{direct}$ can be positive as in the case of PV or negative for the grid. Furthermore, except for c_{feedin} the electricity prices rise every year by a fixed rate r_{el}. Finally, the model considers variable costs ($c^{l,a}_{el,prod}$) due to electricity production ($P^{t,l}_{el,prod}$) as in the case of the CHP.

The specific costs and earnings for directly consumed electricity are further explained in equation 4, 5 and 6. Equation 4 shows the earnings for directly consumed PV-electricity. The landlords' earnings are compiled of the tenants' electricity price (c_{tenant}), a percentage of the price of the BEP (c_{basic}), and the tenant electricity premium(c_{TEP}). Their expenditures consist of the EEG-levy (c_{EEG}), value added taxes (VAT) and cost for metering and invoicing ($c_{M\&I}$). (The tenant electricity premium and the feed-in tariff are gradually reduced from a size of the PV-system smaller than $10kWp$, smaller than $40kWp$ and smaller than $100kWp$.) For CHP, equation 5 is composed similarly. There is a CHP-premium for directly consumed electricity (c_{CHPP}) and a premium for avoided grid charges (c_{AGC}). For electricity from the grid, landlords have to pay electricity fees of their electricity provider ($c_{landlord}$) and simultaneously sell the purchased quantity to the tenants for the TEM retail price (c_{tenant}).

$$\max NPV, NPV = -\sum_{l\in L} C^l_{inv} + \sum_{a=0}^{A} \frac{acf^a}{(1+i)^a} \tag{1}$$

$$C^l_{inv} = c^{l,a=0}_{inv} \cdot cap^l + \frac{c^{l,a=clt^l}_{inv} \cdot cap^l}{(1+i)^{clt^l}} - \frac{clt^l_{rem}}{clt^l} \cdot \frac{c^{l,a=A}_{inv} \cdot cap^l}{(1+i)^A} \tag{2}$$

$$acf^a = \sum_{l=1}^{L} -c^l_{O\&M} \cdot cap^l + \sum_{t=1}^{8760} (P^{t,l}_{direct} \cdot c^{l,a}_{direct} + P^{t,l}_{feedin} \cdot c^l_{feedin} - P^{t,CHP}_{el,prod} \cdot \frac{c^{CHP,a}_{el,prod}}{\eta^l}) \tag{3}$$

$$c^{PV,a}_{direct} = c^a_{tenant} + c_{TEP} - c^a_{EEG} - VAT - c^a_{M\&I} \tag{4}$$

$$c_{direct}^{CHP,a} = c_{tenant}^{a} + c_{AGC}^{a} + c_{CHPP} - c_{EEG}^{a} - VAT - c_{M\&I}^{a} \quad (5)$$

$$c_{direct}^{grid,a} = c_{tenant}^{a} - c_{landlord}^{a} \quad (6)$$

The assumed prices are based on the year 2018. The input parameters are shown in the appendix table 2. The building is assumed to be in Karlsruhe, Germany, TRY-region 12 (test reference weather year of the DWD). The building consists of 10 apartments with a total number of 38 occupants. The area of the roof is $176m^2$, the total electricity consumption per year without EVs is $44,666kWh$ and the total heating consumption is $92,517kWh$ for space heating and $27,208kWh$ for domestic hot water. The driving profiles of the EVs are derived from the German mobility panel[25]. For the analysis, the number of EVs is varied between 0 and 6 EVs. Additionally, the tenant electricity price is altered. The values range between 85% and 90% of the BEP price. The results are compared using the *NPV* for the landlords' and the discounted energy cost savings (ΔC_{el}) for the tenants' point of view for all households over the investment period. ΔC_{el} defines the difference between the electricity cost for a reference price ($c_{el,tenant,ref}$) and the energy cost for the TEM electricity price.

4. Results

Table 1 shows the model results for an increasing number of EVs. The upper part of the table shows results of an optimized charging strategy and the lower part results of fast charging strategy, where EVs are charged with its full power capability as soon as the EV arrives at the home charging station. The results show that the *NPV* increases with a higher number of EVs. More EVs lead to a higher total energy demand ($44.7MWh$ per year for zero EVs, *EV0*, and $51.7MWh$ for six EVs, *EV6*), which leads to a higher self consumption rate. The objective function states that directly consumed electricity generates higher profits than feeding electricity into the grid or buying it from the grid. The effect is most visible comparing the optimized and fast charging strategy. In the optimized strategy, the model has a certain amount of freedom to decide when to charge the EV. Therefore, it shifts many charging periods into high PV- and CHP-production periods, resulting in up to 13% higher self-consumption rates for the optimized case compared to fast charging. In the latter fast charging case, the model has no freedom to decide on the EV charging periods. Furthermore, only in the cases of four or more EVs and optimized charging, it is profitable to install PV-systems bigger than $10kWp$. Above this threshold, the feed-in tariff decreases from $0.122€\backslash kWh$ to $0.1187€\backslash kWh$. The higher investment for a bigger PV-system is only feasible when the self-consumption rate increases substantially. In contrast in the fast-charging-case, the self-consumption rate increases only slightly and no PV-system greater than $10kWp$ is installed. On the other hand for six EVs, the installed CHP-capacity in the fast-charging-scenario is greater than in the optimized-charging-scenario. This can be explained through the overlap of charging-periods and heat-production-periods. Noteworthy, in none of these cases does the model install a battery storage system.

Figure 2 shows the discounted cash flows for the investment period of the respective energy system component over 20 years and the resulting *NPV*. A shows the optimized charging strategy and B shows the fast charging strategy, both for six EVs and 90% of the BEP price. The figure shows that investment in a PV-system by itself is already profitable. However, a TEM with both a PV-system and a CHP-unit creates a higher NPV. The figure shows that the highest expenditures and returns are generated by the CHP-unit. The earnings from CHP are divided into a thermal and an electric component. The operational costs for heating from CHP are passed on to the tenants. The model dimensions the CHP-unit to maximize the directly consumed electricity and reduce its feed-in. This can bee seen in the difference from graph A to B. In B, the optimized charging of the EVs reduces the fed-in electricity of the CHP to zero.

In the presented scenario, electricity consumed directly from the grid generates a positive cash flow. This is explained by the positive difference between tenants electricity price and grid purchase price. Due

Table 1. Results for multiple EVs and a tenant electricity price of 90% of the BEP price. The upper results show an optimized charging strategy and the lower results a fast charging strategy.

to economies of scale the landlord is able to obtain a lower grid purchase price than the respective tenant would be able to negotiate for his sole purchase quantity. At prices below 87% of the BEP, landlords have to spend money. Nevertheless, the financial burden for the landlord is minor.

Figure 3 shows the results of varying tenants' electricity prices in percentage of the BEP price for the 10 participating households with 6 EVs. The solid and dashed line indicate the landlords' NPV of the optimized charging strategy and the fast charging strategy respectively. The dotted line indicates the discounted electricity cost saving(ΔC_{el}) of the tenants, optimized and fast charging. In case of fast-charging, at around 88% the NPV is almost as high as ΔC_{el}. Increasing c_{tenant}, the investment is more beneficial for the landlord than for the tenants and vice versa. If tenants would agree to charge their EVs in an for the landlord optimized manner the NPV of the landlords would rise while ΔC_{el}would remain the same. In the optimized scenario, to reach a state where the NPV and $\Delta C_{el}$are equal, c_{tenant} would need to be reduced to 87%. In this state, the NPV is still higher than following a fast-charging strategy at c_{tenant} of 89%. The findings emphasizes the symbiotic relationship between landlords and tenants.

5. Discussion and critical reflection

The results show that for MFBs PV-systems and CHP-units are complementary technologies. This is in line with findings of [12]. Under current prices, the installation of a battery storage system is not profitable. Simultaneously, integrating EVs in the system leads to a higher energy demand, which increases the profitability of the TEM. When the demand increase coincides with a higher degree of demand flexibility, as for the optimized charging process of EVs, even greater NPVs can be reached. For this case, it is more profitable to install more PV-capacity than a greater CHP-unit. The heat demand constrains the capacity expansion of the CHP-unit. Furthermore, the results show that the profitability depends strongly on the self-consumption rate. This rate depends on the electrical load of the households and eventually on the EV-charging pattern. Therefore, assuming perfect foresight and a representative load profile offers a high degree of uncertainty. Moreover, the financial risk of landlords for buying electricity from the grid is low. As a result, the highest risk is in over-sizing the technology dimensions resulting in low self-consumption rates. Additionally, the findings emphasizes the symbiotic relationship between landlords and tenants. Usually, these parties are trapped in an principal-agent dilemma (landlord-tenant dilemma), which is based on opposing interests. The results show that a reduction of the tenant electricity prices would increase the electricity cost savings for tenants. This could be an incentive for tenants to follow an optimized charging strategy. Ultimately, this could lead

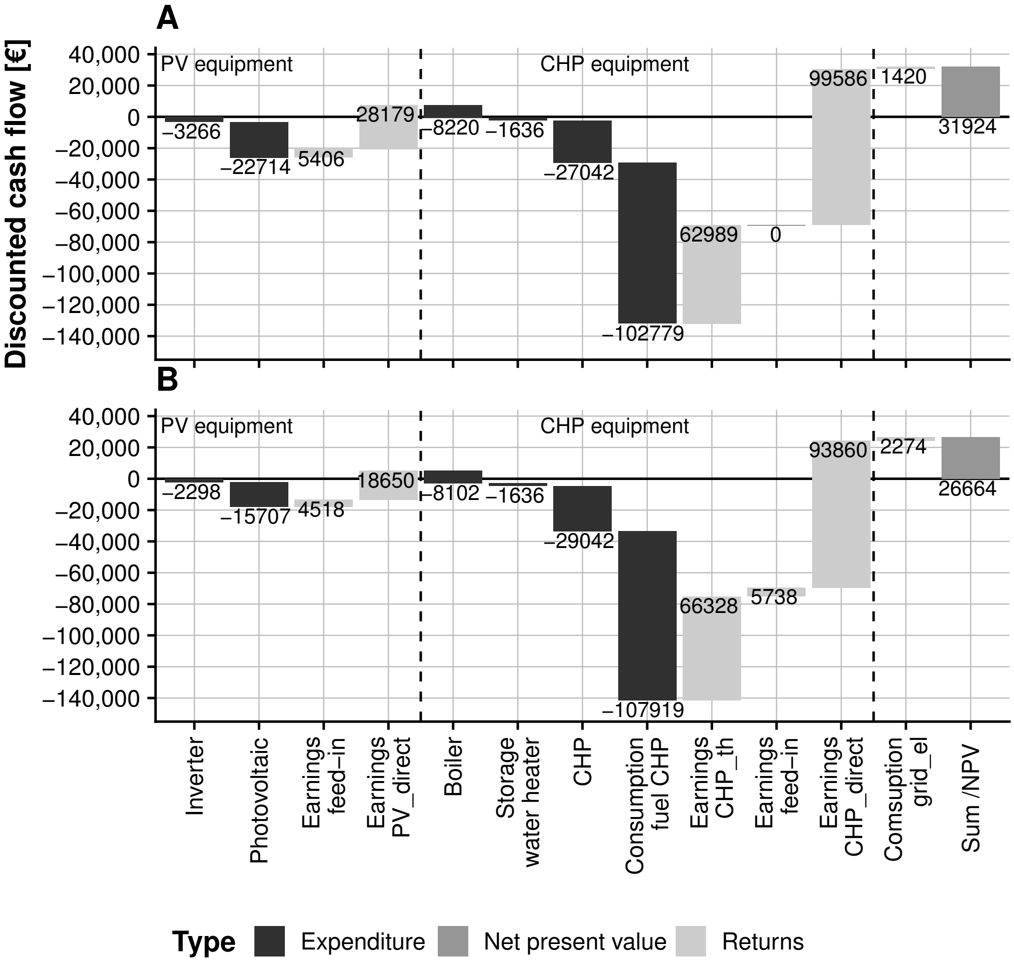

Figure 2. Discounted cash flow and *NPV* sorted by system components and operation (six EVs, $c_{tenant} = 90\%$). A shows optimized charging strategy, B shows the fast charging strategy.

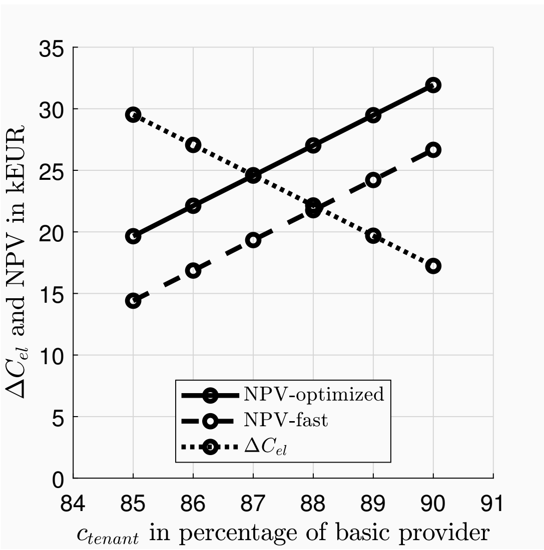

Figure 3. NPV and ΔC_{el} for 6 EVs for varying c_{tenant} in percentage of electricity price of the basic provider. Shown is the case of optimized charging and fast charging for six EVs. (The lines are for graphical understanding and do not resemble model results.)

to an increase in the NPV, electricity cost savings and CO_2-mitigation. The current installation rate of PV-systems that participate in a TEM in Germany since 2017 is constant. The total installed capacity is $9.74MW$[26]. It seems that awareness and acquaintance with the TEL is the most prominent hurdle for its successful implementation. While this contribution considers solely the NPV, a more detailed insight into other economic performance indicators could reveal different effects. Finally, some of disputable assumption and constraints of this study are mentioned in the following. For the analysis all tenants participate in the TEM continuously over the investment period of 20 years. Then, landlords profit from scaling effects and acquire electricity to better conditions than tenants. An electrical and heating load of one year is used, as well as driving and charging behavior of EV-owners. The EV-charging infrastructure is given and integrated into the MFB's electricity grid. No additional grid charges are considered.

6. Conclusion and outlook

With their high energy demand, MFB are well suited to make a substantial contribution to the German energy transition. The newly introduced TEL incentivises landlords and tenants to increase the self-consumption rate for directly produced electricity from PV-systems and CHP. This paper investigates the optimal energy system for a MFB that applies a TEM. The objective is to maximize the NPV for landlords considering a varying number of EVs. The EVs are charged with an optimized or a fast charging strategy. Additionally, the tenant electricity price is varied between 85% and 90% of the BEP price. For future studies, one should apply a holistic approach that includes heating and building refurbishment. The results indicate that he profitability depends strongly on the heat driven dispatch of the CHP-unit. Additionally for general applicability of the results, future studies need to consider different building types, construction ages and renovation states. They should focus on different locations, varying PV-potential, different electric load and heating load resulting in a alternate CHP-potential. Furthermore, investigations should be conducted that consider the variety of decision making techniques for investors in the building sector. Finally in order to properly assess the tenant-landlord relationship, other factors as rent and operational costs need to be included.

Abstract. Achieving the UN sustainable development goals, construction industry shows a great potential. Since 50% of the total resource consumption and 40% of the entire energy demand in the European Union are caused by the construction sector, procurement processes indicate a crucial starting point improving sustainable construction. Currently, organizations struggle with implementing sustainable procurement processes. Missing information on sustainability issues can be stated as an important problem in the sourcing procedure. Consequently, interactions of planning processes and sustainable procurement represent a fundamental topic. To investigate the current situation on procurement especially in Austria, an expert survey has been carried out. Therefore, a set of three central research questions has been elaborated that could be evaluated by a detailed survey. Based on the detection of relevant stakeholders, by means of a standardized online-questionnaire the implementation of life cycle-oriented sustainability issues has been surveyed. The contribution is going to illustrate the current situation of lifecycle-oriented planning, awarding and tendering of construction works in Austria. Furthermore, deductions were made based on the results of the survey, indicating action areas and presenting future potential of the application of building information modelling.

1. Introduction

Fighting climate change is one of our main contemporary tasks. The United Nations stated 17 sustainable development goals to adopt 'The 2030 Agenda for Sustainable Development' [1]. Several of these goals emphasize the importance of construction and building industry in this context. For instance, goal number 7 'affordable and clean energy', number 9 'industry innovation and infrastructure' along with goal number 11 'sustainable cities and communities' and the overall target of goal number 13 on 'climate action' are further linked to construction activities. Approximately 40% of the global energy use is related to buildings as well as 50% of the resource consumption can be linked to construction activities [2].

1.1. Sustainable procurement and sourcing

After determining the requirements for a future building and stating the demands based on its usage, the procurement stage begins on how the conceptional design should be developed further in what specific contractual arrangement. Procurement sets up legal boundaries, based on the specific conditions within a project is going to be developed. Thus, the procurement process represents an important starting point for implementing sustainability issues. Therefore, over the last few years several initiatives on European and national level targeting public responsibility have been published; cf. COM 96 (583) final and COM 98 (143) final. Focussing on the integrations of environmental aspects in public procurement the European directive 2004/18/EC supports the awarding of contracts based on the most economically advantageous tender. Following this approach, specific criteria have to be provided, supporting the decision-making process during the awarding stage, to reach the goals of a sustainable development focusing on a life-cycle performance. Supporting sustainable sourcing, the European directive 2014/24/EU enables such a procedure by empowering a more life-cycle orientated perspective in terms of highlighting specific awarding criteria.

1.2. Role of public authorities

Public procurement especially indicates a main driver for implementing sustainability aspects into the sourcing processes of construction services. Due to market size and the potential related to public contractors, the public sector should lead the market and influence the private sector towards a more sustainable building supply chain. But focusing the practical implementation a different view arises. The current procurement process within harsh and competitive market conditions is characterized by a strong focus on emphasizing financial issues.

2. Methodology

Investigating the current situation and getting a better understanding of the challenges on public procurement, sustainable sourcing in construction and building industry an expert survey has been carried out, focusing the current situation in Austria. Therefore, a set of three main research questions has been elaborated:

- What's the situation of sustainable procurement and sourcing of construction works in Austria?
- What are the main requirements, to facilitate sustainable sourcing in the construction and building sector?
- How can data-information management tools like building information modelling support sustainable sourcing in construction industry?

To investigate and evaluated these main research questions an online-questionnaire has been developed. The aim of the expert survey was to use an empirical primary data collection, for generating valid data to understand the relationships of planning, tendering and awarding processes regarding the consideration of sustainability aspects.

2.1. Research design and questionnaire development

The questionnaire was developed based on previous explorative studies [3] [4] serving as an extensive question pool for the current survey. Additionally, a comprehensive literature review on sustainable public procurement has been conducted [5]. These measures have been part of a major research project at Graz University of Technology on sustainable design processes and integrated facades [6].

The questionnaire comprised five parts as shown in Fig. 1. General questions are covered in part 1. Part 2 focused on notions and concepts of sustainable and life-cycle orientated buildings. Part 3 targeted the design process. Part 4 concentrated on tendering and awarding aspects. Finally, part 5 considered the implementation of building information modelling in the context of sustainable building.

According to the classification of experts, the questionnaire was structured into three different paths (clients and planners, researchers and legal experts), allowing the participants to answer only questions related to their field of expertise and professional activity.

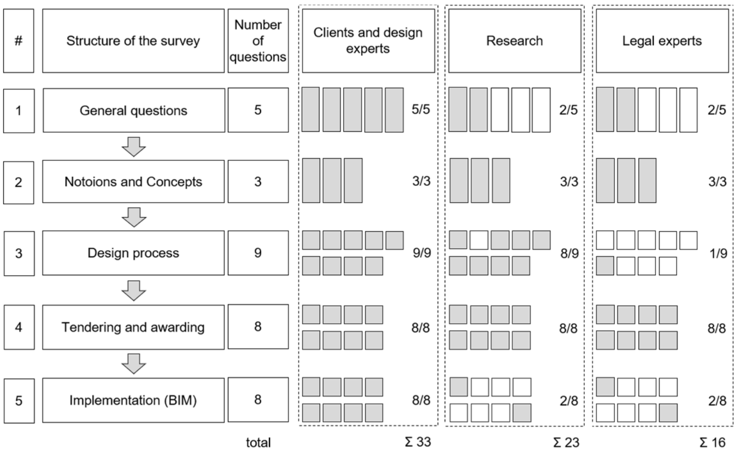

Figure 1. Structure of the questionnaire.

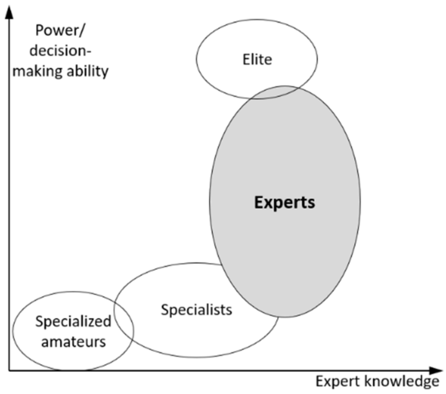

Figure 2. Definition of experts.

2.2. Selection of participants

Conducting an expert survey, it is crucial to identify appropriate participants by answering the following questions: Who is an expert for the specific subject area? Who got relevant information? Who is able and ready to provide and share this information? Experts can be characterized with many years of experience in a responsible and senior position related to subject-specific knowledge of the implementation of sustainable construction. Furthermore, experts are people with special knowledge, insights and information as well as contributing significantly to the decision-making process; illustrated in Fig.2 [7]. The chosen experts have been associated to the sphere of the client, representing the view of the contracting authorities and their agents.

The survey was conducted in April and May 2017. Overall 320 experts have been invited and 96 participated (in terms of complete replies to the questionnaire). The demographic information revealed that respondents could be classified into the following groups: public clients (30%), project controlling and management by clients (17%), designers (21%), researchers (10%), consultants and experts (12%), legal experts (5%), and the remaining 5% could not be assigned further. The respondents possessed 21 years of work experience in average. They majority of them is in an executive position (managing director, head of department, project manager) and all of them are involved in implementing sustainable construction.

3. Results

In the following section selected results from the survey are shown. Starting with general statements about the situation of sustainable procurement in Austria, followed by a closer examination of planning processes. Also, the level of implementation and the role of building information modelling is presented.

3.1. General statements on sustainable procurement in Austria

Despite the fact, that public authorities are addressing sustainability through a wide range of strategies and initiatives, the survey illustrated that implementing sustainable sourcing seems to be limited to individual aspects (e.g. energy efficiency) - an integrated holistic concept is often missing. That's because of insufficient consideration and implementation of sustainability aspects in early design stages. Referring to this, the survey showed, a prevalent application of sequential planning processes. Which means, each planner only focuses on his area of expertise, without taking contributions from others into account and not valuing possible interactions to improve a common project goal. As a result, only limited quantifiable issues and methods being used for sustainable sourcing. Establishing a sustainable sourcing process, awarding and selection criteria are key elements for sustainable procurement justifying the tendering decision, therefore the planning stages are crucial to identify such issues.

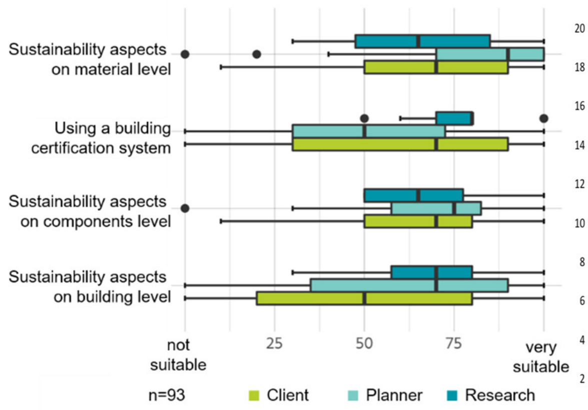
The current practical situation on sustainable sourcing can be characterized by considering sustainability issues mainly as individual ones without a common implementation and reference to the whole building performance.

3.2. Importance of the design process

Furthermore, the results of the survey showed, that the design process is very crucial for setting up the procurement process and providing evaluation and awarding criteria for sustainable sourcing. Based on various groups of experts, there is a different level of awareness, at which project stage sustainability issues should be considered. Planners need requirements and certain target values to consider these aspects during their design process. Clients have another perception, they seem less focused on sustainability aspects in early project stages, but when it comes down to the point of construction completion and commissioning, they are getting more aware of the future operational performance of the building including the life-cycle perspective [8]. However, the client is usually in charge of providing adequate information to define the specific qualities and quantities especially targeting the life-cycle performance of a building. Because without this input it is hardly possible for the design team to reach a certain quality level, when relevant information is missing.

3.3. Level of implementation of sustainability aspects

Trying to answer the question on what level sustainability aspects should be implemented, different views arise from the surveyed experts. As shown in Fig. 3, especially the planners would recommend implementing these aspects on material level. Using a building certification system is seen as a suitable approach by the group of clients and researchers. Building certification schemes as a comprehensive assessment method with a straightforward illustration on performance achievement (levels of certification depending on the respective organization range from bronze, to silver, gold and platinum) can support the communication of sustainable qualities easier compared to sustainability aspects on building level. This seems comprehensibly, especially according to the perspective of decision makers with limited knowledge on life-cycle orientated buildings.



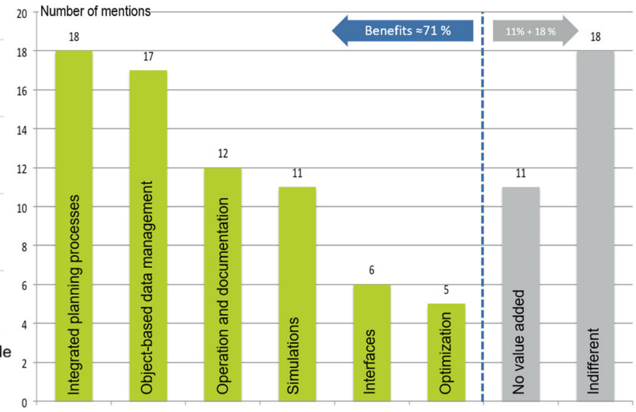


Figure 3. Implementing sustainability aspects. **Figure 4.** Benefits of using BIM.

3.4. Benefits of using building information modelling

Focusing on possible benefits of using building information modelling as a project management tool, the participants reported their expectations on improved integrated planning processes and a better object-based data management. Also, simulations and detailed coordination of interfaces are expected as benefits of using BIM as illustrated in Fig. 4. However, there are still a lot of responses reporting no real additional value or have indifferent opinions on using building information modelling.

4. Fields of action

Based on the results of the survey, specific fields of actions have been identified. In the following section three action areas have been selected and described in more detail:

- Information flow (interactions of planning and sourcing)
- Process-thinking and design
- Process support using data information management tools

4.1. Information flow

Missing sustainability aspects in sourcing of construction services are often caused by incomplete information flows between the planning and procurement stage. Improving consistency and enabling such interactions, it is crucial for the sourcing unit to understand not only the single requirements in terms of a specific label or evidence, but also the intended overall performance of the building with its elements.

The results of the study explored aspects on how procurement processes should be structured and suggested starting with the definition of requirement as a basis for the call for tender in earlier project stages to include the knowledge of different experts from the integral planning team. Applying systems thinking in such a context with consistent information flows, not only single improvements are possible but also a holistic approach can be targeted. Therefore, conventional sequential planning processes need to be considered in detail how to improve and structure interfaces for better information workflows [9]. This would enable a progressive value creating achievement as well as reducing additional expenses. Having a comprehensive knowledge on the targeted performance, improvements are possible when examining design alternatives. Collaboration in general is associated with a higher intensity of innovation.

Therefore, transparent information flows are required, which make it feasible to recognize the overall value and single contribution of each task. This helps to overcome insufficient information sharing between designers, contractors and suppliers. Doing so, process thinking becomes more significant.

4.2. Process thinking and design

Due to increasing complexity and interdisciplinarity of construction projects, especially if targeting and improving the life-cycle performance of buildings, the need arises to focus more on processes. Taking the building life-cycle performance into account, it is crucial, implementing user and operational requirements into early design stages, to allow the planners to consider these issues for a better building design.

Facilitating a holistic approach, various interfaces between the contributing disciplines and experts need to be arranged in a certain way, to maintain a value creating workflow. Therefore, several initiatives and research activities are performed to implement and improve process thinking, c.f. [10]. Additionally, over the last few years lean management principles from the production sector influenced the construction workflows. Starting at the construction site form operations planning and scheduling but focussing more and more on the detailed design and execution planning processes [11].

Lean philosophy concentrates on the elimination of all waste form a process, while targeting the maximum user value. From this point of view lean philosophy could be used as a control system to be implemented in sustainable building projects, improving the life-cycle performance of buildings. Both approaches (lean construction and sustainable building) are targeting the reduction of environmental impacts. Doing so, process thinking is necessary to focus on the value and further contribution to the overall performance. Especially if specific criteria are needed for the sourcing procedure awarding the contract.

Other helpful tools are building certification systems (e.g. BREEAM, LEED or DGNB/ÖGNI). They can provide guidance through the project workflow supporting the stakeholders to keep the overall performance in mind. Overall a collaborative workflow is determinant of the successful adoption of sustainable building.

4.3. Process modelling and visualisation (BIM)

Over the past few years digitalisation gained importance in the construction and building industry in terms of implementing building information modelling. Using BIM is expected to solve or at least reduce various problems like e.g. insufficient or missing information and poor collaboration. Still there are technical boundaries like missing connectivity and interchangeability of data and information. Based on the results of the survey, integrated planning processes and an object-based data management are expected benefits of using BIM. But to unlock these potentials, a common baseline of understanding the requirements and workflow is necessary.

Standardisation is necessary to communicate attributes and properties of building elements. There is the need of interchanging data and information on sustainable buildings, without any losses between the various stakeholders. Additionally, the properties should be interchangeable with possible suppliers fitting future requirements on e-procurement in the context of building information modelling.

Focusing on public clients, BIM should be encouraged by the government and industry to act as an information data management tool. Furthermore, transparency would be increased, supporting the information flows e.g. on building material properties, starting from the early drafts to contractors and suppliers. This would help to provide the right information to each project partner at the respective project stage.

5. Conclusion and outlook

Based on their market share and responsibility, public clients can act as a role model for several action areas on implementing strategies fighting climate change focusing the building sector. Thus, several strategies on procurement solutions are available, but their practical implementation seems to lag. Therefore, sustainable sourcing can be identified as a major issue to deal with the complex situation of supplying and purchasing in the building and construction industry, due to the various suppliers and trades involved.

Focusing on the current situation in Austria, an empirical study has been conducted. Experts in the field of sustainable construction have been queried with a standardized online-questionnaire comprised of five thematic categories: general data, notions and concepts of sustainable and life-cycle orientated buildings, design process, tendering and awarding procedures and the implementation of building information modelling.

The findings illustrate, that sustainable sourcing is currently based on single criteria or the use of building certification systems. Inconsistent information flows during the planning stages can be seen as a major reason for missing a holistic approach. A lack of incentives to adopt sustainable procurement in construction has been reported by previous studies [12].

Another result from the conducted study highlighted the importance of green procurement policies. Additionally, the need to open up the ‘golden triangle‘ of cost, time and quality to more comprehensive aspects and also targeting the life cycle perspective, taking into account the usage stages - not only focusing on the construction phase of the building.

This paper emphasized the relevance of interactions on sourcing and life-cycle orientated planning processes. Therefore, not only product/object-related aspects of construction works are important to focus, also process-orientated aspects need to be considered in more detail. Consequently, the design process needs to be targeted and arranged towards a better information flow. The main requirements are stated by the client in early design stages and the implementation of sustainability into the sourcing process is still limited to the willingness and capability of the client and how comprehensive his requirements are described in early planning stages [13].

Additionally, the responsibility of the involved stakeholder needs to be improved for stronger collaboration on the sustainability performance of a building. Facilitating such a performance-based approach, focusing the practical implementation of data-information management tools can be helpful. Therefore, BIM is just a tool, not bettering projects itself. In this context the clarification of a crucial baseline (definition of sustainable properties) and common project standards are necessary. Performance requirements can be communicated using standardized information with potential suppliers allowing them to adapt their solutions to the project specific requirements.

Further research is required on how e-procurement in context with building information modelling can support a more sustainable sourcing process [14]. But without a clear and structured workflow and a specific definition of the expected building performance at the beginning, their application doesn't seem effective. [15] Implementing sustainability starts with the know-how of all project members and a high level of collaboration.

rmeglin@hsr.ch

Abstract. Traditionally, gravel, cement and concrete producers focus on their role as material or resource suppliers. The higher the material turnover, the higher the economic success. Hence, the business-model conflicts with the societal goal of increased resource efficiency. Driven by stricter regulations, companies started to extend their business models with additional services in waste management and logistics.
In the research project "Co-Evolution of Business Strategies in material and construction industries and public policies" the most relevant business-models of gravel, cement and concrete producers in Switzerland are identified based on case studies of ten different companies. The analysis reveals how these business-models differ with regards to value added, resource consumption and CO2-emissions. To analyse the relevance of the different business-models on regional scale, an assessment model is developed based on Material Flow Analysis. It is used to analyse the value chain of construction minerals in an alpine region and its effect on value added, resource consumption, waste generation and CO2-emissions. A comparison between the results of both analyses – companies scale versus regional scale – reveals how alternative business-models could affect resource management and economic development on a regional scale and which types of business-models accelerate or hinder the transition towards a sustainable built environment. The study will show, that it is essential to identify alternative business models in the building materials industry and understand their impacts on the use of primary and secondary resources.
In this paper, we identify two business models, which, at first glance, seems identical as they produce and sell concrete and gravel, but show that the success of a business model highly depends on the source for raw-materials (gravel pit, river extraction or processing excavated materials with high gravel content), the possibility to landfill excavated material and the resulting effects on resource consumption.

1. Introduction

Traditional business models in the construction industry link economic success to material turnover. This promotes an inefficient use of natural resources and contradicts macroeconomic objectives, such as circular material flows and reduced material consumption. Decreasing construction activity and increasing competition among construction material companies provide a complex and challenging environment to these business models. Business model adjustments have been observed along the entire value chain, challenging a rather static industry. For example, building contractors become service agents in materials management of construction sites, and their turnover and profit will become more independent of the consumption of natural raw materials (decoupling of economic growth and resource consumption). This transition to a circular economy can be seen already on entrepreneurial level and regional scale in Switzerland, as an increasing number of companies focus on the preparation and use of secondary building materials. A dominant driver of this transition is the geographical and social limitation of access to natural resources, leading to fierce land competition among companies.

Yet, it is difficult to clearly differentiate between alternative business models in the Swiss building material industry. Today, a diversity of companies varying in size and degree of vertical integration can be found. Few large players with vertical integration dominate the market for concrete, ranging from the production of cement as well as concrete and aggregates. A number of innovative niche players are very strong on regional markets in urban areas with growing market shares. In recent years, some construction companies started providing material management as service on large construction sites including construction waste management, on-site recycling as well as concrete production.

- Can the success of alternative business models be explained by boundary conditions in the specific markets, in the regional supply of natural resources or incentives from public administration?

- If a business model is considered favorable in the transition towards a circular economy, can it be transferred from one region to another without losing its economic benefits?

- How does such a transition towards alternative business models affect regional resource consumption, emissions and value added on regional scale?

In the research project "Co-Evolution of Business Strategies in material and construction industries and public policies" we try to answer these questions by identifying the most relevant business-models of gravel, cement and concrete producers in Switzerland based on case studies of ten different companies. We analyze how these business-models differ with regards to value added, resource consumption and CO_2-emissions. In a second part of the research project we analyze how business model innovations can be encouraged by public policies to stimulate a transition towards a circular economy.

In this paper we present first results of our research focusing on two business models that we could identify and describe so far. The relevance these business-models on regional scale is assessed for a case study region.

2. State of research

2.1. Business-Models and transition management

In our research, we focus on the concept of co-evolutionary transition dynamics, which can be described as the developments within subsystems, influencing the development of a larger system. For example, co-evolution between science and technology, between culture and technology and between technology and society [1], or between institutions and technology [2], or between organisations and institutions [3] haven been researched. A number of studies presented empirical evidence for interdependencies between different societal subsystems, e.g. environmental regulation and the firms' competitive performance ([4],[5]), environmental taxation and resource management [6] or alternative business models (e.g. niche players) and mass market players [7]. For the case of construction materials, [8] and [9] showed the importance of planners and engineers as mediators between builders and construction industries for a transition towards resource efficiency. The importance of competing business-models in a changing regulatory environment, however, has not yet been analysed for construction material industries. We try to fill this gap in our research. In our analysis, we consider a business model as the articulation of a company's strategy [10]. Literature suggests that value proposition (product/service, customer segments and relationships); value creation & delivery system (key activities, resources, technologies, etc.); and value capture (cost structure and revenue streams)" form key components of business models [11]. Research on sustainable business models expand this traditional framework by including social and ecological value creation for an extended range of stakeholders [7].

2.2. Assessment of resource consumption, environmental impacts and value added

For the assessment of transition management in the built environment, defined as business environments for construction industries, material flow models are frequently used (an overview is given in [12]). These studies mainly focus on stock-flow-models of defined regions (e.g. Switzerland) [13]–[17], but also comparisons between nations or regions (e.g. EU 25) are available ([18], [19]). Yet, these models describe the underlying cause-effect only with coefficients related to the technical efficiency of processes involved (e.g. recovery rates). The main drivers of development are exogenous parameters such as rates of construction, demolition, or assumed correlations with socioeconomic parameters such as population number or GDP (e.g. [17]).

As a component of the analysis of material flows, Input-Output-Analyzes (IOA), in form of Input-Output-Tables (IOT) can be used in combination with environmental and economic performance indicators to form economic and environmental extended Input-Output-Tables (an overview is given in [20]). IOT, as a tool for analyzing interindustrial interdependence, have become the standard since the 1930's. At this time Wassily Leontief developed the first detailed IOT for the United States [21]. In the following decades the IO-Analyses have constantly developed. An overview of the developments of IO-Analyses gives [22]–[24]. Today IOT are used by most governments to carry out analyses of the respective national economy [25], [26].

This paper will introduce an assessment model for environmental and economic impacts in form of environmentally and monetary extended input-output-tables based on Material-Flow-Analysis (MFA). This method was first presented in [27] and is applied on scale of companies as well as regions.

3. Methods and Data

In our study, we identify and describe alternative business models combining methods from business administration as well as environmental and process engineering. In addition, we analyse a regional resource management system for construction minerals. In this section we present the methods used to collect relevant data.

3.1. Definition of criteria for classification and indicators

The analysis of business models is based on the definition of business models presented in [11] and complemented with aspects of research on sustainable business models [7]. For each company the following aspects are analysed:

Value proposition: It describes how the organization attempts to create the willingness-to-pay of its target group to pay for the offered product or services [11]. Furthermore, it describes the intended target audience, enabling evaluation whether the proposed value, relative to the company's competitors, is creating competitive advantage.

Value creation: Describing the operationalization of the company's strategy and internal value chain clarifies how the companies uses their resources and capabilities to create value for its stakeholders.

Building on aspects from research on sustainable business models, the attempt to satisfy a wider range of stakeholders, influencing consumption itself becomes a crucial aspect of corporate responsibility.

Value capture: Value capture completes the picture by examining how the company captures economic value from the consumer and the modes of transaction. Richardson (2008) highlights that economic value is especially dominant in traditional entrepreneurial literature, distinguishing between the economic and revenue model. In essence, the captured value from incorporating sustainability describes the "business case for sustainability", combining profits with positive impacts.

In addition, we analyse how each business model effects regional resource management systems, economies and the natural environment. To this aim, we define a number of indicators (see table 1). To compare different business models, we use each companies output (in tons) per year as functional unit, differentiating between two major product categories: concrete and aggregates.

table 1: indicators for the assessment

Indicator	Unit	Description
Amount of virgin gravel/sand extracted	ton per year	Most companies extract virgin gravel/sand from surface water or mine in gravel quarries. The rate of substituting virgin material with secondary resources can vary from company to company.
Amount of excavated material deposited		Excavated material is mostly used to refill empty gravel pits. In certain areas in Switzerland, however, the gravel content in excavated material is high enough to use this material as substitute for virgin gravel. In this case, natural resources can be preserved.
Amount of recycling materials used for producing construction materials		Crushed concrete and mixed construction waste can be used to substitute virgin gravel in the production of aggregates and concrete. A high content of these secondary resources the overall material input can indicate a transition towards a circular economy.
Value added	CHF per year	This value is used to indicate effects on the regional economy. It represents factor income generated by labour and capital on regional scale. For each company, this factor income is analysed for each process in the production chain (including internal transports) by subtracting material costs from material turnover, both estimated by multiplying material flows with material prices. Costs of electricity are only considered in cement production.
Global Warming Potential (GWP)	Kg CO_2 eq. per year	This value is used as indicator for environmental impacts. It is estimated for all processes in the production chain of each company including greenhouse emissions generated in the supply chain (e.g. for electricity production)

3.2. Collection of data

A case study with ten companies is used to determine the relevant business models. Each company covers a specific step in the value chain of construction minerals, ranging from extraction of primary materials, over processing virgin/recycling aggregates, producing concrete, producing cement, constructing building and infrastructures and providing services in logistics, demolition, to sorting of construction wastes and waste management. Most companies' activities in this study focus on concrete production with a variation in the degree of vertical integration as well as major resource input (primary versus secondary).

table 2: collection of data

Workshop no.	Aim of the workshop	Data collected	Methods	Reference
1	Understand fundamental business model logic	Socially and environmentally extended business models perspective	Flourishing business models canvas	[28]
2	Identify physical flows economic indicators associated with key resources, value proposition and value capture.	Material flows and respective prices and costs	Material flow analysis	[20], [29]

With each company, two workshops are carried out (see table 2). In the first workshop, the companies' business model is analysed using the business canvas introduced in [30]. Thereby, the data collection exceeds purely economic aspects and includes social and environmental dimensions. In the second workshop, material flows and production costs are analyzed using MFA on company level. The results of each workshop are discussed with the companies' representatives and validated with company internal data on material flows and costs. CO_2-emissions are assessed with data from the ecoinvent database using the indicator GWP (global warming potential) to cover all emissions relevant for climate change.

The analysis on regional scale is intended to provide a reference system for evaluating the effect of alternative business models. Yet, identifying a region for that purpose posed a major challenge. [13] showed that consumption of construction minerals varies significantly from canton to canton due to imports and exports across the Swiss border as well as between cantons. To eliminate such effects, we chose an alpine region which is self-supplied with gravel and sand as well as landfill capacity. It is densely populated with around 82'000 inhabitants and its settlement growth rate is near the Swiss average. In this region, we can identify companies with different business models. In order to ensure confidentiality of all company data, we decided not give any additional information on the region itself but to use it as a representative "model region" named ALPVAL (for "alpine valley").

The material flows in this region were assessed by interviews with representatives of all mayor companies located in the area. In addition, data was gathered from reports of the cantonal waste management authorities as well as statistics of gravel extraction from ground as well as rivers. Data on communal data was collected to additionally assess fees on gravel extraction.

3.3.Assessment of business models

The assessment of each company is based on a Material-Flow-Analysis (MFA) with data collected in workshops as described in section 3.2. Each company MFA was transferred to an Input-Output-Table (IOT) describing input, output and internal flows. IOTs were used to combine MFA data with additional information on prices of products, services and production factors and estimate factor income (value added) for each process in the production chain as represented in figure 1. For each process CO_2 eq. were estimated to assess GWP according IPCC 2013 based on data from the database ecoinvent (version 3.4) using standard datasets of gravel, concrete and construction waste in Switzerland.

4. Results

Following workshops with different companies, distinguishable features of each business model emerged. Building on features that are present in both business models, the unique attributes are summarized in table 3. To differentiate between these two idealized companies, the value proposition, value creation and value capture are further discussed. As mentioned earlier, competition for land has increased the value of accessible land for extraction and disposal purposes. The relevance of these boundary condition will further be highlighted in the remainder of the discussion.

table 3: insights and differences between the two business models

	Similar features	Distinction company A "Extraction"	Distinction company B "Recycling"
Value proposition	• Provision of gravel & concrete according to norms to construction companies. • Intake of disposable and excavation material	• Desired equilibrium between intake of disposable material and output of gravel	• Material management on construction site as service. • Vertical integration →Construction services • Development of Niche products for (1) specific application and (2) reduced primary raw material input
Value creation	• Disposal volume is profitable and scarce • Machinery and infrastructure	• Gravel extraction creates volume for disposal of material.	• Gravel extraction does not create volume for disposal. • Increase available volume for intake of disposal material with treatments • Cooperation's with engineers aim at adjusting norms in favour of recycled products
Value capture	• Sales of loose gravel/ concrete (CHF/m3) • Accept disposal and excavation material (CH/m3) • Tie incoming and outgoing deliveries	• Community management is crucial for access to key resources (land/gravel quarries)	• High quality products to increase uptake of recycling products.

4.1. Identification of idealized business models

To showcase preliminary results from this ongoing research project, two representative business models are identified and discussed: company A "extraction" and company B "recycling". Extraction, as well as recycling companies, provide raw materials for the built environment and handle the material flows that leave the building stock. Along this value chain, extraction and disposal processes are different, whereas the technical processing of raw materials is rather similar (see figure 1). The access to gravel quarries, being a key resource, appeared to be central to the extraction business model. Both business models strongly depend on the access to land, either for the storage of material before processing, or for mining purposes. The negative externalities for the local communities appear to be significant in both business model, yet the financial compensation for mining purposes has gained more traction in recent years. Thereby, a tendency of extraction companies to focus on community management to ensure long term access has been observed. Recycling companies appear to be focussed on actively influencing market demand, by promoting the uptake of recycled products among engineers and planners. Increased material turnover frees capacity to accept more valuable volume for storage and processing of excavation material.

We find that both business model builds on similar value propositions and value capture, yet fundamentally differ in terms of value creation. As both business model build on similar processes and differ mainly in the access to gravel quarries (see section 4.2), we elevate these process to a regional level to understand the systemic implication (section 4.3).

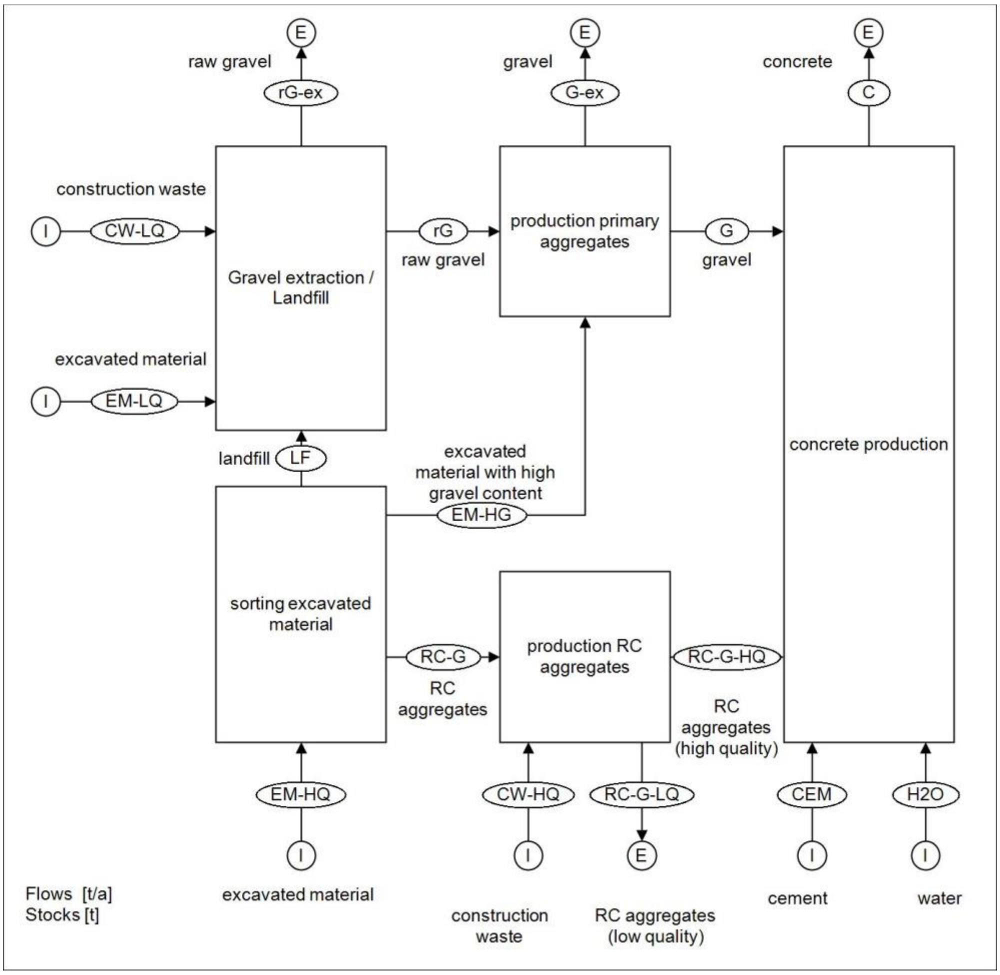

figure 1: Generalized system definition of gravel and concrete producers

4.2. Assessment of business models

Two companies were identified as representatives of the two idealized business models described in section 4.1. The company representing “Extraction” (Company A) owns several gravel pits and sells waste management services for depositing excavated materials (in empty gravel pits) and sorting and processing mineral construction waste. It sells mostly concrete and a comparatively small amount of gravel. The company representing “Recycling” (Company B) produces gravel and aggregates using virgin gravel extracted from rivers, excavated materials with a high gravel content and processing mineral construction waste. It sells concrete as well as gravel. We calculated all values for the indicators listed in table 1, but a comparison of the total numbers is not meaningful as both companies differ in product mix differs as well as total amount of material turnover.

For a meaningful comparison, value added is used as reference value. For both GWP and primary resource consumption, the performance of Company B “Recycling” exceeds the performance of Company A “Extraction” with 2.21 GWP per CHF (Company B) to 2.66 GWP per CHF (Company A) and 0.01 tons of virgin gravel per CHF (Company B) to 0.02 tons of virgin gravel CHF (Company A). To better understand these differences, we also compared the indicator values per tons of concrete and gravel produces by each company. For one ton of concrete, company A “Extraction” uses 0.49 tons of virgin gravel whereas company B “Recycling” only needs 0.32 tons. This difference is even more distinct for gravel production with 0.77 tons of virgin gravel for one ton of gravel sold (company A “Extraction”) compared to 0.44 tons of virgin gravel for one ton of gravel sold (company B “Recycling”).

To compare value added of processes in both companies, it is interesting to look at the contribution of the different processes as well as the different products. As shown in table 4, the sums of value added generated by the different products vary only slightly between the two companies. Company B "Recycling" has a higher value added for concrete and recycling aggregates than company A “Extraction” whereas company A performs better in the production of primary aggregates. In the results of the value added of the production of one ton of primary aggregate, it can be seen that the value added shifts from the gravel pits and landfill in the case of company A “Extraction” to production of primary aggregates (gravel) in the case of company B “Recycling”. This is due to the fact, that company B processes excavated material with high gravel content to produce primary aggregate and increases the value added significantly.

table 4: value added of the two companies

	Change in Value added per ton of concrete		***Change in Value added per ton of primary aggregate***		***Change in Value added per ton of recycling aggregate***	
[CHF]	**company A**	**company B**	**company A**	**company B**	**company A**	**company B**
landfill	*3.38*	-	*5.67*	-	*-1.30*	-
gravel pits	*7.34*	*4.83*	*11.50*	*6.54*	-	-
production primary aggregates	*1.58*	*7.10*	*2.47*	*12.19*	-	-
production recycling aggregates	*2.81*	*2.60*	-	-	*15.49*	*14.63*
concrete production	*19.50*	*21.60*	-	-	-	-
	34.61	***36.13***	***19.64***	***18.73***	***14.18***	***14.63***

The global warming potential according IPCC 2013 can be seen in table 5. By assuming, that both companies produce concrete with the same mix design (355 kg cement CEM II A-LL, 1855 kg aggregates and a water-cement-value of 0.53) and normalizing the material flows, company B "Recycling" has a slightly lower GWP than company A. This can be explained by the lower GWP of the production of recycled aggregates in contrast to the production to primary aggregates. It has to be noted, that the transport outside of the company, e.g. transport from construction site to the company, is not considered. It can also be seen, that the GWP is mainly influenced by concrete production due to the input of cement. Furthermore, it is interesting to see, that concrete production has a much higher impact per ton on GWP than on value added.

table 5: GWP of the two companies

	Change in GWP per ton of concrete	
[kg CO_2-Eq]	**company A**	**company B**
landfill	-	-

4.3. Influence of alternative business models of regional scale

The results of regional MFA for construction minerals is shown in figure 2. It includes the following processes:

Gravel pits/landfills: In ALPVAL gravel is extracted from rivers as well as traditional gravel pits, that are also used as landfills to deposit excavated material from construction sites. In 2018, the amount of gravel extracted exceeds the amount of excavated material deposited.

Production primary aggregates: Primary aggregates are produced with either virgin gravel/sand from gravel pits and rivers or excavated material with a high content of gravel. This is a typical situation for an alpine valley where glaciers deposited virgin gravel on the entire valley bottom during ice age. The majority of aggregates is used to produce concrete.

Production RC aggregates: RC aggregates are produced with mineral construction waste. High quality aggregates (mostly from crushed concrete) are used to produce concrete; low quality aggregates are used for road construction and similar purposes.

Concrete production: Only 14% of all concrete in the region is produced with RC aggregates. All concrete is used in regional construction.

Building stock: The building stock is still growing as the amount of construction minerals used exceeds the amount of construction waste. Yet, there is a significant amount of excavated material generated in construction. Only a minor share of construction waste is landfilled.

Sorting excavated material: This process is defined to simplify material balancing. In reality, sorting takes place on the construction sites and is determined by the capacity of companies to use excavated materials with high gravel content to produce primary aggregates.

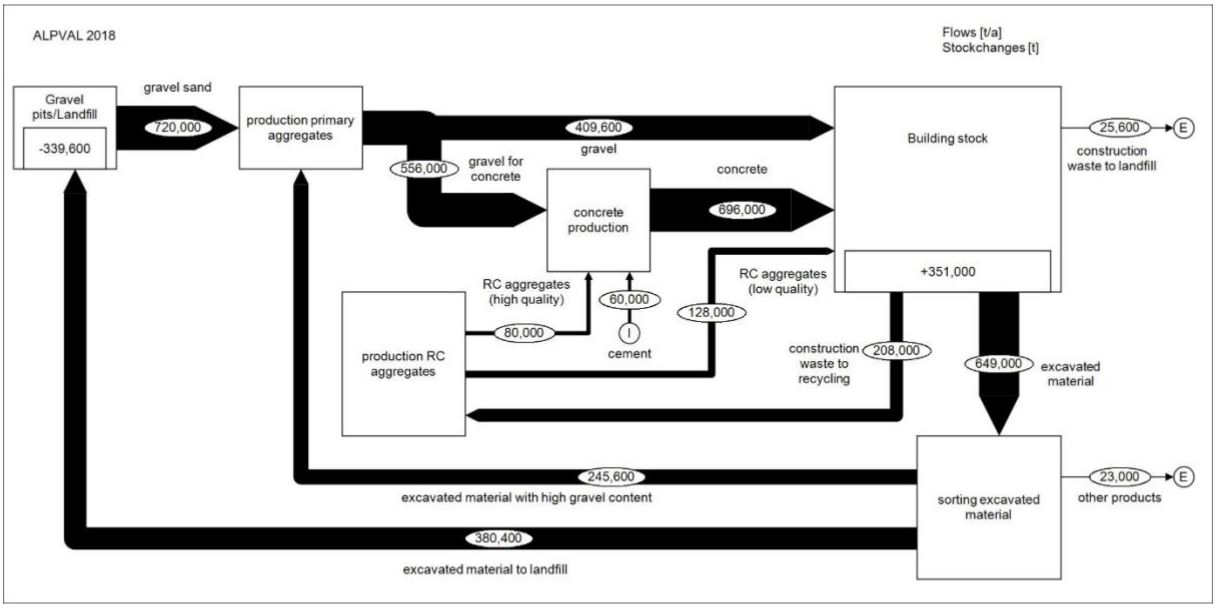

figure 2: material flows of the region ALPVAL

To assess the impact of alternative business models on regional scale, we analyse two alternative scenarios and compare it to the status quo presented in figure 2:

Scenario A: All concrete and gravel produced in ALPVAL is produced by company A "Extraction"
Scenario B: All concrete and gravel produced in ALPVAL is produced by company B "Recycling"

Table 6 presents the results of the scenario calculation. It shows that the amount of virgin gravel/sand extracted per year decreases in both scenarios: by 44% in Scenario B "Recycling" and in Scenario A "Extraction". This implies that the company we chose as representative for the business model "Extraction" uses more secondary resources than the average company in ALPVAL. Yet, it also deposits more excavated materials per year than an average company in ALPVAL because a smaller share of virgin gravel is gained by processing excavated materials. In scenario B "Recycling" no excavated material is deposited because the entire amount is used in gravel production. The amount of recycling materials used in production increases in both scenarios.

table 6: comparison of the companies on a regional level

	status quo	Scenario A	Scenario B
Amount of virgin gravel/sand extracted (tons per year)	720'000.00	656'432.00	402'944.00
Amount of excavated material deposited (tons per year)	380'400.00	485'264.00	0
Amount of recycling materials used for producing construction materials (tons per year)	208'000.00	253'280.00	253'280.00
Value added (CHF per year)		33'948'144.00	34'690'928.00
Global Warming potential (kg CO2 eq per year)		71'715'840.00	71'486'160.00

Value added and GWP are calculated for both scenarios but no comparison to the status quo is possible due to lacking data. But if we calculate GWP and Value added per capita for ALPVAL we see the industries relevance on regional scale. The production of gravel and concrete is of minor importance for the regional economy with a share of 1% in the regional GDP per capita. For climate gas emissions, however, concrete production accounts for 19% of the direct emissions (per capita) and 6% of the global emissions (per capita) – both closely related to CO_2 emissions in cement production.

5. Conclusions

For a transition towards a circular economy in the building materials industry it is essential to identify alternative business models and understand their impacts on the use of primary and secondary resources. In this paper, we identified two business models which, at first glance, seems identical as they produce and sell concrete and gravel. By investigating these businesses in detail, we wanted to answer the following questions:

Can the success of alternative business models be explained by boundary conditions in the specific markets, in the regional supply of natural resources or incentives from public administration?
It could be shown, that the success of a business model highly depends on the source for raw-materials (gravel pit, river extraction or processing excavated materials with high gravel content) and the possibility to landfill excavated material. Both have a relevant impact on value added and lead to different strategies to create and capture value. Demand for primary and recycled materials can vary from region to region, as different public policies influence the market (e.g. share of recycled concrete, availability of land/gravel quarries). For the business models described in this paper, the availability of raw material is crucial and both companies developed strategies to cope with this challenge. It is interesting to see, that both strategies are economically beneficial with a comparable amount of value added per unit of output. Compared to the case study region, both business models use more secondary resources that an average gravel and concrete producer. In the further course of the research, we will

have to find a better representative for the business model A "Extraction" to get a clearer distinction between both business strategies.

If a business model is considered favorable in the transition towards a circular economy, can it be transferred from one region to another without losing its economic benefits?
In this study, it is assumed that both companies produce with same costs and sell at comparable prices. In reality costs for gravel pits (e.g. concessions) and landfills differ significantly due to geological, political and economic boundary conditions. Also prices highly depend on demand of building materials and waste management services induced by building activities and economic development on regional scale. Based on our current results, no well-founded answer can be given to question above. In the further course of the research, we will analyze more case study regions that differ in the level of building activity, geological boundary conditions and vicinity of the national border. We expect to find significant difference in costs and prices that will have an impact on the development of business models.

How does such a transition towards alternative business models affect regional resource consumption, emissions and value added on regional scale?
As seen in section 4.3 the effects on resource consumption can be significant. In the cases shown here, resource consumption on a regional scale differs widely. Above all, the amount of excavated material deposited has to be mentioned. But also the amount of virgin gravel used in production strongly depends on the dominant business models in construction industries on regional scale. The effect on the regional economy is negligible. Concrete production has a significant impact on GWP on regional scale if the cement is produced in the region itself (direct emissions). But even if imported from other regions, the impact is not negligible. For our further research, we will analyze how different business models affect the use of cement in concrete production.

In this paper we compared a traditional, linear business model "Extraction" with a circular business model "Recycling". Building on quantitative data, we demonstrated their impact on a regional scale. It appeared that in terms of value generation, the differences were marginal. These indifferences results from the coupling of value capture and material turnover. A higher material turnover leads to a higher revenue, a logic that is inherently contracting concepts of sustainable business models. Nevertheless, business model so far do not fully decouple this logic, but expand their value proposition with additional services such as waste management. While these have not been fully captured in this paper here, further research will detail how circular economy ideas change business models towards more sustainability, and their impact on regional resource consumption, emissions and value added.

Possible strategies and obstacles in the pathway towards energy transition of residential building stocks in Switzerland

Flourentzou F

Estia, EPFL Innovation Park, Lausanne, Switzerland

flourentzou@estia.ch

Abstract. The Swiss strategy for energy transition towards a sober energy world targets a 2000 W per capita society in 2050. This objective for an owner of a building stock is translated to a refurbishment of all existing residential buildings to near zero energy buildings, consuming less than 55 kWh/m² of primary energy for heating with a rhythm reducing the overall energy consumption by an average of 2.6 kWh/m² until 2050.
The article analyses energy consumption of 10'000 residential buildings in Geneva Canton since 1994 and shows that the target of energy reduction at this rate has been achieved in the period 1994-2016, decreasing from 187 kWh/m² in 1996 to 134 kWh/m² in 2016. However, projections for the next 3 decades with the current refurbishment rhythm (0.8-1.5%) and the current real energy performance after deep refurbishment and energy upgrading, show that at this rate and with the performance gap not resolved, the final target will not be achieved.
Based on the analysis of real energy consumption after refurbishment actions on statistically significant building samples and analysing the potential energy refurbishment actions of a 161 buildings stock, we have simulated possible and realistic ways to achieve the 2000 W society target.

1. Introduction. The 2000W society and strategic energy and CO2 targets.

The Swiss strategy for energy transition took the name of "2000W society". This idea started in the years 2000 in the academic circles. It was accepted as a political target in the majority of the cantonal energy Laws and communal Energy Regulations. The Swiss Engineers and Architects Association (SIA) edited a documentation describing the targets of this strategy focusing on buildings: exploitation energy consumption, gray energy for construction or refurbishment and mobility [1].

The 2000 W society targets to reduce the 6000 W nonrenewable energy intensity per capita during the year 2000 to 2000 W of non-renewable energy consumption in 2050 and 2000W total energy consumption of which 500 W nonrenewable in 2100. It also targets 2 tons of CO2 emissions per capita by the year 2050 (1 ton in 2100). This energy intensity was experienced in Switzerland in the fifties and it is argued by the promoters of this idea that it is possible to achieve these targets preserving the current comfort and welfare. The world mean energy intensity was 2000 W in the nighties while at present it is around 2500 W. The application of the 2000 W society idea worldwide, considers equal access to energy resources for all citizens of the world.

The SIA documentation 2040 analyzed the Swiss national statistics in terms of surface area per capita for living, working, learning, etc. and translated the global per capita nonrenewable primary energy and CO2 targets to building targets per square meter, distinguishing new and refurbished buildings.

	Surface /person	Embodied Energy	Energy for Operation	Energy for Mobility	Global Target
	[m²]	[kWh/m²]	[kWh/m²]	[kWh/m²]	[kWh/m²]
New Construction	45	30	90	40	160
Refurbishment	45	20	**100**	40	160

Table 1 Surface and primary energy targets for new construction and refurbishment

The CO2 emission target for operation is 6 kg/m² for new construction and 8 kg/m² for refurbished residential buildings. These CO2 emission targets are very ambitious and cannot be reached with the use of fossil fuels. For existing residential buildings (multi-family houses), it is illusionary to imagine complete abandon of fossil fuels by 2050, except if there are massive investments in urban infrastructure to provide urban district heating with low CO2 and low nonrenewable primary energy content. Buildings complying to primary energy targets but not to CO2 targets may be considered as "in transition" towards 2000W society. A building may be considered compliant "in transition", if it may reach the 2000W society targets with future modifications of the technical installations. As in this article we focus on apartment building stocks for housing and the strategic actions of their owners, we focus only on primary energy targets for heating and hot water production. A building complying to primary energy targets, heated provisionally with gas, may be classified "in transition", because it does not comply to CO2 targets. These targets may be attained with future actions on heat production installations changing the energy source.

As we see on Table 1, refurbished and new buildings have the same total target for construction/refurbishment, operation and mobility. However, as refurbishment impacts less than construction of a new building, it is allowed 10 kWh/m² more primary energy and 2 kg/m² CO2 emissions for operation of refurbished buildings.

Energy for building operation counts heating, hot water, ventilation, cooling, lighting and electricity for housing appliances. SIA 2040 desegregates theses energies providing typical values for each type of use. Using these typical values, and the values of table 1, we may find the targets for heating and hot water consumption: 55-60 kWh_P/m^2 of nonrenewable primary energy. This indicator is important because it can be read directly on fuel energy bills for heating and hot water.

This target is coherent with the targets of low energy building labels. Class B buildings corresponds to <63 kWh/m² of final energy and Minergie – Refurbishment to 60 kWh_{CH}/m^2 of weighted[1] energy for heating, hot water and ventilation. We keep as refurbishment target value of 2000 W for residential buildings heating and hot water consumption 55 kWh_{CH}/m^2 of weighted energy. This value is coherent with Minergie-Renovation targets that takes into account electricity for ventilation and auxiliaries.

In the year 2000 the mean energy performance of residential buildings in Geneva was 181 kWh/m² of weighted energy. To get the target of 55 kWh/m² in 2050 it is necessary to reduce energy consumption by 126 kWh/m² in 5 decades. This means a rate of reduction of 26 kWh/m² per decade or 1.4% per year with basis the 2000 energy consumption.

2. Geneva Canton residential building stock energy consumption since 1994

In Geneva Canton, every residential building owner with more than 5 energy consumers, has the obligation to communicate to the Cantonal Energy Office the heat consumption of the building. These data are collected since 1992, and since 2010 all buildings of a certain importance have to communicate

[1] Weighted energy is a Swiss speciality replacing the primary energy factors with « state energy policy weighting factors », having 2 for electricity, 1 for fossil fuels and 0.6 for biomass instead of 2.69 NRE for electricity, 1.22 for oil, 1.05 for gas and 0.1-0.33 for biomass with unit symbol kWh_{CH}.

their energy consumption. All these data are public and accessible on the Canton Information Service on the web.

We filtered and analyzed the data of all residential apartment buildings present in the database. The statistical set is composed by 6874 buildings of 12 million m² in 1994 and up to 10’000 buildings, 16.2 million m² in 2016. Every year more buildings are added in the database. This statistical set is constituted of practically the whole stock of residential apartment buildings of the Canton. If we consider 45 m² per inhabitant, this building stock concerns potentially housing of 266’000 people out of 495’000 population of the canton.

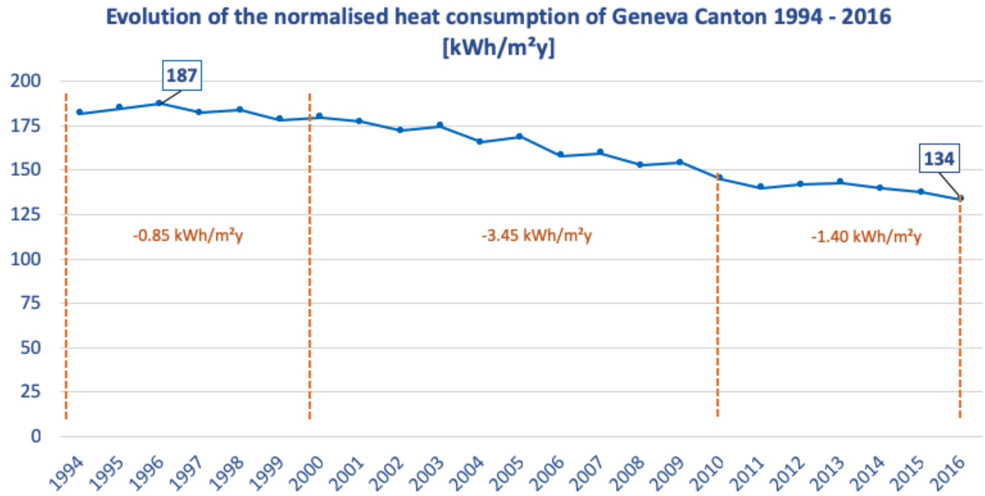

Figure 1. Evolution of the final energy consumption of 10’000 residential buildings, 12 million m², in Geneva.

As we see on Figure 1, in the period 1994-2000 the energy reduction was tiny, -0.85 kWh/m². In the period 2000-2010 the significant boost of energy savings gives an energy reduction of 3.45 kWh/m² per year. After 2010 we observe a deceleration of the evolution with 1.40 kWh/m². During these first two decades of energy transition, 1996-2016, we observe a significant reduction of energy consumption of an overall of 53 kWh/m². This represents a reduction of 28% with a mean rate of 26 kWh/m² per decade. The transition targets towards 2000 W society for the first two decades are achieved successfully, although the reduction rate was not constant during the whole period.

We observe a downturn after 2010 with weaker rate of reduction although the national energy requirements become more ambitious. The lower energy prices of this period and other macroeconomic reasons might play a role for this. Another factor of the downturn of energy consumption reduction is the low refurbishment rate. According to the report of the Cantonal Energy Directors [2], in Geneva Canton, more than 60% of the buildings built before 1990 have not been refurbished the last 30 years. This means a refurbishment rate lower than 1.5%. According to the same source, refurbishment rate of facades is between 1 and 1.1%, roofs 2-2.4% and windows 3.5%. As the energy reduction is due to optimisations and partial interventions rather than global energy upgrading, energy-saving potential is reducing year by year, because the most efficient actions have already been implemented.

2.1. Evolution of the energy classes during the first 2 decades of the energy transition

We classified the buildings according to their specific heat consumption. We calculated the partial class thresholds according to the Swiss national classification regulation. According to this standard, normal heat consumption determining the threshold of class B is 63 kWh/m² (heating and hot water). This determines the module of the x axis of the following graphs.

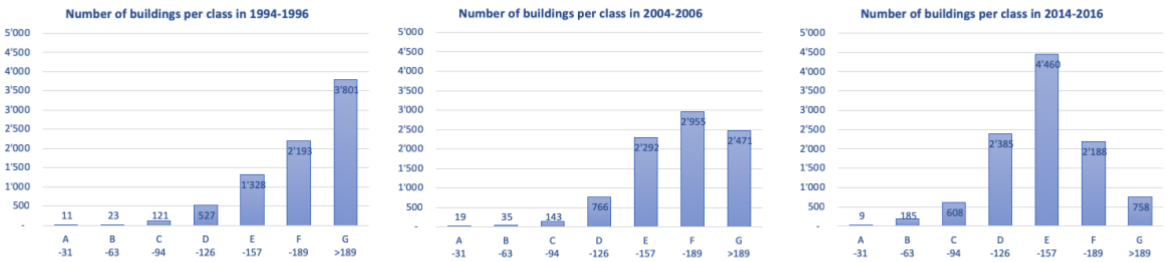

Figure 2. Evolution of the class distribution of residential buildings in Geneva, 1994-96, 2004-06 and 2014-16.

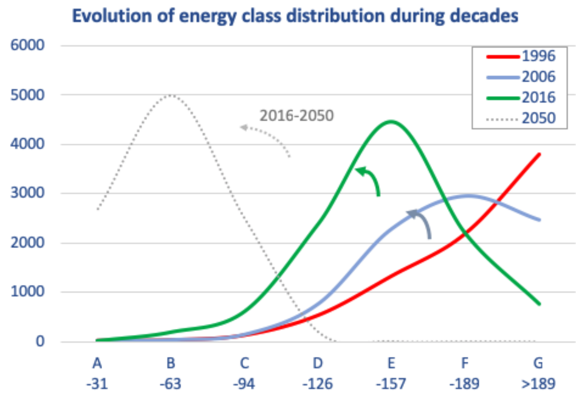

Figure 3. Evolution of energy class distribution during decades.

As we may see on Figure 2 and Figure 3, the residential building stock classification evolves towards lower energy classes. In 1996 there were 3801 buildings out of ~8000 in class G, in 2006 this number was reduced to 2471 and in 2016 they remain only 758 buildings out of ~10'000. The median class was reduced by more than one class during 2 decades. If the energy transition towards 2000 W society continued with the same rhythm until 2050, the energy target would be achieved. The distribution curve of that time might seem like the dotted line, centered on class B with the majority of the buildings, more than 25% of buildings in class A with buildings easy to refurbish with accessible cheap renewables and 25% of class C and some exceptions in class D. These class C and D buildings could be the protected heritage buildings or buildings not yet refurbished.

2.2. Major risks of low refurbishment rate and insufficient real energy performance.

Analysing these graphs, we may identify and quantify 2 major risks:

The first one is the current rate of refurbishment. If during the last 3 decades, only 3500 buildings were refurbished according to [2], what is the driving force that will modify the motivations of the building owners to retrofit 6500 buildings in the next 3 decades? As we see in Figure 1, the rate of energy consumption reduction decelerated, and it is less than the average value since 2010. With the current rate of energy consumption reduction, the targets of 2000 W society cannot be achieved.

The second risk that we may observe on Figure 2, is the few buildings of real energy class A and B. If in 2016 we have only 9 buildings of class A and 185 buildings of class B, someone may question why there are so few low-energy buildings, although there were subsidies since 2010 for deep refurbishment and hundreds of new buildings have been built with high energy standards? What will change so that the building sector may manage to perform for 7'500 buildings in the next 30 years what it has not managed in the past decade?

3. Refurbishment strategies

If we analyse the energy performance distribution of the building stock, we may see that 2/3 of the buildings are of energy class E, F and G. We also know from [2] that more than ~2/3 of the buildings built before 1994 have not been refurbished over the last 30 years. This means that many of the buildings of class D achieve their energy performance without deep refurbishment and therefore, we may bring the buildings consuming more than the median consumption to the median with partial refurbishment and energy optimisation actions.

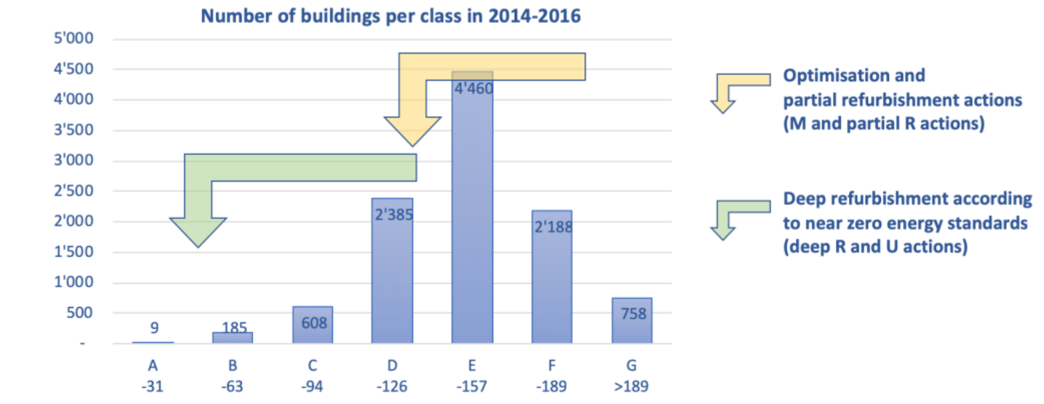

Figure 4 Energy consumption distribution of residential buildings in Geneva and actions to change their energy class.

According to the Swiss Norm SIA 469 [3], we may classify building conservation measures to 3 categories:

- Maintenance with ordinary and extraordinary limited actions.
- Refurbishment, bringing the building components to habitability normal conditions.
- Upgrading, with actions offering better performance.

Optimisation actions do not imply any investment, other than the monitoring cost. Simple settings, like a more adapted heating curve, night setback of the heating and water system, more adapted ventilation rates, correction of dysfunctionalities of production and distribution systems, optimisation of the operation of existing installations.

A list of building elements may be replaced independently from a deep global refurbishment without compromising future coherence of the energy systems. Windows, ventilation system, roof or ground slab insulation, an installation of solar collectors for hot water preheating, a new smart control of the heating system, or boiler replacement, are such actions. They may generate significant energy savings waiting deep refurbishment in the near of far future.

Concerning deep global refurbishment, some cantonal regulations define it for buildings investing more than 40% of the reconstruction value and apply special complying procedure to the norms. Upgrading actions target higher energy performance than the minimum legal target. Minergie®-Renovation label, Minergie-P® are such labels, but in Geneva and other Swiss cantons there are also regional labels, like HPE and THPE (Haute Performance Energétique and Très Haute Performance Energétique).

We have simulated the most usual refurbishment actions for a typical building of 1965 (Table 2). The building presents the dimensional and energy consumption characteristics of the median non-refurbished building of our cantonal database (3 entrances of 1800 m² each, 20 apartments each, measured energy class E). We calculated the theoretical energy savings of each action or combination of actions. As we are interested in the real impact of the different options on energy savings, we identified sets of buildings of significant statistical sample and tested the real energy saving effect of different actions. We compare the evolution of energy consumption of the test set of refurbished or optimised buildings with evolution of the reference set (generally the whole building stock). This shows the real impact on energy performance due to the action on the test set.

3.1. Monitoring and optimisation actions

We compare the evolution of specific heat consumption of a group of 123 buildings under energy performance contract with the whole building stock. As we may see on Figure 5, the selected buildings for optimisation consume a bit more energy than the whole building stock before 2014 when optimisation actions started. Before the beginning of the optimisation actions in 2013, the set of optimised buildings consume 149 kWh/m² instead of 143 kWh/m² of the whole building stock. 3 years later, this group consumes 127 kWh/m² instead of 134 kWh/m² of the whole building stock. The whole building stock reduced its energy consumption for heat by 9 kWh/m², 6.3%. As the reference building stock is huge and the deep refurbishment actions insignificant (less than 1% per year) we may suppose that the reference building stock without optimisation is the whole building stock with 10 000 buildings. The optimised group of buildings reduce its energy consumption by 22 kWh/m², 14.8% compared to 9 kWh/m² of the reference set. The pure reduction of the optimisation actions counts for 13 kWh/m², 9.1%. As the results are normalised with a reference meteorological year according to the year heating degree days, we see only the action influence independently from weather variation. Here we simply compare the mean energy consumption of each group. More detailed statistical methods may be used to compare the two groups of buildings.

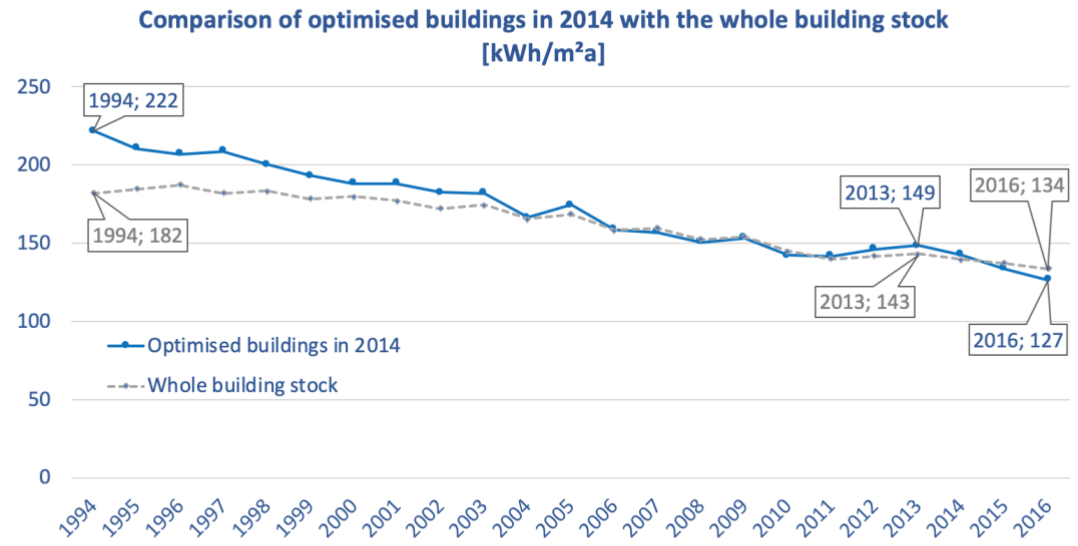

Figure 5. Comparison of the evolution of specific energy consumption for heat of a group of 123 optimised buildings with the whole building stock

3.2. upgrading actions with deep refurbishment.

Comparison of a significant set of 59 refurbished buildings according to the high and very high energy standards shows the real potential of these actions. The target was 30 kWh_{CH}/m^2 for the very high energy standard and 60 kWh_{CH}/m^2 for the high energy standard, including weighted electric energy for ventilation (6-7 kWh_{CH}/m^2 for buildings with heat recovery and 1 kWh_{CH}/m^2 for buildings with simple systems). Electricity for ventilation is not included in the measurements of heat consumption in the database. The majority of these high-performance buildings are designed with heat recovery systems. Excluding ventilation, we keep the indicative target of 55 kWh/m² for heat. An official compliance verification certified the design objectives of these buildings.

As we can see on Figure 6Figure 6, refurbished buildings according to high and very high energy standards, reduce drastically their energy consumption for heat. However, the real energy performance does not achieve the theoretical performance according to the declared objectives and does not meet the 2000W society goals. Although there is a reduction of 85 kWh/m² in heat consumption since 2005 (46%), there are 45 kWh/m² missing to meet the goals.

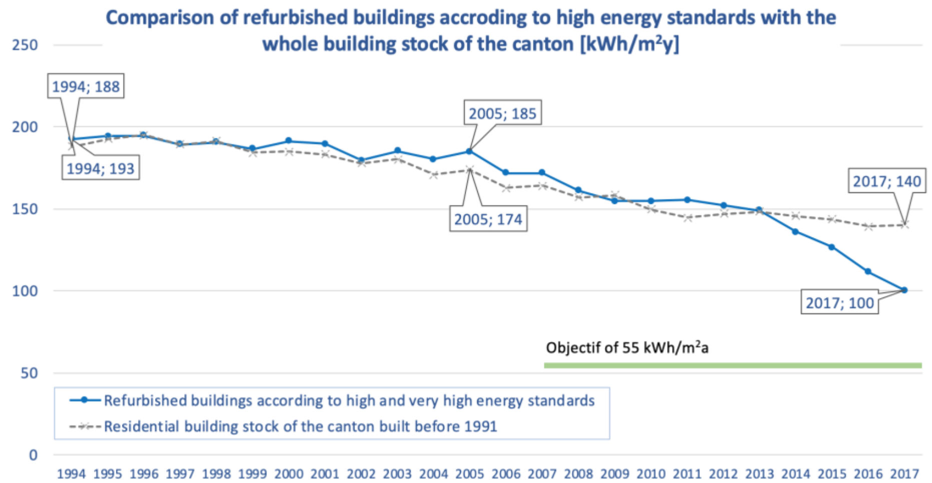

Figure 6: Comparison of 59 buildings upgraded to high and very high energy standards with with the whole building stock of residential buildings built in Geneva before 1991.

The real heat consumption of this set of refurbished buildings is 100 kWh/m² instead of <55 kWh/m² that it should be. The majority of these buildings are still heated with oil or gaz. The following graph shows the energy consumption distribution of these buildings.

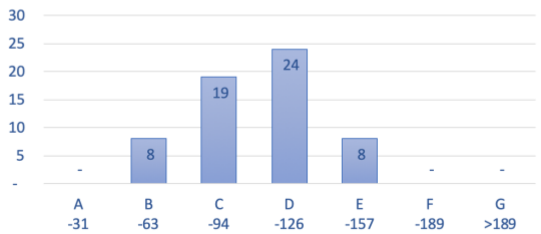

Figure 7 Number of "High Energy performance" buildings per energy class (normally class A and B)

The phenomenon of the performance gap of refurbished buildings in Geneva has been studied by several research projects [4][5][6]. According to Khoury [6], in a sample of 26 buildings, targeting 153 kWh/m² energy savings, they realised 101 kWh/m², 65% of the ambitions. These results on a smaller sample, but analysed deeply in detail, are of the same order of magnitude as those of Figure 6. According to [5], the reason for this kind of performance gap is 30% due to bad settings and 30% due to lack of monitoring, resulting overheating of the apartments to >23°C and window openings >15% and poor heat production efficiency. In the following table, we compare the expected energy savings simulated on our typical building according to standard conditions and the energy savings observed on relevant statistical sets.

	Calculated savings		Performance gap
	kWh/m²	%	
Smart heating control	**28**	16%	+
Replacement of windows	**33**	22%	+++
Roof Insulation	**16**	11%	+
Boiler replacement	**7**	5%	+
Wall insulation	**42**	28%	++
Demand control ventilation	**9**	6%	-
Solar DHW preheating	**6**	4%	+++

Table 2. Theoretical energy-saving potential of most usual refurbishment and optimisation actions and potential performance gap.

4. Simulation of energy transition pathway of a building stock towards 2000W society.

From Table 2 action list we may combine two types of refurbishment strategies for the buildings:

- Optimization and partial refurbishment actions, concerning the buildings of classes E, F, G that are not going to be refurbished in the next 15 years. The theoretical potential target is 100 kWh/m² but the real observed energy performance is ~125 kWh/m².
- Deep refurbishment following a given strategic refurbishment rate. The theoretical potential target is 55 kWh/m² but the mean real observed performance 100 kWh/m². The best refurbished buildings after optimization consume 70-75 kWh/m².

We analyzed a building stock of 161 buildings of the total surface area of 324'032 m². Its energy consumption for heating and hot water in 2016 is 133 kWh/m², very similar to the whole Geneva building stock average. The evolution of the energy consumption since 1994 is following very closely the cantonal building stock evolution. 95 buildings, 59%, are of classes E, F, G with mean energy consumption 150 kWh/m². The current rate of deep refurbishment is less than 1%. However, the investment rate is ~1.5% of the building reconstruction value. This means that almost half of the current investment budget is for partial refurbishment.

We tested 2 refurbishment strategies.

Scenario 1: realistic rate of refurbishment according to the current practice, the current budget and available personnel. This is translated to 1.5 buildings per year with deep refurbishment (1%). To this we add 8 buildings per year partially refurbished or optimized for the next 10 years. We use the energy targets observed in reality.

Scenario 2: an ambitious scenario, with 8 buildings per year partially refurbished or optimized and 1.5 buildings deeply refurbished until 2029, and 3 buildings per year refurbished from 2030 until 2050 (2% deep refurbishment after 2029). Until 2029 we use the energy targets according to those observed in reality and after, we use the potential theoretical ones.

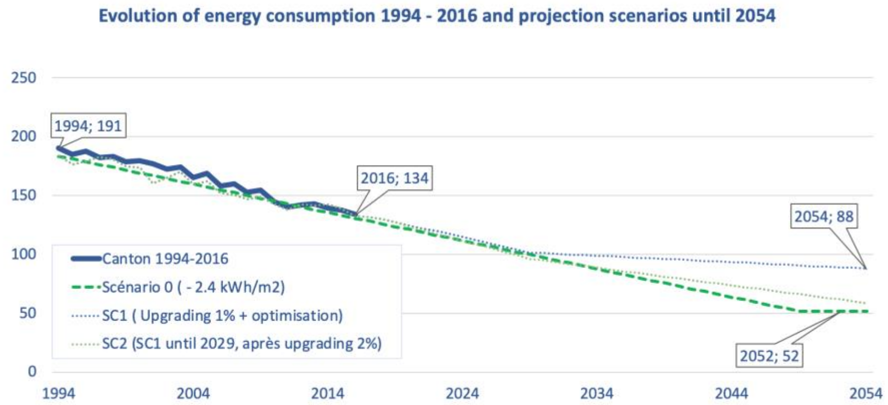

Figure 8. Evolution of energy consumption and projections until 2054

As we see on Figure 8, the evolution according to the current parameters of refurbishment rate and real energy savings does not lead to a 2000W but to "a 3200W" society (scenario SC1). However, combination of the low current rate for deep refurbishment with partial refurbishment and optimizations may be acceptable to stay on the course for the next decade. In order to approach the resulting energy to the 2000W society targets, it is necessary to double gradually the rate of refurbishment to reach 2% and make the performance gap negligible for the decades after 2029.

5. Conclusions.

In the first 2 decades of the energy transition, 1996-2016, the mean rate of energy consumption reduction was following the objectives, although the rate of reduction was weakened since 2010. For the next decades there are 2 considerable obstacles to meet the goals: the low rate of deep refurbishment and the performance gap. In order to catch the objectives, it is necessary to rise gradually the rate of energy refurbishment to 2% per year and reduce the performance gap to obtain a mean of <55 kWh/m² after refurbishment, instead of 100 today.

Abstract. CO_2 emissions need to be reduced by 40% in 2030 in Portugal as an intermediate target of the Paris Agreement. This challenging goal is expected to be achieved through incentive-based regulations and voluntary actions. This study improves the understanding of renovation strategies to reduce emissions caused by the built environment. A fleet-based Life Cycle Assessment (fb-LCA) is adapted and applied to the building sector. Fb-LCA integrates LCA and a fleet model to describe stocks and flows associated with a class of products over time. The method is tested for a neighbourhood in Lisbon, Portugal. The analysis compares 3 scenarios of dynamic renovation rates for the next 30 years: business as usual, a public economic incentive to renovate, and mandatory renovation. Different technology scenarios including bio-based ones, are compared. Among the latter, alternative material solutions, e.g. insulation cork boards, are emerging, providing carbon sequestration. Results highlight the environmental benefits of bio-based materials considering the temporal profile of renovation activity. Furthermore, the cost and sensitivity analysis help stakeholders to justify retrofit actions from an environmental and economic point of view. The adaptation of a fb-LCA approach proves to be an easy-to-use method to assess technology options and policy scenarios at a neighbourhood scale.

1. Introduction

1.1. The built environment as a cause of pollution and as an opportunity to tackle climate change

The Paris Agreement aims to tackle climate change by limiting global temperature rise this century well below 2° Celsius above pre-industrial levels, or even limit it to 1.5° Celsius. The ambitious goal is an 80% reduction of CO_2 emissions by 2050 compared to the year 1990. By ratifying the agreement in October 2016, Portugal and many other countries have committed themselves to comply with the intermediate targets of reducing the national CO_2 emissions at least by 40% in 2030 [1]. This challenging goal is expected to be achieved by means of incentive-based regulations and voluntary actions.

The built environment consumes 62% of final energy and is a major source of greenhouse gas emissions (55%) [2]. In Portugal, almost 70% of the buildings were built before 1990, when the first Portuguese regulation regarding thermal comfort in buildings was published. In 2010, 35% of the buildings in Portugal needed major retrofit works and about 3% presented a high level of degradation

[3]. According to 2014/15 European work program, the renovation of buildings represents more than 17% of the primary energy savings potential of the EU for 2050 [4].Therefore, the renovation of buildings has a high capacity to influence the environmental impacts and global objectives of climate change mitigation.

1.2. Bridging the gap between embodied and operational energy

In the existing literature, direct emissions during the use phase of buildings and indirect emissions in the production, construction and waste management phases, are usually disconnected. To achieve climate sustainability goals, we need to find a way to understand the dynamics of the built environment by bridging these two levels. Low-impact solutions, on both levels, for example through thermal refurbishment of the façade, are needed. In this regard, traditional insulation materials for retrofit might not always be the best solution in terms of impacts, but alternative material solutions, e.g. insulation cork boards, are emerging [5]. Bio-based products offer the opportunity to account for carbon sequestration, which offers an environmental benefit that might compensate for the impacts caused during production and construction [6].

The objective of this study is to explore potentials of greenhouse gases (GHG) and other emissions reductions associated with the renovation of buildings. It wants to improve the understanding of renovation dynamics in relation to achieving climate targets. For this purpose, a method called fleet-based Life Cycle Assessment (LCA) will be adapted and, in a simplified way, applied to the building sector.

1.3. Technology diffusion

The question if "a product-centred approach to LCA is always the best" was answered by Field *et al.* [7] by introducing the "fleet-based" LCA (fb-LCA). This approach deals with effects distributed over time, and integrates LCA and a fleet model that describes the stocks and flows associated with a class of products over time. Instead of making use of a single element for the declared unit, it looks at a set of units in service. Fb-LCA is able to model temporal changes and effects of technology diffusion because it considers the dynamics of replacing products that reached their end-of-life with new ones. And because it considers how resource consumption and environmental impacts change over time, it is a useful method to analyse technological transitions.

Even though until now the application of purely fb-LCAs is relatively restricted to fields that underlie high technology innovations, e.g. cars, the method shows advantages that seem beneficial also for assessing building stocks and scenarios for retrofitting. This method can be used to assess the dynamics of introducing or increasing the share of a specific type of insulation material, considering different retrofitting rates depending on the location. In a study on the development of residential building stocks [8] used an approach that reminds of fb-LCA. The authors estimated country-wide future renovation activities on the residential building stock that needs retrofitting by defining building cohorts. However, a Europe-wide analysis would require generalized parameters to model the composition of the building stock.

1.4. Building stock modelling

A model is always a simplification of reality. A complex system like a building stock needs an appropriate model to be analysed. There are two general approaches in building stock modelling: top-down and bottom-up models. Top-down models work with aggregated data. Bottom-up stock accounting uses material intensity coefficients to estimate the material quantity in a single unit of the examined end-use objects at a specific moment in time. With simple typologies, it is already possible to obtain interesting results regarding future policy and technology scenarios for a building stock at the urban scale [9].

This study will make use of a bottom-up approach and will focus on a defined set of buildings and materials to explore the opportunities of a fb-LCA applied to the diffusion of retrofit strategies.

2. Data and Methods

The framework for the model, presented in figure 1, reminds of a typical LCA, but it uses an up-scaled declared unit that is the whole opaque façade area of all buildings under study. The product stages A1 "Raw material supply", A2 "Transport", A3 "Manufacturing", and construction process stages A4 "Transport" and A5 "Construction installation process", as well as the use stage B6 "Operational Energy Use", are taken into account to estimate environmental impacts. The analysis focuses on the impact categories Global Warming Potential (GWP) and Primary Energy Non-Renewable (PE-NRe), but Abiotic Depletion Potential (ADP), Acidification Potential (AP), Eutrophication Potential (EP), Ozone Depletion Potential (ODP) and Photochemical Ozone Creation Potential (POCP) are also considered to be in line with the European recommendation for the application of LCA to construction products and services [10]. Moreover, the study also estimates the economic costs associated to Life Cycle (LC) stages A1 to A5, cradle to gate, and the energy cost of heating and cooling during the study period related to LC stage B6.

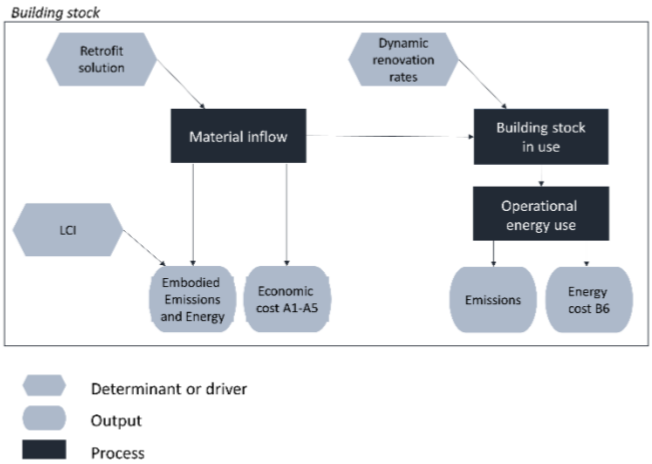

Figure 1. Framework of the model

The developed method is tested for one type of construction typology in the Lisbon neighborhood Alvalade. This neighborhood is of particular interest since it was built within a short period, between the 1940s and the 1960s, promoted by an urban expansion plan of the Lisbon municipality in 1944. Here, a specific type of construction called "Placa", mixed masonry-reinforced concrete, is particularly prominent. In total, 230 buildings were identified to be similar to that type and considered in the present study. The declared unit is the total opaque façade area of all buildings: 124,577 m^2.

The analysis incorporates the fleet-based approach by analysing dynamic renovation rates (see figure 2). It describes the next 30 years in accordance with the EU energy directive [11], which is also a commonly chosen time frame in Economic and Energy LCA. The Business as Usual (BAU) is compared to two scenarios: one assumes that a public economic incentive is introduced to promote the renovation of exterior walls. For the public economic incentive scenario, a Weibull probability density function is applied. The other scenario is that of a legislation that makes renovation of exterior walls within the next 30 years mandatory. For the mandatory renovation scenario, a Normal distribution is assumed, which is often used in building stock modelling.

Furthermore, different technology scenarios are analyzed: the building stock as it is without any retrofit action is compared to two different scenarios with an external thermal insulation composite system (ETICS) applied to a single leaf wall: one with the commonly used insulation material extruded polystyrene (EPS); and the other one with the bio-based insulation cork board (ICB). The technology scenarios are paired with the dynamic renovation rate scenarios described before. Also, a sensitivity analysis on heating and cooling use is carried out. The default value for the consumption of energy during the B6 sub-stage is assumed to be only 10% of the heating and cooling needs, in accordance with the national use pattern. This value is compared to fulfilling 20%, 30%, 40% and 50% of heating and cooling needs.

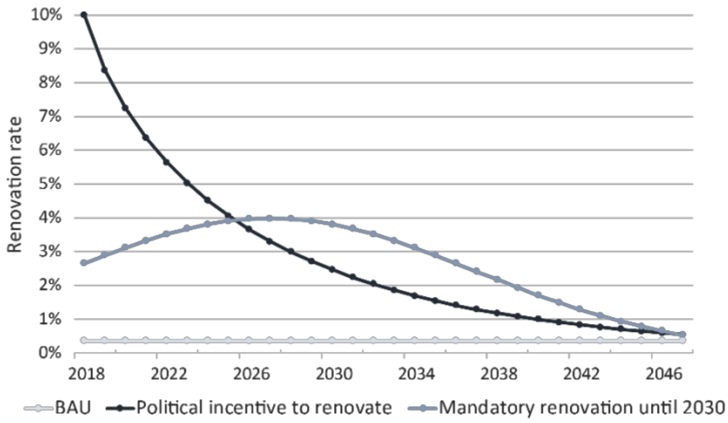

Figure 2. Renovation rates under study.

The costs of LC stages A1 – A5, that include the installation of the ETICS system in the building, in units of m^2 of wall, were taken from various sources [12–14]. The calculation of the energy cost in each year, per m^2 of external wall, relates to the energy use for heating and cooling, based on the method given in the national regulations [15].

3. Results

3.1. Environmental impacts - Renovation all at once

As a first step, the cradle to gate impacts for the declared unit were calculated for the hypothetical case that everything is renovated at this moment in time. The alternative of not renovating has 0 impacts for LC stages A1 to A5. The impacts for the two technology alternatives, an ETICS with ICB and an ETICS with EPS, in both cases 0.08 m thick, are compared in figure 3. GWP is negative for the ICB solution since biogenic carbon capture is considered based on a recent Environmental Product Declaration [16].

Furthermore, the embodied energy related to heating and cooling needs, for the default value of 10%, was estimated for the reference case and the two retrofit scenarios. The U-values are 2.41W/m^2K for no retrofit, 0.42 W/ m^2K for the ICB solution and 0.38 W/ m^2K for the EPS solution. The results for PE-NRe and GWP can be seen in figure 4. In both impact categories, the reference case "no retrofit" performs the worst. The differences between the two ETICS scenarios are small with 2,202 kg CO_2 eq. for the ICB solution vs. 2,176 kg CO_2 eq. for the EPS solution, and 34,040 MJ vs. 33,639 MJ respectively.

During LC stages A1-A5 and B6 for 30 years the ETICS with ICB causes less 53% GWP and less 28% PE-NRe compared to no retrofit. ETICS with EPS has a smaller reduction potential than the one with ICB with 19% less for GWP and 17% less for PE-NRe compared to no retrofit.

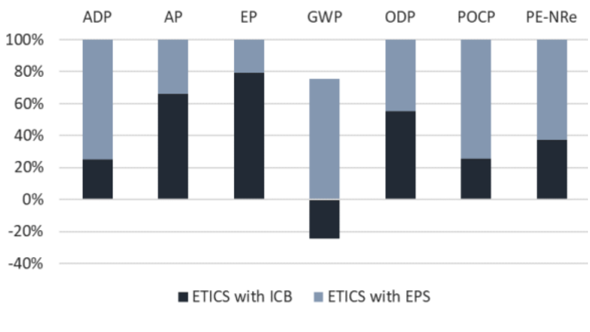

Figure 3. Comparison of environmental impacts for LC stages A1 – A5.

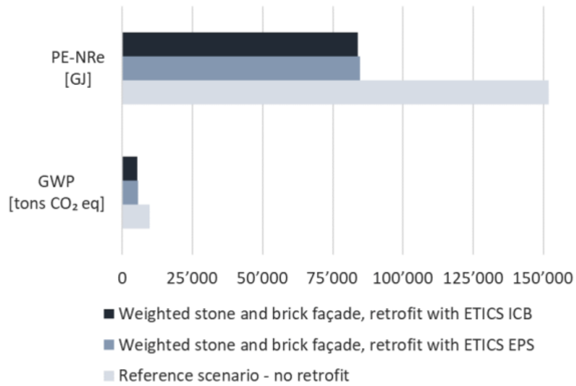

Figure 4. Heating and cooling impacts during 30 years (LC stage B6) for the declared unit.

3.2. Economic and energy costs

The economic cost for LC stages A1-A5, and the energy cost in LC stage B6 with the default value of 10% consumption of energy needed to fulfil the heating and cooling needs during the next 30 years, were estimated for all scenarios. The assumed discount rate was 3%. The economic performance considers market prices, e.g. the acquisition cost including manufacturing, transport to site and installation in the building, as well as the economic savings potential that the thermal retrofit solutions offer. This includes the potential improvements of energy performance of the building envelope after the installation of the ETICS system and the related energy saving potential. The economic costs and energy costs for the three different options are shown in figure 5. It highlights than none of the suggested retrofit solutions offers economic savings compared to the reference case “no retrofit”.

The energy costs are € 22.63 for the energy use for heating and cooling after 30 years study period for 1 m^2 of non-retrofitted wall, compared to €12.64 for 1 m^2 of wall with ETICS with ICB and €12.50 for 1 m^2 of wall with ETCS with EPS. Moreover, EPS has a lower market price than ICB. These values scale linearly with the opaque façade area. However, the energy cost was calculated based on the assumption that only 10% of heating and cooling needs in LC stage B6 are fulfilled. Since in many cases more than 10% needs need to be fulfilled, a sensitivity analysis on this parameter was conducted. Figure 6 shows the results of the sensitivity analysis. Illustrated are the relative differences of the sum of economic and energy cost, compared to the reference case “no retrofit”. One can see that, with an increased value of 40-50% heating and cooling needs fulfilled, the two ETICS solution became equally cheap or even slightly cheaper than the reference case.

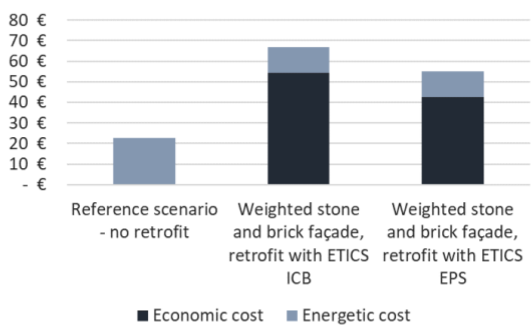

Figure 5. Comparison of the economic cost for LC stages A1-A5, and energy cost for the LC stage B6, after 30 years for 1 m^2 of exterior wall.

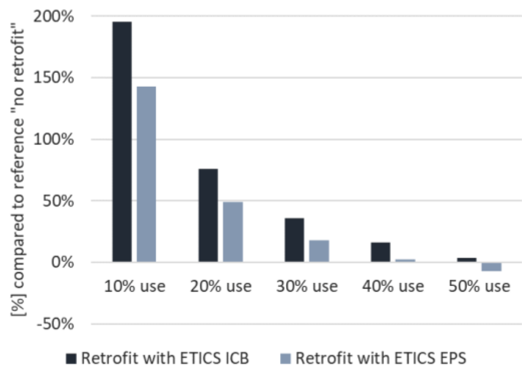

Figure 6. Sensitivity analysis of heating and cooling needs. Based on the total economic cost for LC stages A1-A5 and energy cost for B6.

3.3. Environmental impacts – dynamic renovation rates

Renovation rate as a driver of the model has direct impact on the emissions released over time. The translated GWP for the three different renovation rates under study, as described before, are shown in figure 7. The values in the figure were obtained by holding the renovation technology fix, which is ETICS with ICB, and comparing the different policy scenarios. The chart shows renovation with ICB compared to doing nothing. Only LC stages A1-A5 are considered. If compared to a renovation scenario with EPS the CO_2 saving potential of ICB would be even bigger. In fact, only with bio-based construction materials such as ICB, carbon can be stored in the building. This needs to be considered when analysing the policy scenarios: not only renovation activity as such needs to be promoted but also bio-based materials. The CO_2 savings related to LC stage B6 follow the shape of figure 7.

The BAU has a linear trend line that does not offer a significant potential regarding negative CO_2 emissions. In contrast to that are the two hypothetical policy scenarios, where renovation is either mandatory or promoted with an economic incentive. The first critical step regarding the intermediate goals of the Paris agreement is the year 2030. In that year, the estimated cumulative negative CO_2

emissions will be only -40 tons CO_2 eqv. for the BAU scenario compared to -383 tons CO_2 eqv. for the mandatory renovation scenario and -546 tons CO_2 eqv. for the public economic incentive to renovate.

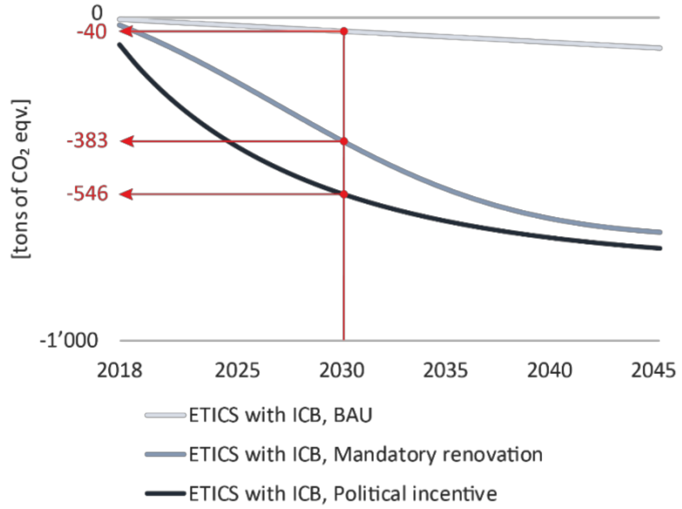

Figure 7. Dynamic cumulative GWP in kg CO_2 eqv. for the declared unit for cradle to gate impacts.

4. Discussion

The purpose of the present study is to improve the understanding of possibilities to reduce emissions caused by the built environment given the fact that binding global climate deals set targets that need to be fulfilled by every participating member. Based on the literature, we propose to use a fb-LCA with a bottom-up building stock modelling that helps to assess the combined potential of technology and policy scenarios. The technology aspect stands for different exterior wall insulation systems and the policy aspect for different renovation rates.

4.1. Technological retrofit options

The present study analysed different retrofit scenarios from an environmental and economic point of view. It was found that, regarding the cradle to gate impacts arising during A1-A5 and the operational energy use in B6, an ETICS system with EPS required slightly less PE-NRe than the one with ICB, 33.9 MJ vs. 34.2 MJ. However, cork as a bio-based insulation material offers the advantage of capturing carbon during its growth which can be accounted for as a negative GWP during construction stage. Both solutions caused significantly less GWP and PE-NRe than the reference scenario "no retrofit". Other researchers have tried to translate that environmental advantage into monetary units by applying weighting factors to make the different dimensions of sustainability easier comparable in a decision making process [17]. Yet, the monetization of impacts is a controversial topic [18] and many scholars argue that is very subjective to trade between economic, social and environmental dimensions sustainability. An option here would be to weigh costs and emissions from different point of views, for example a "green" approach vs. a cost-saving vs. a focus on the service life vs. architectural aspects etc. [19,20]

Regarding the cost analysis, the overall cheapest option was not to renovate. In that case there is no economic cost related to life cycle stages A1 to A5, and the overall cost, economic cost plus energy cost during the 30 years under study (B6), was lower than for the two technological retrofit scenarios with ETICS. The cheapest energy cost was obtained with an ETICS with EPS. The difference to the ETICS with ICB however is small, not even 1%. Moreover, the default value for consumption of energy for all these values was only 10% of the heating and cooling needs and therefore very low. The sensitivity analysis revealed that, with an increased amount of consumption of energy, the energy cost gains importance compared to the economic cost. By assuming that the consumption of energy is around 40-50% of the heating and cooling needs, the two ETICS systems under study had an equally low total cost, economic plus energy for 30 years, as the reference case "no retrofit". An energy consumption in that range is becoming more realistic, considering that people stay at or work from home more often, that some of the apartments are used as, for example, medical practices, or that the cost of electricity might increase in the future [21].

4.2. Dynamic renovation rates

A fb-LCA approach, which has not yet been applied to the building sector, was used to assess technology transitions over time. The model was simplified such that neither changes in background processes nor technological improvements over time were considered. Both are characteristics that are important in the fb-LCA in sectors with fast technological innovation, such as the electric car industry, but not so much in the construction industry, which is traditionally a rigid sector and little prone to technology innovation. In that way the method is well suited to answer the given question. The renovation rates were modelled dynamically because buildings have a long lifespan and should be understood as service providers with different future scenarios. Therefore, it is important to consider the temporal profiles of emissions so that the LCA result for each emission is a function of time rather than a single number. The results of the present study showed that, firstly, the emission profile is directly related to the assumed dynamic renovation rate, as was shown with the linear BAU projection compared with the policy scenarios (vs. the normally distributed renovation rate of legally mandatory renovation and vs. a public economic renovation incentive based on a Weibull distribution). Secondly, the difference between a linear rate and a dynamic one is big regarding the cumulative emissions and the emissions at each moment in time, which was shown in figure 7 regarding the critical year 2030. In that year, given the assumptions made for the public economic scenarios, a public economic incentive to renovate proves to be more effective than a law that makes renovation mandatory. Even though after 30 years these two scenarios reach basically the same cumulative negative GWP value, the incentive proves to be more effective at the time step 2030, which is an interesting finding regarding how to translate climate goals into action-making.

The model helps understanding the temporal profile of emissions. However, it is needed to understand how much GHG emissions CO_2 eqv. Are the actual target by 2030 and, further down the road, this needs to be known by sector and geographic boundary, e.g. for Portuguese building stock.

4.3. Limitations of the study and future research

There is a high uncertainty of the renovation rates and dynamics. The here presented rates should be understood as such. However, they can provide policy-makers with the relevant figures to make informed choices on how to achieve climate targets. There is also uncertainty in the heating and cooling needs. For this reason, a sensitivity analysis was performed. Yet, these interesting dynamics of operational energy needs should be included in future studies, such as the one done by Peuportier *et al.* [22] who already modelled the energy demand of buildings and districts with a dynamic LCA approach that accounts for the temporal variation of electricity production, and of its consumption in buildings.

5. Conclusion

The present study used a specific type of building in a well-defined geographical area to test the effects of retrofit actions of exterior walls of residential buildings considering LC stages A1 to A5 and B6. The results highlight the environmental savings potential of bio-based material to support reaching national and global GHG emission targets. The cost and sensitivity analysis provides information for stakeholders to justify retrofit actions from an environmental and economic point of view. The adaptation of a fb-LCA approach and its application to the building sector has not been done before and proves to be an easy-to-use method to assess different technology options and policy scenarios at a neighbourhood scale.

Potential for energy savings in Czech residential building stock by application of a prefabricated mass retrofitting system

University Centre for Energy Efficient Buildings, Czech Technical University in Prague, Třinecká 1024, 273 43 Buštěhrad, Czechia

antonin.lupisek@cvut.cz

Abstract. Buildings are responsible for a significant share of EU energy consumption. To improve energy efficiency of the building stock, it is needed to significantly increase renovation rates. To overcome actual barriers related to this problem, such as partial and non-systematic renovations, lasting unrest during renovation or time-consuming wet processes, an industrialized construction system using prefabricated modular elements seems to be a possible way. Such system for mass energy retrofitting of residential buildings in Central Europe was developed in H2020 project MORE-CONNECT. The work presented in this article aimed to roughly estimate potential yearly energy savings by applying this new modular retrofitting system on one typology segment of the Czech residential building stock: non-renovated multifamily residential buildings built between 1946 and 1960 with total gross floor area covering over 7 million square meters. The main objective of the research presented in this paper was to make a hypothetic rough estimation of potential yearly energy savings by applying the new modular retrofitting system on a target typology of the Czech residential building stock. According to the calculations, application of proposed retrofitting system on the chosen building type would reduce the total energy consumption in Czech residential buildings by 2.9 % and by 1.8 % compared to energy consumption in all Czech buildings.

1. Introduction

1.1. Need for improved renovation rates in EU building stock

As the European Commission states, *"Buildings are responsible for approximately 40 % of energy consumption and 36 % of CO_2 emissions in the EU. Currently, about 35 % of the EU's buildings are over 50 years old and almost 75 % of the building stock is energy inefficient, while only 0.4–1.2 % (depending on the country) of the building stock is renovated each year. Therefore, more renovation of existing buildings has the potential to lead to significant energy savings – potentially reducing the EU's total energy consumption by 5–6 % and lowering CO_2 emissions by about 5 %."* [1] Thus, finding new ways for unleashing the potential of deep energy retrofitting of the existing building stock is a major concern.

1.2. Barriers

Directorate-General for Internal Policies of the European Parliament in its study on boosting building renovation [2] identified five categories of barriers to renovation: awareness; process; regulatory; financial; and technical.

Since in Czechia there are ongoing public subsidies for renovation and energy savings campaigns, the last barrier – technical – was determined as the crucial one to boost the building renovation in short time period. A technical solution that would overcome disadvantages of present practice was needed.

The technical barriers are in the report further split into three sub-categories: lack of technical solutions; cost of technical solutions; lack of knowledge of the construction professionals. A potential response to these barriers was identified in creating a new retrofitting system that would engage industrialized production of elements at improved level of automation for a specific sub-group of the existing building stock due for retrofitting in the coming years.

1.3. European and Czech residential buildings stock

According to Buildings Performance Institute Europe BPIE [3] in 2011, residential buildings represented 75 % of the EU building stock. At least 80 % of residential buildings were older than 20 years and it seems that residential sector represents a major proportion of the energy-saving potential.

For Czechia, there is available an analysis of the national residential building stock [4] published by the Czech NGO Chance for Buildings. The report indicates that the group of single-family houses built before 1990 (built in poor energy standard) approximately accounts for a total gross floor area of at least 179.3 M m^2. For the multifamily residential buildings, the study presents 104.5 M m^2 in buildings built before 1980. Building stock built between 1946 and 1960 covers approx. 15.7 M m^2 according to the study, which represents 10.0 % of the total gross floor area in Czech multifamily residential buildings (as of 2011).

In another report on building stock renovation strategies [5], Chance for Buildings presents outcomes of a complex modelling of the Czech building stock that the total national energy consumption in buildings in 2016 was 349 PJ, of which residential buildings accounted for 224 PJ and non-residential buildings 125 PJ. The modelled energy consumption included the same consumption categories as energy performance certificates (heating, cooling, ventilation, air conditioning, hot water preparation, lighting, and auxiliary energy).

1.4. Modular retrofitting system for residential buildings as potential tool for significant energy savings in the Czech residential building stock

The EU project MORE-CONNECT [6–8] developed a new modular system for deep energy retrofitting of residential buildings in Central Europe to various energy levels including net zero energy level. The system is based on timber frame panels with thermal insulation for external insulation of façades and roofs and it integrates HVAC, monitoring and renewable energy systems in one package [9].

1.5. Objectives

The main objective of the research presented in this paper was to make a hypothetic rough estimation of potential yearly energy savings by applying the new modular retrofitting system on one typology segment of the Czech residential building stock. The question of interest was, whether it the energy saving potential is significant (i.e. at least 5 % of the final energy consumption of the Czech national building stock), or rather negligible (i.e. bellow 1 % of the final energy consumption of the Czech national building stock). When it turns to be significant, then it would be worthy to seek for policy support to make it happen. On the other hand, when it turns out to be negligible, it would not be worth further investigation.

2. Methods

To estimate the potential yearly energy savings, description of the building typology of concern had to be made at first. Second, a brief summary of the developed retrofitting system with key parameters was composed. Third, a case study of a typical multifamily residential building suitable for application of the new retrofitting system was made. Fourth, the results were roughly extrapolated to the suitable building stock using estimated savings in specific yearly energy consumption and the estimated floor area available for retrofitting.

2.1. Building typology of concern

The system developed in the MORE-CONNECT project was intended primarily for multifamily residential buildings typical for the post-war era. After 1945, there was a huge demand for new flats. At the same moment, left-oriented and since 1948 communist governments ruled the country having socially oriented agenda with the aim to secure jobs and flats for the people. A typical building of that era, that dominated the category of new multifamily residential building until 1960's, was a simple building of up to four floors, with flats of minimum floor area, massive structural external walls made of bricks of typical thickness of 45 cm, pitched roof with ceramic tiles on timber rafters with free loft area, typically with cellars partially underground (see CZ.N.AB.03 in Figure 1). After 1960, a new type of massive prefabrication stepped in and replaced the brick-and-mortar buildings by concrete slab housing, typical in Eastern part of Europe (CZ.N.AB.04 and CZ.N.AB.05 in Figure 1).

Both these typologies together present a major group in Czech building stock. The newer concrete slab houses were examined by Estonian partners of the MORE-CONNECT project, this paper deals with the multifamily residential buildings built before 1960 (CZ.N.AB.03). Their building typology has a high potential for application of precast modular retrofitting solution because of its energy inefficiency; simple design with low architectural quality; or high number of similar building with unified design. It also carries further challenges concerning low quality of after-war materials and thus its structures.

Figure 1. Overview of Czech residential building typologies with a highlighted typology of concern. Figure taken from TABULA report [10].

2.2. New system for modular retrofitting of post-war residential buildings

To provide desired rapid refurbishment to the building owners and users, the new system was designed to integrate as much functions as possible. Complete building refurbishment thus uses number of structural prefabricated modules (wall, roof, basement module, balcony) and technological modules (ventilation module, engine room etc.). These modules get combined and connected to the existing building using tailor-made steel anchors. The main load-bearing core of the structural modules was created by timber frame and strengthened with fibre boards. Interior side of the modules is designed to fit tightly to the uneven original façade surfaces. The system is variable; the total *U*-values of the refurbished envelope can vary within wide range of values. The core is fitted with main layer of thermal insulation and the module is finished with external thermal insulation of variable thickness with final façade layer. Where needed, the thermal bridges are minimized using aerogel. Windows equipped with electric window blinds are part of the module. The system also enables extension of the unit's floor area by attaching an additional balcony.
Structural elements are fitted with all necessary technologies: HVAC providing air ventilation with heat recovery, hydraulic heating pipes, electric window blinds to control overheating. In the Czech case, the engine room would be installed in one of the empty rooms in the building basement. There were developed inter-modular connectors that enable connection of the integrated sensors for monitoring indoor air humidity, temperature, or moisture content with control system and equipping each apartment with new Wi-Fi routers. The indoor environment in apartment can be controlled by app on smart phone or tablet. Further technical information is available in [9].

Complete solution is protected by national utility model.

2.3. Case study of a typical representative of the typology

2.3.1. Description of the building. As a reference building, a post-war residential block in Milevsko, Czechia, built in 1958 was chosen. The building by its typology and material basis represents a significant part of the residential housing stock of Czechia suitable for retrofitting. This particular building, used as social housing, has 24 studios (living/sleeping room, kitchen, bathroom), 31 m^2 each, in three stories (see Figure 2).

Figure 2. The building type from the case study in Milevsko, Czechia.

Each flat has two windows oriented either to the east or to the west. Technical and housing facilities and cellars are put in the basement, which is partially underground. Entrance to the building is from the north, leading to the wide central hall with north-south orientation. At the southern façade, central hall is ended with a loggia. The building has a gable roof (33°), attic space is currently unused. Building has longitudinal wall structural system made of bricks (450 mm), ceilings are made of reinforced concrete. Façades are plastered, original windows and exterior doors have been replaced with insulating double-glazed ones with plastic frame.

2.3.2. Retrofitting strategy. The general strategy came out from the analysis of typical representatives of the select typology, their technical shape and needs, and from the SWOT analysis of typical common retrofitting interventions offered on the market nowadays. The limitations given by the building typology are given by the fact that the major part of the building envelope is at the same moment the load bearing structure – typically the masonry walls of 450–600 mm form the supporting structure for the concrete floor structures. Therefore, there is no option for their replacement, the only way is to make an addition upon the existing walls. There is also planned an additional layer of thermal insulation to be placed in the attic and the floor above the cellar will be insulated as well. A mechanical ventilation system with heat recovery supplies fresh air into each of living rooms and can also provide space heating. The air ducts are integrated in the wall panels together with sensors for controlling the indoor environment in each apartment.

2.3.3. Simulation outcomes. For the case study building, a set of computational simulations has been performed both for the state before renovation and for the renovated building. Results of these simulations have been used for estimation of energy savings presented in this section.

Before renovation, calculated total energy consumption accounted to 308–318 kWh/(m^2·a), energy consumption for heating was 230–237 kWh/(m^2·a) (depending on a heat source – district heating system and natural gas boiler were considered as initial state). The report [10] indicates for the given typology typical specific energy consumption for heating 222 kWh/(m^2.a), which is in line with our case study.

Common retrofitting practice is wall insulation with ETICS supplemented with insulation of attic and the floor above the cellar, and windows replacement. However, as can be seen from the report [11], the renovation employing the MORE-CONNECT system provides a solution of a higher standard with comparable costs. Therefore, a potential of energy savings presented further in the text is based on the MORE-CONNECT solution.

Depending on a renovation level and a possible heat source replacement (see [11] for details, results presented there expressed in primary energy and GWP), total energy consumption can decrease up to 33–90 kWh/(m^2·a) (89–71% savings), which corresponds to specific energy consumption for heating between 25–41 kWh/(m^2·a) (89–82% savings). Thanks to mechanical ventilation, *U*-values at a passive standard level (mean *U*-value is 0.25 W/(m^2·K)), and generally deep energy retrofitting, this surpasses the predictions reported in [10] where typical energy need for heating after application of progressive measures reaches 63 kWh/(m^2·a). Expressed as specific energy saving potential, retrofitting using MORE-CONNECT solution can save 251 kWh/(m^2·a) from total energy consumption in average (up to 285 kWh/(m^2·a) at maximum).

2.4. Extrapolation to the building stock

For further calculations, the total gross floor area of the Czech multi-family residential building stock built between 1946 and 1960 of approx. 15,657,000 m^2 [4] was used as a basis. The developed solution has limitation given by the national fire safety regulations, which forbid combustible products to be used in the envelopes of buildings with fire height above 12.0 m (i.e. distance between first and the upmost flooring). This regulation reduces the applicable gross floor area to 10,926,000 m^2 of buildings up to four floors. As mentioned in the introduction, 35 % of the Czech residential buildings have already been retrofitted, so the remaining gross floor area available for retrofitting has to be reduced to 7,101,900 m^2.

3. Results

The result of the rough estimation comes from a simplistic multiplication of the gross floor area available for retrofitting by the specific energy saving potential coming from the case study. The resulting hypothetical energy consumption saving potential (when the proposed system gets applied to all suitable multifamily residential buildings in Czechia) is 1,783 GWh/a. The figure represents 1.8 % saving on the total national energy consumption in buildings and 2.9 % of total national energy consumption in residential buildings (compared to 2016 baseline).

4. Discussion

4.1. Limitations of the study

There are many sources of uncertainties in the study. Firstly, it is based just on one case study, which cannot be taken as representation of the whole residential building stock. At the same moment, the statistics behind the figures on the Czech building stock are potentially inaccurate.

On the other hand, the purpose of the study was only to tell globally whether the potential energy savings from the proposed mass retrofitting would be significant or negligible.

4.2. Conclusion

The result of the calculation showed, that the potential for savings in the energy consumption of the residential buildings is 1,783 GWh/a, which represents 1.8% saving on the total national energy consumption in buildings and 2.9 %, of total national energy consumption in residential buildings (compared to 2016 baseline). The result is not significant, but not negligible. A bold policy action on the national scale would not be justified, on the other hand, it is worth trying to discuss with the policy makers inclusion of the support of this type of energy renovation into the national subsidy schemes for energy savings in buildings and to look for suitable industrial partners for market uptake.

Abstract. European Directive (EU) 2018/844 amending Directives 2010/31/EU (EPBD) and 2012/27/EU (EED) aims at decarbonizing the European building stock. Energy efficiency measures and renewable energy use play an important role, especially regarding retrofit of existing buildings. Identification of retrofit opportunities and aggregation of projects to benefit from economy of scale are a precondition for the implementation of large-scale renovation projects. The ENERFUND project, funded by the HORIZON 2020 programme, provides data from Energy Performance Certificates according to EPBD publicly available in the form of a map and combines them with other geo-referenced data and general information to allow for the rating of deep renovation and carbon reduction opportunities. In this way, the tool assists in identifying retrofit opportunities and aggregation of projects for financing. It also assists in supply-side energy spatial planning, because it shows where energy consumption is likely to decrease due to economic renovation potentials. This contribution shows an overview of data available for thirteen European Member States. Data sources and differences regarding the type of data are explained, and challenges such as data quality issues and data protection concerns are discussed. It is demonstrated that the ENERFUND tool certainly assists in decarbonizing the European building stock, although some improvements are still necessary.

1. Introduction

The Energy Roadmap 2050 is the European Union's long-term strategy to achieve the goal of securing sustainable energy supplies. This effort builds on the first package of climate and energy policies adopted in 2008 and on the framework for climate and energy policy until 2030 agreed upon in 2014, representing the so called Energy Union. Among other important aspects such as research, innovation and competitiveness needed for the transformation of the energy system, climate protection and the conversion to a low-carbon economy, the priority for energy efficiency is explicitly stated.

On 30 November 2016, the European Commission presented several documents intended to achieve the transition to a sustainable energy system. Among others, there were proposals for the revision of Directive 2012/27/EU (Energy Efficiency Directive EED), Directive 2009/28/EC

(Renewable Energy Directive) and Directive 2010/31/EU (Energy Performance of Buildings Directive EPBD), as well as the proposal for a regulation on governance, in order to ensure Member States' coordinated reporting on compliance, particularly with the EU Energy and Climate Targets by 2030.

In this article, the focus is on the building sector and especially on improving the energy efficiency of existing buildings. The amending Directive (EU) 2018/844 resulting from the proposals for revisions of the EPBD and the EED, transfers the long-term renovation strategy from the EED to the EPBD and introduces the obligation to specify detailed targets and milestones. Furthermore, the progress achieved shall be reported thoroughly. The new EPBD article 2a "Long-term Renovation Strategy" stipulates that each Member State must ensure a highly energy-efficient and decarbonized national building stock, with a roadmap of indicative milestones for 2030, 2040 and 2050. In order to support the mobilization of investments in renovation, Member States shall, inter alia, facilitate access to appropriate mechanisms. For example, the bundling of projects provides a possibility for small and medium-sized enterprises to gain easier access to financing (article 2a number 3 (EU) 2018/844). The goal is to develop large-scale renovation projects that can be implemented more cost-effectively than many small individual renovation projects. The new article 2a is a reaction to the fact that the 3% renovation rate has not been achieved despite years of effort (see also rec. 10 (EU) 2018/844).

With regard to energy performance certificate (EPC) databases, Directive (EU) 2018/844 introduces two new paragraphs 6a and 6b into Article 10 (6) of Directive 2010/31/EU, stating that EPC databases allow the collection of measured or calculated energy consumption of the buildings covered. At the minimum, the anonymized data collected in accordance with the data protection requirements of the Union and its Member States, shall then be made available for statistical and research purposes. These data will also be at the building owner's disposal.

The ENERFUND project explicitly aims at making use of EPC databases having been established in many EU Member States in the process of implementing the independent control system according to article 18 EPBD. A tool was developed to display energy related building data in a geo-referenced way by means of a Geographical Information System (GIS), in order to allow for identifying areas of interest for large scale and deep building renovations.

This article explains the development process of this instrument, describes encountered challenges, and shows an overview of selected country results. It concludes with a presentation of lessons learnt and future outlook.

2. Developing the ENERFUND Tool

2.1 Objectives and technical solution

The aim of the ENERFUND tool is to be a quick evaluation instrument, assisting financial institutions, owners and ESCOs interested in examining the feasibility or usefulness of deep energy renovation of commercial and other buildings in a thorough way. Therefore, identified open source databases with significant information about building energy performance were integrated in the tool in a user-friendly manner. The interface of the tool is a European map which displays buildings and building units with coloured dots, in accordance to their energy label and with several filtering options in order to assist the user to narrow the range of screening buildings according to his or her preferences. At the home page of the ENERFUND tool, a drop-down list with all countries involved is available, in order to minimise the processing duration due to the large amount of integrated data. Additionally, after selecting the country of interest, the user can compare buildings and view detailed information regarding their energy performance along with other information for the building. Furthermore, the tool provides the ENERFUND score per building or building unit on a per cent scale. This score can be used to compare buildings of any country, since the score formula used is common for all countries. Finally, the user can produce a report based on the selection criteria. As a future development of the tool, in order to increase the tool's functionality and accuracy, user inputs regarding the selected buildings will be enabled.

2.2 Available data source

In order to identify the most important data and parameters for the development of the ENERFUND tool, several key elements and criteria were initially examined according to previous studies, expert's opinions and surveys conducted in the framework of the ENERFUND project. EPC databases were identified as the major databases for the ENERFUND tool since they include a variety of important information for the energy performance of the buildings [1]. Nevertheless, additional available databases, including significant data for the energy renovation decision making process, such as Noise Databases and Building Price Databases were embedded. The level of publicly available information in EPC databases varies between Member States. In some cases, open access to EPC data is provided directly from the database of the competent authorities (such as Denmark, Bulgaria, the Netherlands, the United Kingdom); whereas in others, only aggregated results are made publicly available (such as Greece, France and Romania). However, in most of the countries studied (i.e. Cyprus, Austria), there is no publicly available access to the EPC database. Complete access to the core of the database, meaning access to all raw data, is not provided by most Member States [2]. Furthermore, in none of the studied cases data were geocoded in a way that would allow automatic mapping on the ENERFUND map.

2.3 ENERFUND score

The ENERFUND score assists the decision-making process for the energy renovation of buildings and is based on a Multi Criteria Analysis methodology. It is a result of an equation that uses eight main parameters, with different weight factors, which have been selected as key parameters for building energy retrofitting: Total Area and Energy Saving Potential (Mandatory Parameters), Construction Year, Average Building Sale Price, Occupancy Level, Own Contribution (to financing renovation), Noise Levels and Building Ownership Status. ENERFUND score uses data only from open databases available in the EU, in order to maintain up to date data. In case that any of the above parameters are not available, default values have been used. The highest score that can be granted is hundred.

3. Member States data embedded in the tool

3.1 Overview of country data

In February 2019, approximately eight million EPCs were mapped across thirteen Member States. In total more than seventy million unique data entries (such us wall energy efficiency, construction year, etc.) are available in the context of this tool, but still availability differs from country to country. For example in Slovakia, only the EPC rating and the building type are available in the tool, while for the UK, ten parameters per EPC are available. In the following sections, three countries, representing different situations, are described in detail by answering the next questions:

- How were the data made available for ENERFUND? What had to be discussed, agreed upon, or clarified?
- Is the full EPC data set included or only part of it?
- What are the reasons for a country-specific partial availability?
- What difficulties were encountered to get the data for ENERFUND and what were the solutions provided?
- What is the opinion regarding data quality and data protection?
- Which specific features are especially interesting for which target groups?
- What are the lessons learnt?

3.2 Denmark

Ever since the first EPC scheme was launched in 1997, all Danish EPCs issued were uploaded to one central database hosted by the Danish Energy Agency. Following EU legislation, the legal framework of the Danish EPC scheme has undergone several revisions. The last major revisions were in 2006 and 2011.

The first time the Danish EPC database was made available to the ENERFUND tool, all EPCs issued since 2006 were part of the data transfer. This first transfer was based on a 2015 copy of all Danish EPCs including domestic and non-domestic buildings. A quality filter ensured that only EPCs with reasonable data would be accepted. Therefore, by definition the full Danish EPC data based on the 2015 copy have been made available for the ENERFUND tool. Due to lack of permission to use data from the live database, all EPCs issued at a later date could not be included. This difficulty has now been overcome thanks to a direct University access to the EPC database. Put otherwise, now a new updated EPC data copy can be extracted at any time and transferred into the ENERFUND tool.

The quality of Danish EPCs has been increasing steadily. Since the revision of 2006, all EPCs are presumed high quality records. Concerning data protection, only buildings owned by the Ministry of Defence must be observed.

Since COP 21 and the Paris agreement, Danish target groups, especially Danish municipalities, have put special interest on the ENERFUND decarbonizing rating feature, i.e. the possibility to compare buildings concerning their carbon reduction potential. This not only applies to municipal owned buildings but also to private domestic and non-domestic buildings located on the territory of the municipality. The reason is that politicians and local authorities of a number of municipalities hold themselves responsible to meet the Paris agreement, and buildings stand for a large share of greenhouse gas emissions.

3.3 Spain

Spain follows a regional approach for the certification procedure, therefore there are no central registers, but smaller, regional ones instead. Considerable effort was necessary to transfer EPC data into the ENERFUND tool. First, it was analysed which data were available online. It was found that only ten out of nineteen registers were accessible through the internet; furthermore they use different search parameters depending on the region. The EPC rating is the only parameter all of them have in common. Secondly, the availability of geocoded data was investigated. Only two out of these ten regions displayed geocoded data, but only one presented it in such a way that it was downloadable as open data. In Royal Decree 235/2013 it was stated that the registers would allow citizens to access the information on energy performance certificates. Implementation is being realized little by little.

Finally, data for four regions are available on the tool: Comunidad Valenciana, Cataluña, Castilla La Mancha and País Vasco. Since EPC data were stored in different ways depending on regional registers, approaches to make these data available for ENERFUND vary accordingly. One region showed special interest to provide data in a quality that allows automatic updating and availability in the tool. This represents one of the ENERFUND success cases.

In Spain the full EPC dataset is not publicly available, that is the reason why only data on the EPC label is accessible within the ENERFUND tool. As a consequence, stakeholders do not consider data protection as a problem: the tool only shows data that is already public anyway. For instance, public buildings must show EPC label data.

Summarizing, the ENERFUND tool is considered to be very interesting and useful by the Spanish majority. Nevertheless, there is a need to standardize the storage and the online public availability of data among the different regions. These data should also be downloadable in a homogeneous format.

3.4 Romania

In the case of Romania, the process of implementing available EPC data in a structured format to meet the program’s requirements, started also with the national EPC database.

The national EPC database was first introduced in the legal framework in 2007 and started to receive EPCs from energy auditors for buildings in 2008. Although a full structure of the database was defined in 2010 (with an xml format for making the system automatic) and another application was developed by the responsible authority in 2016 to facilitate the on-line submission of EPCs, the system is running manually, with EPCs sent by e-mail and stored by the energy auditor.

Since there is a great diversity of received (electronic) formats (pdf, doc, docx, xls, xlsm, xlsx, jpg, tiff, gif, html, etc.), either as the final draft document or scanned copy of the signed and stamped EPC, it is almost impossible to transform the gathered information into structured data that can be further processed to supply meaningful performance information about the existing building stock.

In this context, the data to be introduced into the ENERFUND app were based on about 46,000 EPCs that were entered manually into the structured database (11,300 buildings and 34,700 individual apartments in collective buildings), representing three to four percent of all issued EPCs. The data were geo-located, filtered and introduced on the map, both as individual data and in aggregated form. The first step of aggregating data at county level did not lead to useful information (area too big), so the aggregation was performed later at smaller areas (small city or district in large cities).

The difficulties encountered in entering data into ENERFUND were first in finding relevant data (except EPCs) and secondly geocoding available data. Most of the data needed to calculate the ENERFUND score were not available and thus considered from default values (same for all areas).

The public status of the EPC data is not specifically defined, however no explicit prohibition to publish the EPC information exists in the legal framework. On the other hand, the EPC does not contain any personal data related to the building owner.

The ENERFUND features are widely appreciated by all stakeholders, but without the introduction of relevant data, the tool is not of appropriate advantage for any interested party. Thus, the population of the tool with detailed EPC data together with other type of information (like social and income information aggregated at district area, availability of experts and specialised construction companies, energy and utilities map, renovated buildings etc.) could lead to an important raise in the usefulness of the tool. Moreover, all data should be geocoded in order to facilitate the integration in the tool; the new EPC template (methodology under revision) must include geo-coordinates that should be reported in the database.

4. Challenges encountered and lessons learnt

4.1 Challenges encountered

Regarding the data necessary for a successful transfer into the ENERFUND tool, the following problems have arisen:

- EPC data is not publicly available, or in electric format that can be easily used by the public or even by the relevant authorities.
- EPC data was not geocoded and therefore it took longer than expected to display the data on the map. Geocoded addresses do exist (see for example INSPIRE directive [3]), but are not yet linked with EPC data addresses.
- In some countries, EPCs issued in the course of renting or selling a building or a building unit, are not fully trusted. The reason is that energy performance calculation is done based on default values, and often the building is not even visited.
- EPC data is not harmonised across all Member States. In some cases, all data to calculate the EPC rating is available (i.e. door surface area), while in others, only the EPC rating is available, thus making the database unusable for the needs of the ENERFUND tool. Furthermore, the classification of each data category is not standardized, therefore cross-country comparison is not always feasible.

4.2 Open Government Data (OGD) versus General Data Protection Regulation (GDPR)

Energy-related building data displayed by the EPC and describing the technical characteristics of a building can be classified as non-personal data because energy efficiency indicators are calculated using standardized usage profiles without reference to the actual users of a building. Non-personal data do not fall under the GDPR [4] but can be classified OGD if specific requirements are met, such as reliability of information, relevance for the public, and rights to publish the data. OGD are data of the administration, which are accessible to the general public for free use, distribution, and further disposition. Legal bases are several EU directives, for example Directive 2013/37/EU (re-use of public sector information) and Directive 2003/4/EG (public access to environmental information).

Reference is made here to Directive 2007/2/EC as the basis for creating a common spatial information infrastructure in the European Union (INSPIRE). The visualization of the building address is the prerequisite for the publicly accessible, geo-referenced presentation of EPC data and the utilization of information for project developments and innovations. However, in some cases, the building address could be combined with the registry showing the principal residences and thus represent a case of identifiability of individuals according to GDPR. Under this perspective, the address of a residential building can be viewed as personal data. If the GDPR applies, rules for lawful data processing will be mandatory. Usually, lawful processing takes place according to article 6 (1) e GDPR (if there is public interest) or article 6 (1) f GDPR (if there is legitimate interest).

However, there is a range of interpretation regarding the definition of "identifiability" and also "public interest". While in some countries accessibility of EPC data is clearly regulated, there is no clear view on how to deal with it in other countries, for example in Austria: there is no agreed approach on how to define identifiability and there is no established mechanism how to balance public interest against personal rights. It must be noted that the GDPR is not about data protection as such, but about the protection of personal rights. These rights must be balanced against the public interest in accessible information needed for awareness creation and better decision-making. Public access to EPC data can be seen in the context of the INSPIRE Directive, as illustrated by a JRC report on the harmonization of EPC data for use in a common spatial information infrastructure [5]. However, this report is not strong enough to invalidate GDPR-related concerns. A guidance note issued by the European Commission on the public access to geocoded building related EPC data would be useful.

4.3 Quality of EPC data: reliability, comparability, electronic format

The main data source for the ENERFUND tool is represented by the available set of EPCs for a specific country or region. Since its definition and enforcement, the EPC was acknowledged with the potential to become an effective tool to support the implementation of building policies and incentives to upgrade the energy performance of buildings. Achieving the desired impact in the market strongly depends on the actual quality of EPCs, which can be achieved through the implementation of a clear calculation methodology with explicit procedures, the creation of effective tools for calculating or selecting inputs, and the approval of a robust compliance check frame.

The issue of quality of EPC data is twofold: on the one hand the quality of the energy performance certification process, and on the other hand the quality of EPC data to fit into the ENERFUND tool requirements in order to facilitate the decision for building renovation. Another European project, the QUALICHeCK project, confirmed that problems do exist with EPC quality and input data, as well as with compliance frameworks which are still in the development process in all countries [6]. As an example, a new field study on the assessment of quality and compliance in the EPC system in Romania [7] showed that recalculation of 25 EPCs based on field-proven input data lead to a change in energy class in almost 40% of the sample for the total energy use. Although progress can be seen in most Member States, the status on the ground needs continuous monitoring. More efforts should be put into systematic data collection and the application of validation procedures in order to assure the credibility of energy performance requirements and EPC system.

A solution for these problems could be the implementation of an on-line submission of EPC data, based on a defined electronic format as it is already used by many Member States. Developing the structure and defining the requirements for an electronic format of issued EPCs to feed the central EPC register can facilitate access in real time to building stock data together with tools for the plausibility and quality checks of relevant data. Furthermore, the application of the EPC control system will be facilitated, thus improving the quality of EPC elaboration by providing feedback to energy auditors of buildings.

However, even if country specific information is publicly available in a format easy to display by means of GIS, the problem of lacking comparability remains when data from different countries should be assessed. Energy performance category B of a building in Denmark does not imply the same primary energy demand compared with energy performance category B of a building in Greece. Energy performance requirements of building components such as U-values of windows are different in Austria and Spain, for example. Nevertheless, the purpose of the ENERFUND tool is to present the building data in the most possible coherent way to help the user identifying opportunities for businesses related with deep renovation of buildings. Some information is necessarily specific to a country or even region, due to climatic reasons. Therefore the method of introducing a qualitative scale ranging from “very good” to “very poor” was introduced. However, it will be useful to specify a minimum number of data fields for geo-referenced presentation in a uniform way, such as year of construction, type of building use, m^2 useful area, type of fuel used, year of EPC issuance, overall energy performance rating, rating of energy efficiency of the walls, windows, roofs, and heating system. This format should be made mandatory for all EU Member States, as well as the obligation to make this information publicly accessible.

5. Conclusions and Outlook

5.1 Future tool development

An update of the ENERFUND tool will include a carbon-reduction benchmark. Thereby, the decarbonizing potential of any building or whatever selection of buildings can be benchmarked against any other building or selection of buildings. The carbon emission feature will be based on the actual and potential energy consumption, and in case this information is missing, the actual and potential EPC rating values. Combined with knowledge about the national energy mix or preferentially the energy supply labelling of each building, the buildings can be furnished with a carbon emission reduction benchmark. Moreover, this information can be used for a decarbonizing score.

The first countries are in preparation for GIS visualization of their carbon emission benchmarks. Among these is Denmark with an EPC data set containing the buildings’ actual and potential energy demand, and - in addition - the sort of energy supply for each building like electricity, natural gas, district heating and fuel oil. A list of carbon emission factors of each fuel and regarding electricity and district heating, the actual kg of carbon emission per kWh delivered, completes the data set.

In other words, with these features in place, the ENERFUND tool definitely will be able to contribute to the decarbonizing of the European building stock.

5.2 Recommendations

The EPBD does not require an electronic EPC database to be used as the basis for the establishment and operation of the independent EPC control system. However, many Member States or regions have chosen this approach because effective control is otherwise difficult in a cost-effective way. It also implies the possibility of using the data for energy-related purposes other than the control of energy performance certificates. The EPC is thus not only used for information on the energetic state of the building, but the underlying calculations and technical documentations are also valuable to build up databases for different purposes: for strategic investigations, project developments, and statistical analyses.

Public access to geo-referenced EPC data plays an important role in raising awareness and participation as part of the Long Term Renovation Strategy, and also in strengthening innovation in the development of products and services for greater energy efficiency and reduction of CO_2 emissions. The analysis presented here shows that harmonization across Europe is urgently needed in two ways: first, regarding energy data as such, and second, regarding geo-coding and public accessibility.

Therefore, the ENERFUND project will conclude with a recommendation to the European Commission and DG Energy in particular, that harmonisation of all energy data, not only EPC data, - and their geocoding - should become mandatory across all Member States.

Defining a framework to apply retrofitting optimisation models for long-term and step-by-step renovation approaches

Maia I, Kranzl L

Technische Universität Wien

maia@eeg.tuwien.ac.at

Abstract. The recast of Energy Performance of Buildings Directive (EPBD) 2018/844/EU introduced in the article 19a the possibility of building renovation passports which provide a long-term and step-by-step deep renovation roadmap for a specific building. Preliminary results showed that optimisation models for deep renovation of existing building almost exclusively optimise single stage retrofitting. Different from the single stage approach, in the step-by-step approach the retrofitting measures are not performed at the same time. In the present study, we aim to understand how the methodological approach of optimisation models for single stage retrofitting can be adapted to a step-by-step renovation concept. For this, first, the existing optimisation models were compared in terms of integration with external tools for energy demand calculation, definition of the renovation measures, objective function, and the question to which extent they consider long-term dynamic aspects of step-wise retrofitting optimisation over several years or even decades. Second, after identifying possible obstacles for adapting existing optimisation approaches towards step-by-step renovation, a framework for a step by step renovation optimisation model was outlined. The framework defines how the single stage retrofitting measures could be broken down in different renovation steps over a period of several years or even decades and which criteria should determine the time-wise prioritisation of the retrofitting measures. With this approach, we prepare the ground for the development of innovative tools, supporting the provision of individual renovation roadmaps. Next steps of the present study are testing and improving the outlined optimisation approach, as well as, extending the results to a building stock scale. By that, we aim to develop a method for analysing possible impacts of step-by-step renovation measures on achieving building stock's decarbonisation targets.

1. Introduction

The building sector has been identified as one of the key sectors for achieving the energy and climate policy targets of the EU, as buildings are responsible for 40% of energy consumption and 36% of CO_2 emissions in the EU [1]. Although huge efforts have been made to reduce the energy demand of buildings, recent statistical data about final energy consumption in households [2] and share of final energy consumption per fuel [3] have shown that there is still a long pathway to achieve the EU-targets. Therefore, is it necessary to find alternative deep renovation concepts for the building stock decarbonisation.

The EPBD recast 2018/844/EU introduced in the article 19a the possibility of building renovation passports, which provide a long-term and step-by-step deep renovation roadmap for a specific building. The step-by-step deep renovation roadmap is at its core a home-improvement long-term plan, which considers the occupants' needs and specific situations and avoids the risk of lock-in effects, if future renovation measures are not considered in current activities. This document guide and help building owners through the renovation process, therefore dealing as an instrument to overcome barriers, as lack of acceptance. The building renovation passport is definitely an important instrument at EU level, to support deep renovation of existing buildings and bridge the gap between real renovation processes and the EU-targets for building stock decarbonisation.

In the literature, there is no consensus that deep renovation can also be achieved by a sequence of step-by-step renovation measures, which indicates that in fact, "deep renovation" is not necessarily restricted to single stage renovation. Nevertheless, creating more comprehensive modelling for this alternative retrofitting concept could help on accelerating the decarbonisation of the building stock due to suitable and right timing measures. In Europe, there are already some demonstration projects, which focus on the key concept of building passports, as the iBRoad EU-funded project, which works on eliminating the barriers between house owners and building energy performance, by developing building passport and step-by-step long-term deep renovation planning tool for single-family houses. Also, taking into consideration that in real life, the most retrofits activities are performed step-by-step [4], the main goal of the present paper is to outline a framework for the step-by-step renovation by adapting optimisation models for single stage retrofitting, and preparing the ground for the development of innovative tools, supporting the provision of individual renovation roadmaps.

2. Outlining a framework for step-by-step optimisation

Literature review

A retrofitting optimisation model aims at calculating the optimum solution of retrofitting measures' combination. The optimal retrofit strategy may include ecological (i.e. energy savings, CO_2 emissions, environmental impacts) and economic (i.e. net present value, investment cost, payback time, life cycle costs) objectives and/or restrictions. Many studies have presented different methods for selecting this most suitable solution, differing according to the targeted benefits, which are represented by the objective function. Therefore, the main objective of the literature review is to compare several models and to prepare the ground for outlining a framework for step-by-step optimization modelling.

The models are compared in terms of integration with external tools and database, definition of the renovation measures and, methodological approach and aspects of time wise dynamic retrofitting over several years or even decades. It was observed that most papers studied do not cover the dynamic time wise aspect by considering that retrofitting measures are applied at the same time, so called single stage retrofitting. Further conclusions to that are presented in the end of this chapter.

Most recently, Jafari et al. [5] reviewed at least sixteen literatures about energy efficiency decision-making, including not only multi-objective optimisation, but also other methods like multi-criteria, techno-economic evaluation method and others. The same authors present an optimisation framework to minimize the future cost (life cycle cost minus initial investment costs) of a building. In this approach, the energy savings are indirectly represented by the energy costs, which are part of the life cycle costs. The set of retrofitting measures goes beyond building envelope (ceilings, walls, attic insulation), including load reduction measures (heating and cooling), controlling measures (ie. programmable thermostat) and renewables option (i.e. solar thermal and solar electricity).

Pombo et al. [6] compare different retrofitting solutions, using a multi-criteria methodology. This study combines Life Cycle Assessment (LCA) and Life Cycle Cost (LCC) by expressing environmental impacts in monetary values. Here, the minimum investment cost and minimum life cycle savings are determined through a Pareto curve. The set of renovation measures chosen aimed at reducing space heating and cooling demand by insulating roof and façade, changing the windows and installing a heat recovery system. Asadi et al.[7] developed a model to assist stakeholders in the definition of measures aiming at minimizing the energy needs for heating, cooling and domestic hot water, and maximizing the investment costs. As set of retrofit actions, the authors considered window replacement, external wall and roof insulation and solar collector type. Wang et al.[8] proposed a life cycle cost approach, which

aimed at maximizing energy savings and net present value while minimizing the initial costs. The chosen measures were lighting facilities, heat pumps, chiller, control systems and other devices, with focus on reducing the electricity energy demand. Murray et al. [9] coupled a degree-days simulation with a generic optimisation procedure algorithms and compared both implemented and calculated retrofit solutions. This study aimed at minimizing the energy cost and carbon emissions post-retrofit, under the consideration of a payback period of maximum 5 years and capital investment. The adjustable parameter set were U-value from Attic, external walls and windows, boiler type and infiltration rate.
Table 1–summarises the studies presented above, its methods, main objective functions and chosen measures.

Table 1: Summary State of the Art

Refe-rence	Title	Objective Functions Optimised	Benefits							Time step of the measures	Energy performance method
			Energy consumption	Retroffing measures	Energy cost	Retrofittig cost	Building material charactheristic	Maintenance cost	Thermal comfort		
[9]	Optimization for Building energy retrofits decision making	Minimizes the total life cost Maximizes home owners economic benefits (optimum retrofit benefit) Budget restriction	x	x	x (natural gas, and electricity)	x		x		Single-stage	eQUEST
[11]	Multi objective optimatisation for building retrofit	Minimizes retrofit costs Maximizes energy savings	x	x		x				Single-stage	Simple thermal model – building code based (RCCTE - Portuguese), based on thee ISO 13790
[18]	Sustainable retrofits under uncertainities	No				x	x			Single-stage vrs multi-stage	No
[12]	Multi-objective optimization model for the life-cycle cost analysisand retrofitting planning of buildings	Maximizes energy saving Maximizes the discount pay back period Minimizes initial costs	x	x	x (electricity)	x	x	x		Single-stage	Unknown

[10]	Sustainability assessment of energy saving measures: A multi-riteria approach for residential buildings retrofitting—A case study of the Spanish housing stock	Minimum investment cost Maximum life cycle savings	x	x		x	x			Single stage	Energy Plus and DesignBuilder
[13]	Multi-variable optimization of thermal energy efficiency retrofitting ofbuildings using static modelling and genetic algorithms - A case study	Minimum energy cost Minimum carbon emission Maximum simple pay back time	x	x	x	x				Single stage	CIBSE Guide TM41, Degree Days

In the literature review some differences between the studies were observed, as for example the energy performance calculation method. While some authors used simplified calculation procedures, others used more complex dynamic simulation programs. On the other hand, all methods have in common not presenting any indication about the timing, when the retrofit measures are performed. In terms of the dynamic time wise, any of those papers explicitly mention this aspect, this leads to the conclusion that it is considered that the retrofitting measures are applied at the same time, so called single stage retrofitting.

Different from the single stage approach, in the step-by-step approach retrofitting measures are not performed at the same time. Previous studies [10] on historical energy performance and deep renovation trends in the German's residential building stock proved that in many buildings single renovation measures (only windows replacement, or only roof insulation) have been performed. Beyond that, Steiger [4] affirmed that in real life, most retrofit activities are performed step-by-step sequences, and Menassa [11] presented financial advantages of multi stage retrofitting. Thus, step-by-step renovation modelling deals with following questions: how to define a renovation step? Which retrofitting measures are performed in a step? When are they performed? In which sequence are they performed?

Outlining the step-by-step optimisation approach

In the step-by-step concept, a step consists of combination of one or more retrofitting measures. The literature review showed that common retrofitting measures are: insulating building elements external walls, roof (or top floor ceiling) and floor, replacing windows, and active system (heating, cooling, ventilation, lighting and domestic hot water). In real-life, other aspects like construction site preparation and scaffold costs, are also relevant to define, if the measures will be performed together, or not.

During a building's life cycle, maintenance and operation activities constantly happen to avoid first stages of degradation and failure of building elements [12]. At the same time, usual maintenance activities and/or material replacement provide an opportunity for increasing building element's energy efficiency, and consequently improving building's energy performance. Refurbishment activities can be induced by unpredictable damages, as breaks, leakages and cracks, familiar circumstances i.e. children birth and family members move out, etc. Or predictable parameters, as material's durability, which defines the material's lifetime. In a study about factors influencing German house owner's preferences on energy retrofits, the authors [13] concluded that most homeowners have a rational behavior to wait until building components end of their useful life before approaching renovation or replacement. Therefore, predicting the building materials' aging process helps to determine the timing aspect of the step-by-step approach.

Together with technical aspects, in single family houses retrofitting, the homeowners are a key decision maker. On a study about drivers of thermal retrofit decisions, the authors pointed that the up-front costs are a key barrier to the pursuit of building retrofit [14]. Thereupon, the second important parameter refers to economic aspects. Some authors [5] [8] included the budget restriction in their models, however as a fixed value without a method justification. A plausible assumption is to address existing assets for retrofitting (based on family's income and available budget).

3. Method

This chapter outlines a method for step-by-step optimisation modelling from building owners' perspective. The main target is to maximize the net present value of (cumulated) income available for energy related expenditures minus energy related expenditures over a certain optimisation period. It is assumed, that the building owner allocates a regular part of her/his income and spends part of it for energy related expenses (investment costs for retrofitting measures, running energy and maintenance costs).

Objective Function

The optimisation model should find solutions for maximising the net present value according following objective function:

$$\max NPV = \sum_{t}^{T} \frac{CF_t}{(1+r)^t} + \frac{L_T}{(1+r)^T} \qquad \textit{Equation 1}$$

NPV, energy related net present value [EUR]; *CF*, cash-flow of energy related balance; *L,* residual value of the retrofitting measures in year T; *r*, interest rate [%]; t, time [a]; *T*, optimisation period [a].

3.1. Cash flow of energy related balance

The energy related economic balance (cash flow CF) of the building owner (assuming an owner-occupied building) in every year t is the shared of household's income (CF) (see also 0) minus the energy related expenditures (IC, EC and OMC) (see also 0 to 0):

$$CF_t = INC_t * s - IC_{er,t} - EC_t - OMC_t$$ *Equation 2*

CF, cash flow of energy related balance [EUR]*;* *INC,* household income [EUR]; *s,* allocation factor of total annual income on energy related expenses [%]; IC_{er}, energy related investment cost of retrofitting measures [EUR]; *EC, annual running* energy costs [EUR/a]; *OMC*, *annual running* operation and maintenance costs [EUR/a].

3.1.1. Cumulated and allocated energy related assets and budget restriction. The cumulated allocated asset (A_t) destined to energy related issues in the year (t) is related to the -household's income (INC), its share (s) which is allocated for energy related expenses (including running costs and investments) and previous assets (A_{t-1}) and energy related expenses:

$$A_t = (INC_t * s) - IC_{er,t} - EC_t - OMC_t + A_{t-1}$$ *Equation 3*

A, cumulated allocated energy related asset [EUR]; *INC,* household income [EUR]; *s,* allocation factor of total annual income on energy related expenses [%]; *EC,* annual running energy costs [EUR/a]; *OMC*, annual running operation and maintenance costs [EUR/a].

These cumulated assets in year t (A_t) represent the budget restriction, which the household faces. In addition, the household may take up a certain loan. The amount of the loan which the bank is willing to provide is assumed to be proportional to the cumulated asset and is represented by the variable l (share of the cumulated asset which can be gathered by a loan). Thus, the overall budget restriction in year t (B_t) may be written as:

$$B_t \geq IC_{er,t} + EC_t + OMC_t$$ *Equation 4*

with

$$B_t = A_{t-1} * (1 + l)$$

B; budget restriction [B]; IC_{er}, energy related investment cost of retrofitting measures [EUR]; *EC,* annual running energy costs [EUR/a]; *OMC*, annual running operation and maintenance costs [EUR/a]; l, loan [EUR].

3.1.2. Investment costs (IC). The total retrofitting investment costs (ICtot) in year (t) are determined by the sum of energy related investment costs (ICer) and the maintenance investment cost (ICman) for each retrofitting measure, which has to be carried out for reasons of security or aesthetics: building envelope (external wall, window, floor or roof) and active system (heating, cooling, domestic hot water) (i), considering the probability of material's aging process (pt) (see 3.2.) and a binary variable (xt), which indicates if the measure is performed or not:

$$IC_{er,i,t} = \sum_i [(1 - p_{t,i}) * IC_{man,i} + IC_{er,i}] * x_{t,i}$$ *Equation 5*[1]

where, $x_{t,i}$ = 1 or 0 and $p_t > 0.05$

[1] The approach could be extended by distinguishing different efficiency levels of different renovation measures (d.h. insulation thickness) by adding an additional index j for these levels, where the additional restriction has to be fulfilled that the sum over j of $x_{t,I,j} \leq 1$.

IC_{tot}, total investment costs [EUR]; IC_{er}, energy related investment costs of renovation measures [EUR]; IC_{man}, maintenance investment cost of renovation measures [EUR]; x, binary variable (1 or 0) [-]; p, probability of material's aging process [-]; A, annually allocated energy related asset [EUR].

The assumption behind this equation is, that the investment costs for the maintenance of a renovation measure (ICman,i) only has to be considered as an energy related expenditure, if there is no necessity to renovate a certain building component due to the life time. If the probability that a renovation measure has to be carried out is close to 1, then, ICman is not relevant for the energy related investment decision, because the measure has to be carried out anyway.

3.1.3. Energy costs (EC). The running energy costs of the active system (i) at the time (t) are related to the final energy demand (fed) and the prices (pr) of the corresponding energy source:

$$EC_t = \sum_i fed_{t,i} * pr_{t,i} \qquad \textit{Equation 6}$$

EC, energy costs [EUR/a]; *fed,* final energy demand [kWh/a]; *pr,* energy price [EUR/kWh].

If a retrofitting measure is carried out, the final energy demand is reduced and has to be recalculated. The energy savings achieved are presented by the factor f, which depends on the energy related investment costs IC_{er}:

for,

$$x_t = 0, \quad fed_{t+1} = fed_t$$
$$x_t = 1, \quad fed_{t+1} = fed_t * f(IC_{er,i}) \qquad \textit{Equation 7}$$

3.1.4. Operation and maintenance costs (OMC). The operation and maintenance costs for the active systems (i) at the time (t) are related to investment costs (IC) and the operation and maintenance factor (fOMC):

$$OMC_t = \sum_i IC_{er,t,i} * f_{OMC,i} \qquad \textit{Equation 8}$$

OMC, operation and maintenance costs [EUR/a]; IC_{er}, energy related investment costs of active system [EUR]; f; operation and maintenance factor [%].

3.2. Material's aging process probability (p)

The probability (p) of a retrofitting measures (i) at the time (t) is defined by the Weibull distribution of material's aging process [15]:

$$p_{i,t} = 1 - e^{-\left(\frac{t-t_{i,0}}{t_{i,L}-t_{i,0}}\right)^m}, \text{ where t, } t_0\text{, m>0} \qquad \textit{Equation 9}$$

p; probability of material's aging process*; m,* aging exponent *[-]; t_L,* technical lifetime [a]; *t_O,* period without failure [a]; *t,* time [a].

If the material is retrofitted, than the aging process restarts:

For:

$$x_{i,t} = 1, \quad p_{i,t+1} = 1 - e^{-\left(\frac{t-t_{i,0}}{t_{i,L}-t_{i,0}}\right)^m} \qquad \text{Equation 10}$$

3.3. Residual value (L)
The residual value at the time (t) of the retrofitting measures (i) is related to material's technical lifetime (t_L), depreciation time (t_P) and energy related investment cost:

for,

$t < t_{L,i}$: $L_T = \sum_i \sum_t IC_{er,t,i} * \frac{(T-t)}{t_{L,i}}$

$t \geq t_{L,i}$: 0 *Equation 11*

L, residual value [EUR]; total investment costs [EUR]; t_L, technical lifetime [a]; *T,* optimisation period time [a]*; t,* retrofitting time [a].

4. Conclusions

A literature review showed several approaches for optimisation models of building retrofitting. Despite their particularities in terms of energy performance calculation method and objective function, all methods consider that the retrofitting measures are performed at the same time, so called single stage retrofitting.

In this context, the present study proposes a framework on how to apply retrofitting optimisation models for step-by-step retrofitting approach by formulating a corresponding optimization problem. Our focus are owner occupied single family houses, and therefore, the optimisation framework considers the building owner's perspective. The proposed method aims at maximizing the net present value, which represents the balance between energy related expenditures, and existing assets for retrofitting (based on family's income and available budget).

In the step-by-step concept, a step consists of combination of one or more retrofitting measures at a point of time. A single stage approach can be broken down in numerous renovation steps: building envelope measures – roof, external wall, floor insulation and windows replacement- and active system measures for heating, cooling, ventilation, heat distribution, lighting and domestic hot water. In real-life, lock in effects and thermal bridges have to be take into account. Also, construction site preparation and scaffold costs also affect the aggregation of one- or two measures. Nevertheless, future studies should try to further identify retrofitting measures aggregation boundaries.

To define the timing of the each retrofitting step, the probability of material's aging process distribution [15] in combination with available asset was proposed. We assume that the budget restriction of the investments in maintenance renovation works is not correlated to the budget restriction of the energy related expenses. This might be a simplification, which will be revised in a later stage.

5. Discussion and future outlook

Future planned activities of this study will include testing and extending the optimisation model, as well as, applying its results to a building stock scale and analysing possible impacts of step-by-step renovation measures on the achievement of building stock's decarbonisation targets.

To guarantee accuracy, sensitivity analyses will need to include important parameters as income projection, energy price scenarios and policies.

Further plausibility analyses should include human behaviour aspects (i.e. rebound effect), market value of the building after retrofitting, ambitious of building energy codes in terms of energy efficiency, as unpredicted incomes and assets (e.g. bonus or inheritance).

Abstract. In the context of strategies for mitigating the impacts of climate change within European cities, increasing attention is being paid worldwide to the use of urban green infrastructure which, in addition to the potential for improving the quality of the urban environment, allow significant amounts of CO_2 to be removed from the air. However, considering the peculiarities of the dense European cities, most of the available surfaces in urban areas are the perimeter walls of buildings of considerable age that are in urgent need of measures to upgrade their energy performance. Based on this premise, this paper investigates the potential for CO_2 storage resulting from the application of energy retrofit solutions using biogenic insulating materials. Starting from the analysis of the demand for insulation materials necessary for the energy requalification of the residential existing building stock in 28 European countries, following the renovation target fixed by EU, the research analyses, through the adoption of a dynamic LCA approach, the environmental benefits of bio-based materials compared to traditional solutions. The use of these materials, especially if they are fast-growing - as the study shows - offers several advantages in terms of climate change mitigation by reducing the energy needs and CO_2 emissions of the existing building stock and increasing carbon storage capacity within cities. The results of this study are intended to provide a robust database on which to build a model of circular building renovation that takes into account the environmental long-term effects of measures for increasing energy efficiency of buildings.

1. Background

It is a well-established awareness that the construction sector and, more specifically, the building renovation sector plays a decisive role in the achievement of the European targets for the reduction of energy consumption and greenhouse gas (GHG) emissions. The main strategies implemented by the European Union are aimed, on one side, at increasing the number of buildings to be yearly renovated and, on the other side, at promoting deep renovation measures on the existing building stock [1]. The main objective is to decarbonise the building stock by 2050 by seeking a cost-efficient equilibrium between decarbonising energy supplies and reducing final energy consumption. A recent study confirmed that high energy efficient buildings after deep retrofit show multiple benefits at different scales: a considerable reduction in the overall energy demand and, consequently, a reduction of grid infrastructure and power system operational costs [2].

More than the 75% of the European building stock has been built before 1980, i.e. before the introduction of the first energy performance regulations in several EU countries [3]. Residential buildings account for the biggest segment of this stock and are responsible for the majority of the sector's energy consumption. Within the existing European stock, a large share (more than 40%) - widespread in urban areas - is built before 1960s with low insulation levels and old and inefficient systems [4]. A wide range of retrofit technologies are available and several studies have been carried out in order to identify optimized solutions in consideration of the cost-effectiveness, the improvement of energy performances and indoor comfort [5]. Because of the age of the European building stock and the new European regulations for improving the energy performance of existing buildings, there is a need of extensive solutions for the renovation of exterior walls as they offer a great potential of energy saving due to the decrease of energy losses on a greater surface, both in single housing and apartment blocks. On one hand, the renovation of residential building stock to reduce the primary energy demand represents a priority in EU-28, not only to address the carbon mitigation, but also to mobilize investments in construction [6,7]. On the other hand, when the primary energy demand of a building is reduced due to retrofitting, the contribution on carbon emissions due to insulating materials processing increases [8]. At European scale, an increased inflow of materials is expected for deep renovation scenarios in the coming years and the fossil carbon emitted by manufacturing of materials and construction might significantly affect the carbon saving from operational energy [9]. Thus, the carbon emission for the production of materials and construction is expected to slow down the transition to a low carbon society and significantly reduce the carbon budget available by 2050, i.e. the finite amount of greenhouse gases we can emit to limit global warming to 2 °C [10], ratified by the Paris Agreement as the maximum possible increase without drastic consequences for human life on the planet. In this scenario, the adoption of low carbon materials able to store carbon for a long time horizon is an opportunity that should be taken urgently in order to comply with climate change target [11].

The objective of this paper is to evaluate the global warming potential of different bio-based insulation alternatives when used for the retrofitting of existing facades compared to standard synthetic insulation. More specifically, in order to properly consider the biogenic carbon stored in the product, a dynamic time-dependent life cycle assessment has been introduced in order to verify the contribution of the different bio-based materials in affecting the radiative forcing over time.

2. Methodology

2.1. External insulation system for envelope retrofitting

In this study, five envelope retrofitting solutions have been identified considering their potential for application to the external walls of typical European residential buildings, in order to improve their thermal resistance. In particular, as illustrated in Figure 1, the selected alternatives include both systems with lightweight elements that can be installed on-site and large prefabricated modules, in order to take into account also high-quality renovation options [12].

The Functional Unit (FU) assumed for materials and life cycle impacts assessment (LCIA) is the same for all the investigated alternatives and is defined as follows:

- 1 m^2 of wall;
- U-value = 0.125 W/m^2K;
- non load-bearing structure;
- identical fire safety;
- 60 years lifespan assumed as the same of the reference service life (RSL) of residential buildings.

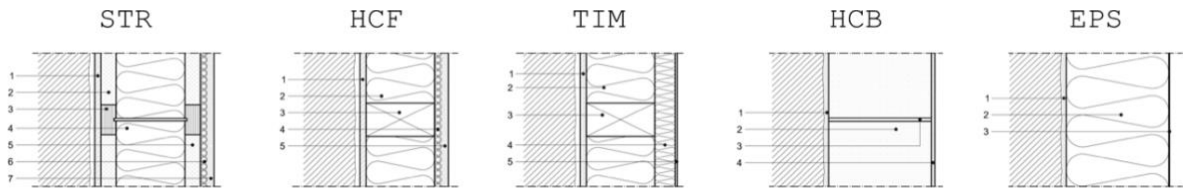

Figure 1. The five alternatives for the external insulation systems investigated in the study: STR (bio-based, prefabricated), HCF (bio-based, prefabricated), TIM (mixed mineral + wood, prefabricated), HCB (bio-based, on-site), and EPS (synthetic, on-site).

In the first four alternatives, different biogenic products are used for the thermal insulation and, in the case of prefabricated modules, for the structural elements as well. The thickness of the insulation for each alternative is a variable and has been chosen considering the required U-value of the walls in the different European Member State after renovation. In particular, for the identification of prevailing wall assemblies of existing building stock in EU, data from relevant databases have been considered, specifically the databases developed in the TABULA and EPISCOPE projects [13], and the information for the different States grouped according to seven prevailing climatic conditions in the framework of a geo-clustering approach [14].

STR – I-joist frame with pressed straw. An engineered I-joist frame is filled with straw which is pressed to a density of 100 kg/m3 to support a thick clay plaster layer mixed with straw on both sides. The structure is finished internally with an oriented strand board (OSB) to create a regular surface on the existing wall. After the assembly, the module is transported on the construction site and, once installed, is finished with a lime plaster on a reed mat.

HCF – Timber frame with injected hempcrete. A timber frame is filled with an insulation mortar of hemp shives bound with lime-based binder. The mass ratio of shives to binder is 1:1. Assembly and drying process is carried out off-site. Anchoring and plastering are executed on site.

TIM – Timber frame with mineral insulation. A timber frame is filled with a layer of glass wool. An additional wood fibreboard insulation is connected to the frame to increase the thermal performance of the wall and create a regular support for the external finishing.

HCB – Hempcrete blocks. After a preliminary preparation of the external surface of the existing wall, precast pre-dried hemp-lime concrete blocks are laid in order to wall up an insulation layer. A lime based plaster and render is applied as finishing.

EPS – Expanded polystyrene for external thermal insulation composite system (ETICS). An ETICS with polystyrene boards has been assumed as a reference system with an amount of bio-genic material equal to zero. EPS panels are applied on the existing wall, after the preparatory works on the existing wall surface, with an external render.

2.2. Dynamic Life Cycle Assessment

In order to analyze and compare the environmental impact of the different alternatives, a time-dependent life cycle assessment has been performed in order to proper account the biogenic CO_2. Normally, impacts of biogenic CO_2 are neglected in a traditional LCA since the same amount of CO_2 released from biogenic sources is assumed to be absorbed during the regrowth of the biomass, and the net emissions are therefore zero [15]. This widely used assumption about biomass carbon neutrality and climate neutrality has been increasingly criticized [16]. For this reason, a dynamic life-cycle assessment (DLCA) approach has been adopted for taking into account the timing of carbon uptake and GHG emissions, which is particularly relevant for bio-based products that temporarily store carbon and delay emissions [17]. The method was implemented taking into account only the GHG effect of CO_2 and methane (CH_4), since it was observed they contribute for the largest share of the radiative forcing impact due to the high amounts released in the process. A Time horizon (TH) of 200 years was assumed, in order to include into the calculation both short-term (2050) and long-term (2100) effects.

System boundaries. The LCA model was developed according to the standard EN 15804:2012 (CEN/TC350, 2012), and includes the following:

- product stage (modules A1-5) - extraction, transportation, production supply to the building site, and construction;
- usage stage (modules B1 and B4) – emissions by replacement of exhausted elements and uptake by the use of biomass and lime-based products;
- end of life (EoL) stage (modules C1-4) - wall demolition, transportation to waste treatment, sorting, waste processing, and final disposal.

Additional benefits, such as avoided virgin materials due to recycling or avoided emissions through energy recovery, are accounted for separately as additional loads and benefits beyond the system boundaries (module D).

Calculation model. The ΔR_T needed to meet the expected U-value limits in the future was evaluated for each European Member State, as well as the surface of the external walls that is expected to be yearly renovated. The two values were aggregated together according to the clustering process for each geocluster, and then correlated to the materials inventory for the five alternatives in order to define the annual material intensity. A life cycle inventory (LCI) from modules A1 to C4 was performed to calculate the impact inventory, measured in terms of kg of GHG emitted per year. In parallel, three different carbon sinks were modelled and included into the analysis in module B1: two sinks from biosphere (forest and crops) and one from techno sphere (lime), to take into account carbonation of lime-based products. On the base of the materials required, the annual carbon uptake, typically time depending, was measured and the resulting carbon removal were correlated to the GHG emitted by renovation of the stock to define a time depending matrix which was used as input to address the dynamic impact assessment. Finally, the results, expressed in instantaneous and cumulative radiative forcing, were converted into $kgCO_{2\text{-eq}}$ according to the IPCC method in order to measure the global warming potential (GWP).

End of life (EoL). Typically, the GWP calculation through a DLCA is particularly sensitive to the assumption concerning EoL treatment. A full understanding of the sensitivity of the results to the disposal scenarios (DS) is needed to succeed a careful interpretation [18]. At the EoL, the following five different waste treatments (WT) were assumed:

- WT1- inert landfill: considered for materials that do not release hazardous substances after building deconstruction;
- WT2 - sanitary landfill: considered as temporary storage for reactive materials as biogenic products;
- WT3 - composting facility: considered as alternative to WT2, where the full amount of methane produced during biological decay is captured and reused as bio-methane as substitution of natural gas;
- WT4 - municipal incineration: consists of incineration of waste with thermal energy recovery;
- WT5 - recycling: consists of generating new products from waste materials.

From the combinations of different waste treatments illustrated in Figure 2, the following three alternative disposal scenarios (DS) were defined:

- DS1: landfill;
- DS2: energy recovery;
- DS3: material recycling.

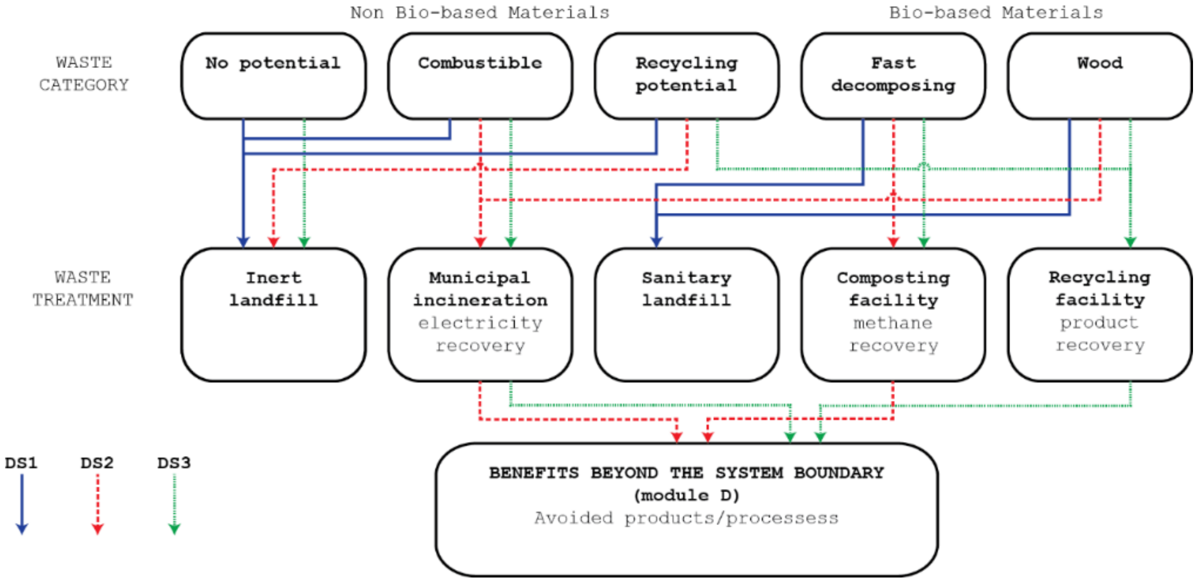

Figure 2. Waste treatments and disposal alternatives for each end of life disposal scenario [19].

3. Results

The instantaneous radiative forcing – which contributes to alter the Earth's radiative equilibrium, forcing temperatures to rise or fall - was calculated for each wall alternative and for the three DSs through the DLCA calculation model. The values of instantaneous radiative forcing calculated per year are summed to show the cumulative effect of the released emissions during the life cycles of the five construction alternatives. Finally, the results are converted into GWP according to the IPCC method in order to quantify dynamically the carbon emissions/removals.

The dynamic values of the GWP for each alternative and each DS are shown in Figure 3.

After an initial positive emission in 2018 of 7.64 Mt of $CO_{2,eq}$, the GWP impact of straw-based alternative (STR) rapidly decreases, with a carbon neutrality which is achieved after just 4 years. Then, the effect of removing carbon from the atmosphere continues with the same positive trend. It is expected that by 2050, almost 100 Mt of $CO_{2,eq}$ are removed from the air due to the massive use of straw. It is roughly equivalent to a reduction by 27% of carbon emissions from industrial processes and product use in 2015 in EU-28, or 23% of emissions from agriculture in the same year, which is equal to 3% of total carbon emissions from all sectors. In 2050, the materials required to renovate the residential building stock with HCF still lead to a positive emission, with a GWP of 3.55 Mt of $CO_{2,eq}$ that are expected to be cumulatively emitted since 2018. In 2100, the GWP registers a negative value, with a mean removal potential of almost 54 Mt of $CO_{2,eq}$, which is equal to a reduction by 17% of carbon emissions from industrial processes and product use, or 15% of emissions from agriculture in the same year or 2% of total carbon emissions from all sectors in EU-28 in 2015. A similar trend is observed for HCB, even if a negative GWP is achieved in 2050 due to the higher amount of carbon sequestered by hempcrete blocks. For the last two alternatives, no carbon removal is expected by 2100. Even if in TIM a large amount of bio-based material is used, the long time required to reabsorb the carbon in the forest by tree regrowth (a rotation period of 45-120 years was assumed in this calculation) drops down the positive effect of storing carbon in products.

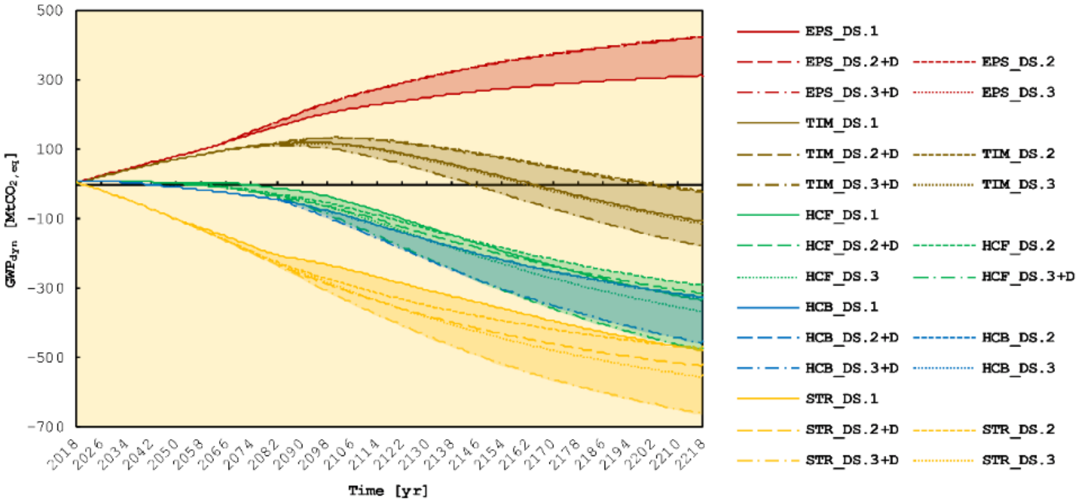

Figure 3. Dynamic GWP for all scenarios. DS1, 2, 3 stand for disposal scenario with landfill, energy recovery and material recycling respectively. DS +D stand for disposal scenario with module D and DS for disposal scenario without module D.

4. Conclusions

Fast-growing bio-based materials, such as hemp and straw, have a considerable potential of capturing and storing carbon when used as thermal insulation for renovating existing facades in Europe. Unlike forest products, they do not require long rotation periods, and the capacity for storing carbon increases when they are used as thick insulation for exterior walls due to the rapid CO_2 uptake in the crop fields. Among the five alternatives selected, STR showed the most promising potential, being the only one able to remove by 2050 3% of the $CO_{2\text{-eq}}$ emitted from all sector in 2015. The other two bio-based alternatives based on hemp start to be carbon negative slightly after 2050, with a carbon storage potential in 2100 of roughly 2% of the emissions from all sectors in EU-28 in 2015. Contrarily, timber-based construction always contributes to increase the emissions from renovation in a short and mid-term prospective, and the carbon capture and storage capacity of wood, if only timber is used in the structure, seems cannot be proposed as a valid strategy in Europe to contribute achieving the Paris Agreement targets. Clearly, EPS, which is nowadays the most used renovation system widely spread in Europe for energy retrofit, reduces the extra loads that the existing facades should support, but cannot contribute to actively remove CO_2 from the air.

Abstract. According to sustainability research the world has exceeded four out of seven planetary boundaries. The areas of climate change, biodiversity loss, nitrogen cycle and land use have left the so called safe operating space for humanity. The built environment is one of the major contributors to environmental impacts. Especially the embodied energy during the construction phase of the built environment and the energy demands during the use of buildings contribute to a high energy and resource consumption. In the year 2015 the United Nations adopted the Sustainable Development Goals (SDGs), a universal development agenda, which goals need to be fulfilled by the year 2030 and by all UN countries worldwide. Amongst other countries Austria has adopted the 2030 agenda and has committed itself to the SDGs. Research objective was to explore the application of systemic approaches in the field of SDGs. The work presents a systematic literature review (SLR) and discusses an application of a qualitative system analysis (carried out with the tool iMODELER) on the SDGs. Results show how interdependencies among SDGs and among chosen concrete actions, e.g. for the built environment, can be visualized for a better systemic understanding. By visualizing synergies and trade-offs, effects of decisions taken can be estimated from a holistic perspective.

1. Introduction

According to ROCKSTRöM [1] three load limits of the earth system processes have already been exceeded. Namely the limits in the areas of climate change, the loss of biodiversity and the nitrogen cycle. The fourth area, namely land use, has also already surpassed the worldwide limits of ecological resilience [2]. The economist RAWORTH [3], takes the planetary boundary concept, expands it and introduces also socioeconomic indicators like education, health, gender equality and peace. In this way she defines a necessary bottom line for the social wellbeing of people on earth. The concept is called the ”Donut” [3]. There she defines the line which needs to be taken in account if humanity wants to stay within its safe limits, not only in ecological, but also in social terms. The described challenges and limits for our social and earth system wellbeing underlines the importance of the Sustainable Development Goals (SDGs), adopted by the United Nations in September 2015 [4], also called Agenda 2030. These Sustainable Development Goals comprise 17 goals, 169 sub-goals, and 232 indicators [5]. Amongst other countries, also Austria has committed itself to the SDGs [6].

1.1. Implementation of SDGs in Austria

In Austria, the mainstreaming approach is used to implement the SDGs. This means the Agenda 2030 is implemented on a federal level and every federal government department is responsible to implement the Agenda 2030 through relevant strategies and programs. On 12th January 2016, the working group ”Implementation Agenda 2030 for Sustainable Development” under the leadership of the Federal Ministry for Europe, Integration and Foreign Affairs (BMEIA), as well as with the participation of other ministries was established. Its task is to coordinate the preparation of the regular progress report complying with the internationally defined specifications on the basis of the agreed indicators as well as to coordinate the implementation priorities for the respective reporting period [7]. The mainstreaming approach as implementation strategy has been criticized by civil society [8] as well as by a report of the Austrian Court of Audit [9]. The civil society platform SDG Watch is advocating for the implementation of the SDGs and called in an open letter in January 2017 on the Austrian government and ministries to be more active in implementing the SDGs [10]. In the open letter, proposals for a better implementation of the SDGs in Austria, are formulated, for example a comprehensive inventory and gap analysis transparent reporting and the involvement of all stakeholders, is required [8]. From the science perspective, an important project to implement the SDGs in the Austrian higher education landscape is the project UniNEtZ, established by the network Alliance for Sustainable Universities. In this project Austrian universities aim towards cooperation for the SDGs on science and research level, furthermore the project tries to establish a better dialog between science-society-policy [11]. One main goal is the creation of an concrete action paper for SDG implementation in Austria, which will be presented to the Austrian government [12-13].

1.2. SDGs in construction industry

The SDGs concern many areas of society, including the construction sector. To achieve the goals of global sustainability in the sense of the SDGs, there is a need for redeveloping the construction sector. The construction sector is globally ”consuming 40 to 75 percent of the total value of materials extracted” [14]. According to figures mentioned in the International Resource Panel 2017 [15] buildings are also responsible for the use of 25 percent of global water. Furthermore the Global Status Report 2018 of the Global Alliance for Buildings and Construction [16] shows that 36 percent of final energy use in 2017 was caused by buildings and construction sector. This sector is also responsible for around 39 percent of emissions in the year 2017 [16]. Moreover estimated trends of the same report show that energy usage, besides improvements e.g. in building systems or building envelopes, is still growing. The emissions related to the buildings stagnate, due to the achieved energy efficiency in buildings as well as the decarbonisation of the power sector, and balance out development in population growth and the floor area growth. This means further reductions are necessary, if targets of the SDGs want to be achieved [16]. The Annex Report 57 of the International Energy Agency [17] is pointing out the factor that embodied energy and embodied energy emissions from construction industry constitute 20 percent of the global energy consumption and CO_2 emissions. This also implies that a reduction in embodied energy and CO_2 emissions can lead to a significant global decrease in energy consumption and CO_2 emissions. Another field where the built environment could act as driver is biodiversity, addressed in the SDG 15 - Life on Land [18].

The aim of this paper is to apply a systemic approach to identify building relevant actions and interactions between them based on the SDGs. As the SDGs have systemic interdependencies [19] and the Agenda 2030 has a systemic nature [20], the goals relate to each other and can create synergies and trade-offs among each other.

2. Applied methodology

The applied methodology described in this paper illustrates the state-of-the-art of the application of systemic approaches in context with SDGs (section 2.1) and shows how to link concrete actions to the SDG framework aiming to the identification and visualization of synergies and trade-offs (section 2.2) with the tool iMODELER (section 2.3).

2.1. Systematic literature review (SLR)

The literature research on systemic approaches in context of the SDGs was carried out by means of a systematic literature review and the snowball approach [21-22]. First, the following research questions were defined: ”Which systemic approaches in context of the SDGs exist?” and ”Why is a systemic approach indispensable for illustrating the interdependencies among SDGs?”. In order to answer these questions, a systematic literature review was conducted in the literature database ScienceDirect[1]. The search for relevant articles was restricted to ”Review article”, ”Research article” and ”Book chapters”. With the defined keywords in combination with the term Sustainable Development Goals the systematic literature review was carried out. Furthermore, only english-language literature was researched. The following table lists all keywords, which were used in combination with the term Sustainable Development Goals, including the number of articles found.

[1] https://www.sciencedirect.com

Table 1: Keywords of the literature research

Key word I	Key word II	Articles found
Sustainable Development Goals	interaction(s)	45
Sustainable Development Goals	trade-off(s)	41
Sustainable Development Goals	synergy / synergies	35
Sustainable Development Goals	links	28
Sustainable Development Goals	linkage	23
Sustainable Development Goals	relation	20
Sustainable Development Goals	correlation	13
Sustainable Development Goals	systemic	13
Sustainable Development Goals	connection	12
Sustainable Development Goals	interdependencies	8
Sustainable Development Goals	interconnection	8
Sustainable Development Goals	interrelationships	5
Sustainable Development Goals	intersections	4
Sustainable Development Goals	interrelations	0

2.2. Systemic approach and systems thinking

The roots of systems science go way back in time. With the statement "The whole is more than the sum of its parts" Aristotle already pointed out that it is not enough to know only the parts of a system, but that the relationship between these parts is crucial. Under the guise of systems science, numerous terms and fields have developed. Often, systems science is divided into systems theory, systems analysis and cybernetics [23]. The insights gained from systems theory and cybernetics led to numerous interdisciplinary approaches. Particularly noteworthy is the approach developed by FORRESTER [24] called System Dynamics to better understand complex systems regarding their nonlinear behaviour. COLLSTE et al. [25] describe system dynamics as "a systems analysis approach that is used to study behavioural patterns of systems". Meanwhile, we look back on more than 50 years of systemic understanding and system dynamics [26]. Systemic thinking, in contrast to analytic thinking, is contextual, which in turn means that systems can only be understood by placing them in an overall context. At the same time, people can not consider the effects of more than four interacting factors at once [27]. This raises the challenge or difficulty of a lack of human understanding for interactions of factors in systemic approaches [28].

Problem-solving methods from the past, due to interconnectedness, complexity, feedback, etc., are no longer adequate for the problems of today's generations. The adaptation of new ways of thinking does not fall victim to the intellectual deficiency of humanity, but rather to the difficulty of storing thought patterns applied over centuries [29]. The first limitations of systemic thinking take place at the latest at the beginning of compulsory education. Through a strict separation of subjects the first interconnections are hidden. Much more seriously, these delimitations of the individual subject areas are then operated in the later school levels and universities. By neglecting the interactions between the subsystems, overarching medium and long term impacts are not visible. Because of the segregation of the individual things according to disciplines and areas of life and the oblivion of the connecting relationships that exist in reality, we lose our cybernetic understanding [30].

Sustainable construction - i.e. taking account of environmental, economic, sociocultural, functional and technical aspects in the planning and construction of buildings - not only represents a megatrend in the construction industry, but in recent years, notably through the signing of the Paris Climate Agreement [31] as well as various progress reports [32-34] already anchored in everyday practice.

Especially in the context of sustainable construction, the importance of systemic approaches in an early design stages, is growing [35-36]. The complexity of construction projects is high, so that their underlying dynamics is difficult to understand [28], [37]. Systemic effects can be modeled and effects can be shown that have not been pointed out yet. This can also lead to systemic improvement processes [38]. Another reason for a systemic approach in the construction sector is construction management itself. Generally a lack of methods for the management of necessary lifecycle processes, difficulties arise in the operationalization of integral planning or imprecise stakeholder requirements. These different goals should be optimally considered through systemic approaches, which in turn can lead to increased building quality in terms of sustainability and process optimization and thus to financial and time savings in the planning and the life-cycle of a building [39].

2.3. SDGs and their systemic nature

The systemic approach plays a role as well for the SDGs. They are integrated [4] and have a systemic character and relate to each other [19-20]. The SDGs are a relatively new and an extensive framing concept. This is the reason why there is only little literature specifically on SDG interactions available so far [40-41]. Therefore tools to analyze their complexity, as well as for enhancing their implementation, are important. To understand and unlock their full potential synergies and trade-offs of SDGs need to be analyzed and integrated in policy frameworks out of a holistic perspectives. As there is "a lack of science-informed analysis of interaction across the SDG domains" [20] more systemic science-based analyses can help to develop more coherent and effective decision-making [20]. Furthermore with the application of a systemic approach interactions can be understood and feedback loops between SDGs and their targets and sub-targets can be managed [42].

ALLEN et al. [19] indicate that in the SDG implementation lacks analytical tools and lack instruments to help countries' to assess interactions of SDGs as well as to optimize and understand the systemic impact of the various interventions. Also in the SDG practice of countries gaps are shown, which hinder the transformative potential of the SDGs. Reasons for this is a lack of skills and lack of awareness in system thinking and systems analysis, as well as the lack of SDG tailored systemic tools [19]. Furthermore, also BAI et al. [43] see the opportunity to exploit potential and positive synergies for the SDGs in the use of a system approach. Therefore a systemic view on the SDGs, their synergies and trade-offs connected with the constructed environment is necessary.

2.4. A qualitative systems analysis with the tool iMODELER

The iMODELER is a tool for qualitative explorative cause and effect modeling. With the iMODELER it is possible to visualize complex systems and show interconnections between factors. The connections are shown with arrows between different factors, marked with pluses or minuses, to show a positive or negative correlation. It is a model helping to understand complexity and complex systems with the advantage of relative simplicity compared to quantitative modelling. The applied software can be used for environmental, economic and social problems at regional or national level. It also allows for participatory modelling with different stakeholders with the benefit of not missing potentially important factors. Beside visualization, also analysis of systems is possible with the goal to reach improved planning, communications as well as decision-making and communications. Other use cases of the tool, if data is available, are test scenarios or as a simulation tool [37], [44].

With regard to the SDGs, NEUMANN et al. [44] have already tried to model the SDGs with their systemic interdependencies on a general level. Building on this approach, this article specifically places SDG 11 at the center of the model and visualizes the effects of concrete actions related to the construction industry.

3. Results

This section presents the results of the SLR and the application of the tool iMODELER for the identification and visualization of synergies and trade-offs among SDGs. The developed model represents an exemplary demonstration for the application of a systemic approach for the causal loop investigation of concrete actions based on SDGs. The focus in the illustrated example was directed to the SDG 11.

3.1. Systematic literature review (SLR)

The systematic literature review (SLR) shows that so far some of the authors use systemic approaches to explore the interconnections within the SDGs as well as certain topics.

Figure 1 shows the number of found articles by keywords indicated in table 1 split up by the year of publication. In the years after the adaption of the Sustainable Development Goals in 2015 by the United Nations [4] the numbers of publications levels off.

In the SLR a number of 263 article entries was found. After checking for double entries, 158 papers were identified. In a second step the entries were filtered, first by title, then by abstract and finally by the full article. The SLR showed that interconnections within SDGs were researched with different methods, also systemic approaches. Moreover literature poses that there should be more research to explore the interactions of SDGs and processes behind them, as well as synergies and trade-offs among the SDGs, to progress toward the achievement of the SDGs [45], [46], [47]. Some papers found through the SLR were not addressing the topic of SDG interconnection at all.

In general literature from different disciplines and journals was found, e.g. from the sustainability or environmental sciences, marine research, engineering or agriculture. The SLR results showed that different

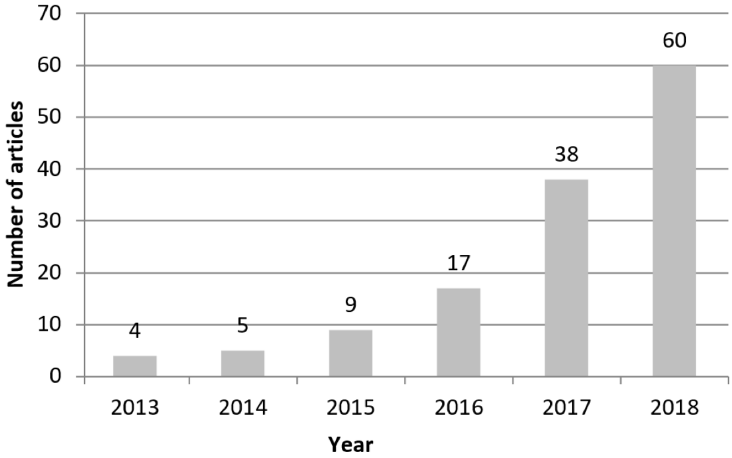

Figure 1: Number of SDG-related articles by the year of publication

authors, depending on their background and discipline, apply different, also non systems-oriented methods and tools to identify SDG interactions and connected synergies and trade-offs.

The thematic topics of the articles addressing SDG interconnections varied as well. Specific topics like salinization or SDG sub-targets like water quality were chosen as a starting point for the exploration of interdependencies among SDGs and the relevant topic. Synergies and trade-offs were not addressed in all papers specifically, sometimes the focus was e.g. just on trade-offs. Furthermore no paper was addressing SDG interdependencies specifically related to the built environment.

The following table 2 lists the titles of the relevant articles as well as their authors and their year of publication. Furthermore, the addressed SDG(s) within the articles are illustrated.

With the SLR only one scientific database has been researched, but for the exploration of the SDGs also grey literature needs to be taken into account. That is why also a snowball sampling was carried out.

One key paper found by snowball sampling, was the article of ALLEN et al. [19]. This paper provides an overview and analysis of expert literature (science-based) and guidelines (evidence-based) for SDG implementation worldwide. In an analytical framework 17 relevant papers as well as eight relevant guidelines and toolkits were identified and analyzed. One criterion was systems thinking and system analysis: in all eight guidelines or toolkits systems thinking and system analysis were applied. Moreover, 12 out of 17 papers used systems thinking. Further applied approaches identified in the expert literature were ”nexus approaches, quantitative modeling, indicator-based-assessments and benchmarking, scenario analysis and MCA[2] decision-frameworks” [19] .

[2] multi-criteria analysis

Table 2: List of relevant articles of the SLR and snowball approach

Article title	Author	Year	Adressed SDGs
Water quality and its interlinkages with the Sustainable Development Goals	Joseph Alcamo	2019	SDG 6, and SDGs 2, 3, 7, 14, 15
Analysing trade-offs between SDGs related to water quality using salinity as a marker	Flörke et al.	2018	SDG 2, 6, 7, 12, 15,
Defining and advancing a systems approach for sustainable cities	Bai et al.	2016	SDG 11, but more cities in general
More than Target 6.3: A Systems Approach to Rethinking Sustainable Development Goals in a Resource-Scarce World	Zhang et al.	2016	SDG 6 and other SDG
A rapid assessment of co-benefits and trade-offs among Sustainable Development Goals	Singh et al.	2018	SDG 14 and other SDGs
Trade-offs between social and environmental Sustainable Development Goals	Scherer et al.	2018	SDG 1 and SDG 6, 10, 13, 15
From goals to joules: A quantitative approach of interlinkages between energy and the Sustainable Development Goals	Santika et al.	2019	SDG 7 and other SDGs
Connecting SDG 14 with the other Sustainable Development Goals through marine spatial planning	Ntona Mara and Morgera Elisa	2018	SDG 14
Articulating natural resources and sustainable development goals through green economy indicators: A systematic analysis	Merino-Saum et al.	2018	SDGs and topic natural resources
Dynamic modeling approaches to characterize the functioning of Health Systems: A systematic review of the literature	Chang et al.	2017	No specific SDGs
Distilling the role of ecosystem services in the Sustainable Development Goals	Wood et al.	2017	SDG 1, 2, 3, 6, 7, 8, 9, 11, 12, 13, 14, 15
Building Urban Resilience for Disaster Risk Management and Disaster Risk Reduction	Etinaya et al.	2017	SDG 11
Towards a governance heuristic for sustainable development	Müller et al.	2015	No specific SDGs
SDG synergy between agriculture and forestry in the food, energy, water and income nexus: reinventing agroforestry?	van Noordwijk et al.	2018	No specific SDGs
The nexus across water, energy, land and food (WELF): potential for improved resource use efficiency?	Ringler et al.	2013	No specific SDGs
National pathways to the Sustainable Development Goals (SDGs): A comparative review of scenario modelling tools	Allen et al.	2016	No specific SDGs
Toward a systemic monitoring of the European bioeconomy: Gaps, needs and the integration of sustainability indicators and targets for global land use	O Brien et al.	2017	No specific SDGs
Towards integration at last? The sustainable development goals as a network of targets.	Le Blanc David	2015	SDG 12, 10 other SDGs
Modeling and measuring sustainable wellbeing in connection with the UN Sustainable Development Goals	Costanza Robert	2016	SDGs and topic of wellbeing
Evaluating agricultural trade-offs in the age of sustainable development	Kanter et al.	2018	SDG 2
Initial progress in implementing the Sustainable Development Goals	Allen et al.	2018	No specific SDGs (Review)
Map the interactions between Sustainable Development Goals	Nilsson et al.	2016	All SDGs
Policy coherence to achieve the SDGs: using integrated simulation models to assess effective policies	Collste et al.	2017	SDG 3,4,7
Connecting the sustainable development goals by their energy inter-linkages	McCollum et al.	2018	SDG 7 and other SDGs

3.2. Application of the systemic approach

As part of the UniNEtZ project, several expert workshops in the area of SDG 11 were held. The aim of these workshops was to develop concrete actions for the Austrian Federal Government in order to contribute to the achievement of the Agenda 2030. In these workshops, first subject areas by experts were defined to holistically cover the targets of SDG 11. In the expert workshops it turned out that there are numerous interdependencies among these subject areas and subsequently between SDG sub-targets and SDGs. In figure 2 the process model is illustrated. In the center of the model is the factor SDG 11. For an initial modeling, the following assumptions were made, which also stem from the framework of the SDGs:

- all SDGs have an equivalent meaning and thus a same weighting[3]
- the targets and indicators were taken as defined by the United Nations
- all targets have an equivalent meaning and thus a same weighting
- interdependencies among the targets were not considered
- interdependencies among the indicators were not considered
- defined subject areas were linked to the indicators only

[3] although is not necessarily the case in reality

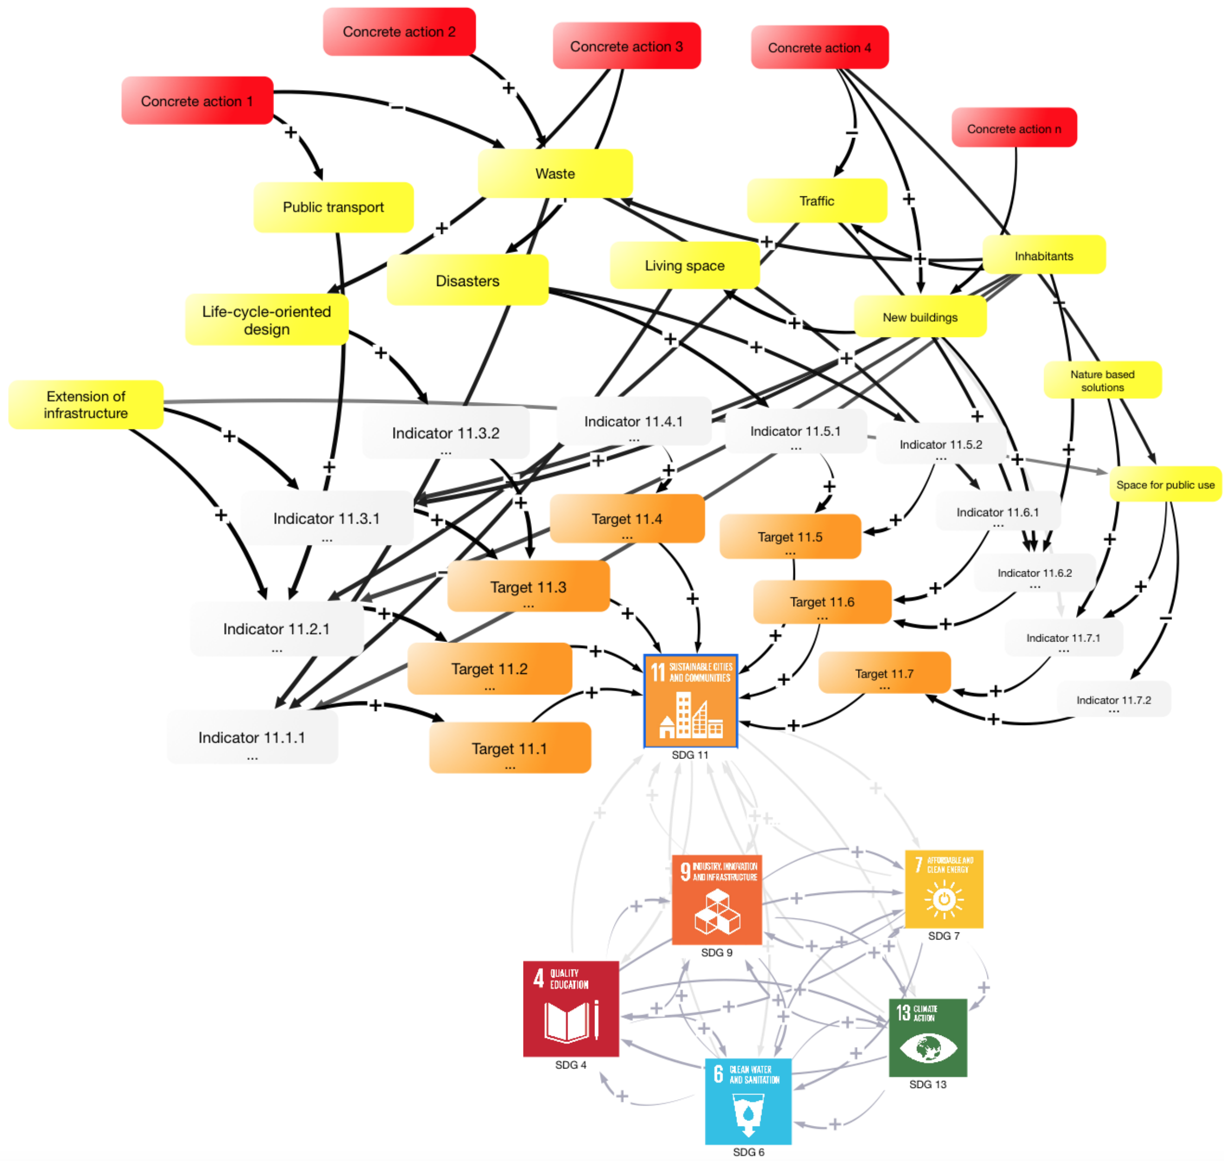

Figure 2: Interdependencies among defined subject areas within SDG 11

In iMODELER direct relations between factors have to be considered. This method is called know-why method [48] and concludes four know-why questions:

- What leads directly to more of a factor?
- What leads directly to less of a factor?
- What might lead directly to more in the future?
- What might lead directly to less in the future?

In the illustrated example (figure 3) an increased fulfillment of target 11.1[4] and target 11.6[5] directly causes to SDG 11. By analogy, the increased fulfillment of the Indicator 11.1.1[6] leads directly to an increased fulfillment of target 11.1.

Further examples for the interpretation of the model:

- more inhabitants lead to more traffic
- more inhabitants lead to more waste

[4] By 2030, ensure access for all to adequate, safe and affordable housing and basic services and upgrade slums

[5] By 2030, reduce the adverse per capita environmental impact of cities, including by paying special attention to air quality and municipal and other waste management

[6] Proportion of urban population living in slums, informal settlements or inadequate housing

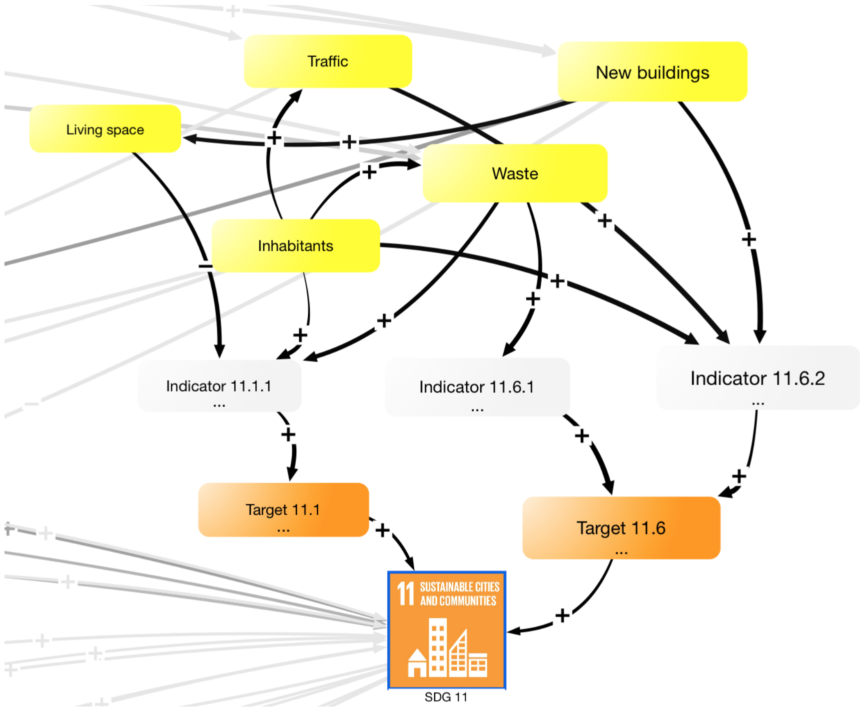

Figure 3: Exemplary illustration of synergies and trade-offs - an excerpt of the model

- more waste leads to more urban solid waste (indicator 11.6.1[7])
- more inhabitants lead to more fine particulate matter (indicator 11.6.2[8])
- more traffic leads to more fine particulate matter (indicator 11.6.2)
- more new buildings lead to more fine particulate matter (indicator 11.6.2)
- more new buildings lead to more living space

As shown in figure 3 concrete actions were linked to the defined subject areas. These concrete actions may influence the subject areas in positive or negative ways. To visualize the interdependencies of single actions or to identify the most useful action for SDG 11 or for one of the targets or indicators, the iMODELER is a helpful tool.

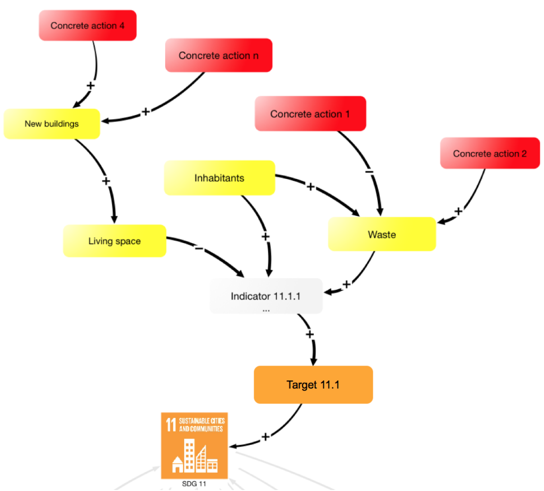

Figure 4: Target 11.1 in the center of the model

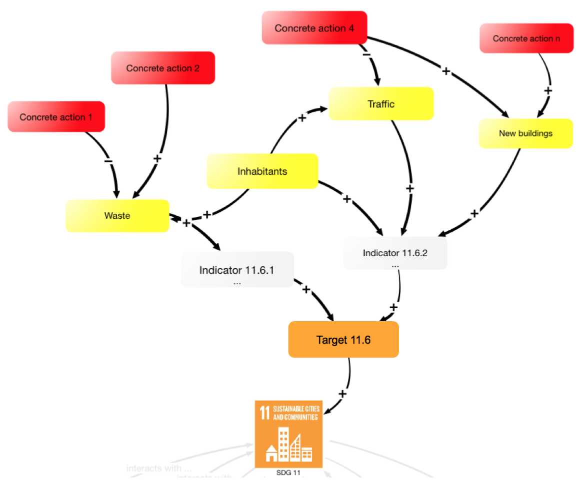

Figure 5: Target 11.6 in the center of the model

[7] Proportion of urban solid waste regularly collected and with adequate final discharge out of total urban solid waste generated, by cities

[8] Annual mean levels of fine particulate matter (e.g. PM2.5 and PM10) in cities (population weighted)

In figure 4 and figure 5 the comparison of influences on exemplary factors is shown. To visualize the systemic effects of concrete actions the tornado chart was used. In order to analyze the influencing factors for a selected target factor, the target factor must be placed at the center of the process model. The tornado chart shows positive and negative influences between the respective actions as well as synergies and trade-offs resulting from this consideration.

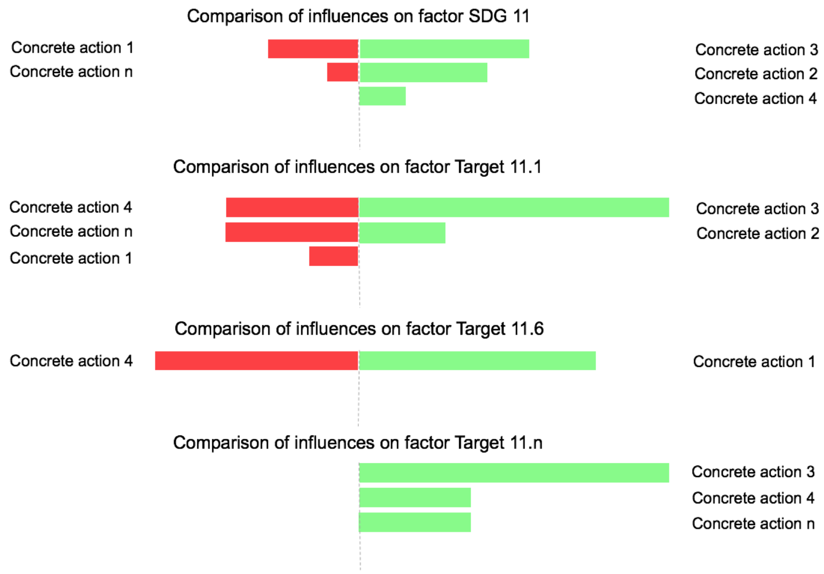

Figure 6: Concrete actions and their synergies and trade-offs shown as tornado chart

Behind the calculation of the effects is an extensive algorithm. The calculation of the tornado chart is done by multiplying the weights of influences between two factors. Starting points of the calculations are loops of inventory factors, which allow an exponential increase of influences in self-reinforcing loops. In order for the potential effect of loops to become clear, they run through the time steps (short-term, medium-term and long-term) twice.

For decision makers, this implies that action 2 and action 3 should be executed first. These actions have no negative effects on any of the centered target factors. Action 4 has a positive impact on the entire SDG 11 but has a negative impact on sub-target 11.1 and on sub-target 11.6. That implies that action 4 must have positive impacts on other sub-targets (not illustrated in figure 6) . If action 4 will be taken decision makers have to estimate how strong the negative effects on sub-targets 11.1 and 11.6 are and whether these have negative effects in the medium or long term. If decision makers only consider sub-target 11.6 and therefore executes action 1, this would lead to a negative impact on the entire SDG 11. With the systemic consideration within the tool iMODELER, these occurring synergies and trade-offs can be quickly identified and visualized.

4. Discussion

This article shows no analyses of concrete actions nor a recommendation for necessary actions to fulfill SDG 11. Rather it recommends a systemic approach supported by the iMODELER to handle the complexity of SDGs and their numerous subtargets. The detailed analyses of actions and their effects is currently under development in the UniNEtZ project. In Austria the implementation of SDGs shall be implemented on federal level. To coordinate the preparation and implementation the Federal Chancellery and other Austrian ministries established an Implementation Agenda 2030 for Sustainable Development. Civil society criticizes the way and intensity of this implementation process executed by the Austrian government and ministries. It is an important topic in regard to SDG implementation and policy. The development of the SDG indicators is already given, nevertheless the completeness and meaningfulness of many indicators can still be improved. The special focus in this work on SDGs in construction industry reveals that there is a need for a complete redevelopment of the construction sector because of its high energy and material use. The systematic literature review shows that literature on the topic of SDGs and interactions has increased in recent years from 4 articles in the year 2013 to 60 in the year 2018. Literature on the systemic nature of the Agenda 2030, and especially on synergies and trade-offs, is still in its infancy. In this relation insights gained from systems theory and cybernetics concepts play an important role in thinking and understanding of interconnections between different aspects and factors.

For the definitions of the SDGs and targets the linking between subtargets is a difficult step because targets are formulated very generally. Even when the SDGs are considered equivalent, the most important SDGs and targets for Austria, e.g. in regard to the building sector, should be identified. The definition and introduction of subject areas is a first attempt to make the model more comprehensible and tangible. In this manner new topics can be added and the extensibility of the model is possible. In any case before implementation the identified measures should be analyzed in regard to their impact. Based on several expert workshops in the area of SDG 11 the qualitative exploration of the interdependencies among SDG targets and related sub-targets and indicators as well as the levels of influence between immediate actions was exemplarily performed with the tool iMODELER.

5. Conclusion

We as a global society face great challenges which can only be solved together. With the SDGs we now have an agenda that addresses them in a comprehensive framework. That is why the Agenda 2030 can be chosen as a starting point to transform society in a sustainable way and it should also be used in science as well as in practice. High energy consumption, CO_2 emissions and material consumption are a problem in the Austrian building sector and must also face its responsibilities. Although it seems difficult, as there are multiple reinforcing and nested interactions among the SDGs, it is important that the Austrian building sector and its actors take into account systemic thinking and systemic approaches to contribute to the SDGs. Moreover approaches like the UniNEtZ project which aims for better science-society-policy dialogues should be implemented and used more often to bring different stakeholders together to identify common solutions supported a comprehensive and integrated know-how, towards the implementation of SDGs. Research recommendations are that the interdependencies within the Agenda 2030 should be explored in a systemic way for the Austrian implementation of the SDGs especially regarding the construction sector and the built environment. The tool iMODELER can help to pave the way for decision makers and assist them with decision-making as well as an argumentation and visualization tool e.g. for presentations. This must happen soon because as the Agenda 2030 should be implemented and reached by the year 2030, it must be clear that this is a very short timespan from this moment on. The research also shows that the iMODELER tool is a reasonable tool to model interdependencies among SDGs, their targets and indicators and helps to visualize synergies and trade-off between different actions connected to them. This tool can support decision makers to opt for the action with the least trade-offs and the most synergies with other SDGs. With regard to the pressing challenges the world and humanity is faced at the moment, such as the huge environmental impact of the buildings and construction sector, there is a need to rethink and redesign the sector to contribute to the SDGs, also in Austria. The Agenda 2030 is an opportunity to lead and initiate a change in this sector. Moreover this work shows that it is essential to work with systemic thinking and systemic approaches towards the implementation of the SDGs, demonstrating a complex and integrated framework, to address challenges of our time until the year 2030 in the optimum way. The tool iMODELER offers decision makers in Austria an option to visualize actions, which will e.g. developed by the UniNEtZ project, and their synergies and trade-offs. In a second step in this way immediate actions can be better prioritized and the actions with the highest synergies and least trade-offs can be chosen.

Retrofitting strata property - a tool supporting long-term retrofit strategy

Ehrbar D, Heim D, Mayer A-T, Schwehr P

Lucerne University of Applied Sciences and Arts, Competence Center Typology & Planning in Architecture (CCTP), CH-6048 Horw

doris.ehrbar@hslu.ch

Abstract. Strata property - ownership of apartments or townhouses consisting of private and commonly owned building components and areas - was established in Switzerland in 1965 and since has become very popular. But, well-needed retrofit work of these buildings is often postponed and long-term retrofit strategies are rarely considered. However, the low retrofit rate must increase to meet the global energy goals. Interviews and workshops with relevant actors showed that missing financial means are not the key issues for the low retrofit rate. Major challenges arise from a broad set of issues, such as difficult processes, unclear responsibility, insufficient communication, missing building information or underestimation of the commonly owned building components. "Luzerner Toolbox" provides eight folders that address the key clusters of challenges. Central to this toolbox are Excel-based tools, which transform accurate technical and financial information into a visual format. An ample diagram illustrates the remaining lifetime of the building parts and a graph relates upcoming retrofit costs and the annual payments into the contingency reserve fund with a forecast of the contingency reserve fund. As such, these tools assists in scheduling appropriate retrofit measures and establishing a balanced financial planning. But, various actors have reported that the retrofit timetable is too complex to be used in management firms. Feasibility studies and further research of their specific needs and work processes are needed to refine the tool accordingly. In a further study, interviews with management firms and architects are conducted to determine the key factors of a useful tool.

1. Introduction

In Switzerland, strata property – apartments or townhouses that consist of private and commonly owned spaces and building parts – was established in 1965 and since has become very popular. In canton Zurich for example, strata property has become an important form of home ownership. Between 1990 and 2014, strata property increased from 4.5% to almost 15% of the total number of apartments while the share of single-family houses remained stable at about 17% [1]. The reason for the success of strata property might be found in the low interest rates along with the increasing property prices. This situation allowed to purchase this limited form of home ownership at an affordable price. And, strata property owners profit from the various advantages of home ownership, such as independency from landlords, investment of capital or freedom to design their own home according to their needs and wishes.

When buying strata property, owners often do not consider the challenges deriving from the building, the organization or the corporation. They focus on their new (privately owned) property. As members of the corporation they are – in collaboration with the other owners – also responsible for the commonly owned spaces or building parts. The commonly owned property, which includes facade, roofs, windows, elevators, underground parking lots or outdoor spaces account for more than half of the property [2]. And, it has to be maintained and retrofitted periodically, until the building reaches the end of life. Missing financial means - which was believed to be the key problem – is not the only reason for the low retrofit rates or postponed retrofit measures of strata property [3]. Major problems arise from a broad set of issues, such as difficult processes, unclear responsibility and communication, missing information on the building and its physical state or underestimation of the commonly owned areas.

Other countries report analogous challenges in retrofitting or dissolving strata property. However, due to the different laws in place, they manifest in different management issues and legal problems [4, 5]. Do to the long lifecycle of buildings, the challenges in Switzerland arise in the retrofit of buildings rather than the dissolving of buildings. As buildings get older and owners change, it gets more and more difficult to find majorities for well needed retrofit measures. The reasons are multifaceted: overall goal of the strata property isn't defined, there's not enough money into the contingency retrofit fund and the inhomogeneous strata property corporation is not willing to pay well needed retrofit measures with extraordinary payments. This leads to the fact, that the effort to manage strata property becomes more and more difficult and unprofitable, the older a buildings gets. As a consequence, management firms more and more withdraw from managing strata property as experienced employees that are skilled to handle the multi-faceted decision-making processes can rarely be found.

Over time, these multifaceted challenges may negatively influence the success story of strata property in Switzerland. Even more, the low (energetic) retrofit rate of the growing number of strata property works against the Swiss federal energy strategy 2050 [6], which assigned the energetic retrofit of the building stock to be one of three key actions. Statistical numbers show that the Swiss building stock still consume about 45% of the total primary energy consumption [6] and, the retrofit rate of the building enclosures remained at about 1% [7]. If the federal goal will be met, both, the energy consumption of the buildings and the low retrofit rate of the buildings have to be increased.

Considering the intrinsic challenges, management of strata property may no longer be seen as the purely administrative task of the commissioned management firms. Strata property corporations will be forced to set up comprehensive management structures, which include all relevant actors and pursues distinct long-term strategies for the maintenance and retrofit of strata property. To do so, property managers and owners must become aware of the multifaceted challenges. And, they must have user-oriented guidelines and tools that enable to set up long-term strategies for the operation, maintenance and retrofit of strata property. Finally, owners must get comprehensive information to take well founded decisions, which help to preserve (or increase) the value of their property and, to improve the energetic performance as asked by the federal energy strategy.

2. Challenges in retrofitting and managing strata property

The research project "long-term strategies for the retrofit of strata property" [8] invested the key challenges of strata property in Switzerland and developed user-oriented guidelines and tools to support long-term strategies for the maintenance and retrofit of strata property. The research based on interviews with relevant experts in planning, building, retrofitting and managing strata property, financial and legal experts, and members of associations as well as workshops with strata property owners.

The interviews with the experts and the workshops with owners of strata property confirmed the results of preliminary work [3]. Challenges are not only found in the retrofit of strata property. They are multifaceted and for example arise from missing information on the building and its physical state at time of purchase, owners underestimating the share of the commonly owned building parts and spaces, insufficient reserves in the contingency reserve funds, lack of knowhow referring to maintenance and retrofit, difficult decision-taking processes, little willingness of the inhomogeneous corporation to approve long-term retrofit strategies, unclear responsibilities and mandates of management firms or little interest of strata property managers to take on the responsibility for technical management.

Figure 1 shows that the key challenges and milestones related to maintenance and retrofit of strata property includes the entire lifecycle of a building as well as all key actors [9]. To structure further work, the challenges were assembled in six superior clusters, which encompass "planning and building", "establishment and purchase", "management and operation". "retrofit", "strata property corporation" and, "cancellation" of strata property. The key challenges of the six clusters are discussed in [10].

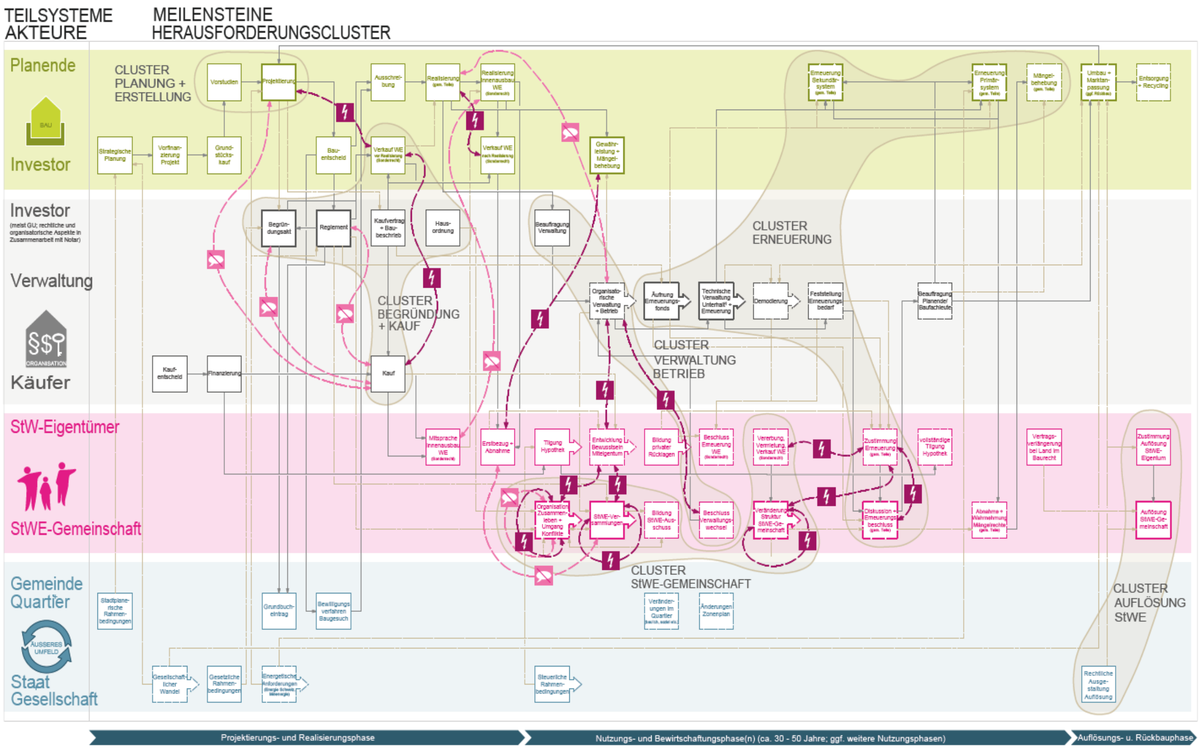

Figure 1. Scheme of the lifecycle of a strata property with challenges in maintenance and retrofit

3. Guidelines and tools for owners, corporations and managements

The interviews and workshops with key actors showed [8], that interdisciplinary work is necessary to overcome the multi-faceted challenges as shown in Figure 1. This means, that property managers – who mostly have a commercial background –need to collaborate with building professionals to manage the needs of technical management. However, this is only possible, if owners attach importance to that work and in consequence, assign the respective mandate and pay for it.

"Luzerner Toolbox" (Lucerne toolbox) [11] consists of 8 folders, which cover the most critical challenges assigned to the management of strata property. They provide useful background information and hands-on tools to manage long-term retrofit strategies of strata property. Folder 1, "Information for strata property", provides basic information on the challenges of strata property. Folder 2, "Optimized maintenance process for strata property", summarizes the key aspects of an optimized maintenance process. The visualization of the lifecycle includes milestones and decisions to be taken by different actors. Folder 3, "Tools for retrofit planning", explains the intention of the three Excel based tools as well as their use and function. Folder 4, "Exemplary rules and goals for strata property", provides guidelines and exemplary paragraphs that help to establish long-term retrofit planning in the regulations. Folder 5, "Specifications for the management of strata property", gives examples on how to stipulate the technical and administrative mandate. Folder 6, "Communication and conflict management in strata property", describes typical decision taking processes and provides guidelines on how to prevent and overcome conflicts. Folder 7, "Incentives for the retrofit of strata property", displays potential incentives that might be considered when retrofitting building and infrastructure. Folder 8, "Planning and design recommendations for strata property", provides guidelines for the planning and design of strata property, aiming at easing maintenance and retrofit as well as avoiding conflicts among owners.

3.1. Tools for the retrofit planning

Folder 3, "Tools for retrofit planning" [11], addresses owners and management firms as well as planners and architects. The three Excel based tools, "Tool A – retrofit timetable", "Tool B – forecast of contingency reserve fund" and, "Tool C – overview over retrofit measures" are designed to foster the planning and communication of long-term retrofit strategies.

The information, which is implemented into of "Tool A – retrofit timetable" and "Tool B – forecast of the contingency reserve fund", provides the base for the "Forecast of contingency retrofit fund" (Figure 2). It gives a graphic overview of the annual payments into the contingency reserve fund (blue line) as well as the relation between retrofit costs (black columns) and the long-term forecast of the contingency reserve fund (red line). If retrofits would be done as recommended by the retrofit timetable in Figure 2, the annual payments would not be sufficient without the three extraordinary payments.

This graph (Figure 2) is the core part of Folder 3, as it allows to displays all relevant information in a well-understandable, visual form. Even more, the graphic overview allows planners and architects or property managers to simulate and communicate consequences of different retrofit strategies or varying financing models. This helps strata property owners to make up their mind and to take well-founded decisions on how to maintain the common parts of the property.

Once the information is implemented, the tools should be actualised on a regularly bases. This might include an inspection of the building and critical building parts to determine the remaining lifetime. Being informed of the retrofit schedule as well as upcoming retrofit measures and the respective costs allows property managers to regularly communicate this issue. It also allows to take enough time for the complex decision taking process. Furthermore, clear and understandable information provides confidence and fosters strata property corporations to set up a long-term vision for the retrofit strategies.

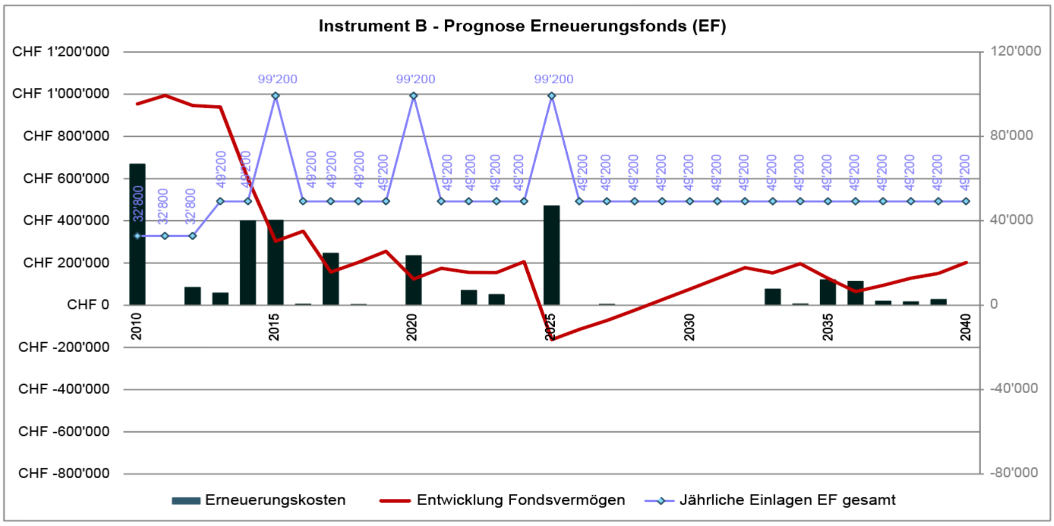

Figure 2. Forecast of contingency retrofit fund

3.2. Retrofit timetable (Tool A)

The retrofit timetable [12] bases on average retrofit costs published by Swiss Centre for Building Realisation [13] and the expected, average lifetime of building parts published by Swiss Homeowners Association [14]. The structure follows the Code for Building Costs [15].

The header of the retrofit timetable [12] includes year of construction, year of first retrofit timetable, year of current investigation and, average increase of building costs (Figure 3). Within a row, column 1 shows the code of the building part followed by its name, year of construction and respective building costs, the average lifetime of the building part or an estimation of the remaining lifetime as well as the year of retrofit or replacement and respective costs.

The entry information in the header and the information on the building parts (column 1 to 8) generate the necessary annual provisions needed to retrofit or replace a building part at the given time (column 9). The total of the average annual costs for the retrofit of the single building parts is shown at the bottom of the table. The remaining lifetime of the building parts is illustrated in an ample diagram on the right hand side of the entry mask. The colours of the ample diagram indicate how urgently a building part should be renovated or replaced. Green colour means, the renovation is not expected in the next 10 years. Yellow and orange indicate that a building part will have to be renovated or replaced in about 5 – 10 years and 2 – 4 years, respectively. Red colour means that the average lifetime is one year or less and an on-site check is strongly recommended.

The tool allows to work on different levels of detail. Level 1 (Figure 3) shows the primary building parts or spatial units (e.g. windows, staircase), whereas the respective ample displays the subordinate building part with the shortest remaining lifetime. This level of detail is only to be used to communicate rough first overview. Level 2 consists of subordinate building parts (e.g. windows of apartments, windows of staircase, etc.) and Level 3 splits the building part or spatial unit up in further sub-items (e.g. wooden windows of apartments in upper floors, wood-metal windows in apartments of ground floor or double-glazed windows of staircase, etc.). It is recommended to work on Level 2 or 3. The more detailed the entry information is, the more accurate is the information on the remaining lifetime of the building parts and the respective costs for retrofit or replacement.

Figure 3. Tool A – Entry mask for data referring to the retrofit timetable

If the initial building costs are not available and it is not clear what physical state the building and its building parts have, it is not possible to fill in the retrofit timetable. In order to get reliable information, it is recommended to mandate building professional with the setup of the renovation timetable.

3.3. *Forecast contingency retrofit fund*

The forecast of the contingency retrofit fund [12] requires basic information on the building (year of construction, insurance value, owner quotas) and financial information, such as first year of investigation and respective balance of contingency retrofit fund, current year of investigation, year with first payment and annual payment into the contingency retrofit fund, interest rates on the reserves in the contingency fund as well as minimal or maximal balance of the contingency retrofit fund. The forecast of the contingency retrofit fund table (Figure 4) transforms and displays the information relevant long-term strategies for the retrofit of strata property. These are the annual payment into the contingency retrofit fund (column 3), extraordinary payments (column 4), the average annual retrofit costs (column 10) and the development of the contingency retrofit fund (column 11).

Figure 4. Tool B – Entry mask referring to the contingency retrofit fund

3.4. *Suitable packages of retrofit measures*

According to the ample diagram of "Tool A – retrofit timetable" (Figure 3), planners and architects can set up suitable retrofit packages, which can be realised in accordance to the timetable. All the relevant information, such as a preview of upcoming renovation periods along with respective retrofit measures and retrofit costs, current state of planning as well as state of decisions and required quorum, can be documented in "Tool C - overview of retrofit measures" [16]. The exemplary structure is meant to support the communication with the strata property corporation and to plan the complex decision making process. Furthermore, it supports owners in coordinating private retrofit work with the common one. Regular update is necessary to keep the tool up to date and reliable.

4. Implementation of tools

Feedbacks of experts and strata property owners have shown, that the tools of folder 3 "Tools for retrofit planning" are of great interest for the planning of long-term retrofit strategies. However, they state that the handling of "Tool A – retrofit timetable" is too complex. It is assumed that this feedback bears two major barriers. First, the detailed information, which is has to be compiled and entered into the tool, requires in-depth knowhow on maintenance and retrofit. Second, the implementation of the broad set of data is time consuming. And, the compilation and entry of the data is not covered by the mandate. Thus, it is necessary to do further work on the role of the management firms as well as on the optimisation of the retrofit timetable.

Research on the role of management firms on energetic retrofit has shown [17] that management firms have a great impact on the renovation of strata property. They often initiate and accompany retrofit measures. In doing so, they evaluate the needs of the corporation, call the experts (e.g. architects) and establish the contact among the relevant actors. Also, they must inform the strata property corporation and, withstand the high expectations of the owners. However, management firms cannot cope with all these requirements. This role goes beyond their core business and, it would require additional organisational and financial effort. For these tasks, they only have a vague or no mandate at all.

"Tool A – retrofit timetable" is based on the work environment of planners and architects. And, it is meant to provide accurate information for setting up long-term strategies for strata property. A reduction of the level of detail has direct impact on the accuracy of the information. Other tools, such as "Stratus" [18] or "Cost Planning for Retrofit" [19] rely on the insurance value or the construction costs of the building, the major building parts as well as rough values for its lifecycle and the respective building costs. As such, they generate a fast overview over the critical building parts and the cost for retrofit. But, this information does not consider the design and construction of the building, nor to the actual state of the building parts. It may only be used for a fast and rough overview of the major building parts. Also, it is not clear, how the privately and commonly owned parts of the building are split. Considering these facts, the new research project will have to get insight into the work processes of planners and property managers and evaluate the appropriate level of accuracy before the tool is overworked accordingly.

5. Discussion

Research has shown, that there is in-depth disciplinary knowhow on how to retrofit building and to calculate the respective retrofit costs as well as to achieve long-term maintenance and retrofit strategies. But, the problem lies in inadequate mandates, inflexible processes and the way key actors collaborate and communicate. A closer collaboration between planners, management firms and the strata property corporation would generate multiple benefits. Within this core team of experts, planners or architects would have a mandate for the technical issues, such as the periodic evaluation of the state of the building, the set-up and maintenance of the retrofit timetable, the overview of the retrofit measures and assist, if necessary, with the technical management. Management firms would be in charge of the administrative and technical mandate and, the corporation board would represent the interests of the strata property corporation. Together, the core team could set up recommendations for the long-term retrofit strategy of the strata property. They also inform the corporation on the strategies and the current state of planning. This approach can help to establish a broad support of the retrofit strategies and to avoid precipitate actions as well as uncoordinated and costly retrofit measures. But, this process can only be initiated, if the strata property corporation sees the benefits and approves the mandates.

Given the fact that processes and mandates are adapted, "Tool A – retrofit timetable", must not be simplified, but, set up a connection between the work environment of planners and architect and the one of the property management firms.

6. Outlook

As property prices rise, the popularity of strata property will further increase in Switzerland. But, the increasing demand of strata property bears the risk that more and more existing multi-family houses are sold to strata property corporations. As these buildings are not planned for strata property and have passed a good part of the lifecycle, special attention has to be given to proper management and communication. Major retrofit – along with major costs – will most probably come up in only a couple of years. At that time the challenges and the effects of discordant strata property will no more be limited to the actors involved.

Considering the growing issue, it might become necessary that the intrinsic challenges are addressed by a broader circle of actors, such as banks, home owner associations or the federation. Banks might consider alternative financing models for strata property owners that cannot increase the mortgage. The strata property association could provide guidelines and exemplary regulations that help strata property corporations to establish long-term retrofit planning in the regulations or, they could intensify further education of strata property owners or property managers. And, last but not least, federal laws and provisions could enforce appropriate and prompt retrofit.

Mobilizing Low Carbon Transition: Transnational Practice of Energy Efficiency in the Urban Building Sector

Feng K, Schmidt J A

Institute of City Planning and Urban Design, University of Duisburg-Essen, Universitätsstraße 2, 45117 Essen

keru.feng@gmail.com

Abstract. In many countries worldwide, low carbon sustainable transition has been planned and implemented through decoupling the economic growth from GHG emissions. Some nations are leading the scene by developing corresponding low carbon development strategies and policy measures to encourage socio-technical innovations. One of the key areas for low carbon urban development is the energy efficiency in buildings. The tendency of the rapidly growing population and urbanization asks for better narratives and practices improving the built environment. Cities and countries are keen on learning from best practice. Through international joint development projects, the "knowledge resources" - transnational, governmental, NGOs, practitioners, and academic actors - are disseminating the low carbon urban development ideas globally. What drives a successful translation of knowledge emerged from one social, economic, cultural, political, climatic and geographical context into a new one needs better clarification. This study explores the process of global circulation of sustainable innovation from a mobility and transition perspective. A conceptual framework is explored and tested through analysing the Passive House concept transferred from Germany to China. The study shows how the succinct form, co-evolving and re-contextualising attributes are key factors in circulating urban sustainability across context. Acknowledging the notion of adaptation and mutation in the translation process is a first step to address the discrepancies between the knowledge lending and receiving side, and further to foster the transformative learning.

1. Introduction

In the international community, transformative actions have been planned and implemented in many countries endeavouring climate change mitigation through decoupling the economic growth from greenhouse gas emissions [1]. They generate proven synergies with Sustainable Development Goals (SDGs) [2]. It is widely acknowledged that a socio-technical transition is necessary for an ecological friendly sustainable development [3]. One of the key approaches for climate mitigation is the energy efficiency and renewable energy in building sector [2], which accounts for 31% of global energy use, and 23% of global energy-related GHG emission [4]. The tendency of increasing population and urbanisation asks for better narratives and practice for better built environment. The largest energy saving potential is in heating and cooling demand, largely due to building envelope improvements and energy-efficiency and renewable energy adoptions [1, 2]. As a result, low-energy, low-carbon design and construction concepts such as ultra-low-energy buildings, passive houses, and plus energy buildings are receiving growing interest globally.

While the COP21 climate negotiations adopted the first ever global climate deal, some nations are already leading the scene by taking corresponding low carbon development strategies through socio-technical innovations. In building sector, socio-technical changes have been observed, for example the development goals and policy measures are promoting the increase of renewable energy equipment in China [5] and net zero-energy building (nZEB) in Europe [6].

Countries are keen to learned from “best practices”. Through international practical networking and cooperation, the “knowledge resources” - transnational, governmental, NGOs, practitioners, and academic actors - are disseminating the low carbon urban development ideas globally. However, what makes an idea of low carbon innovation globally transferable? How is the knowledge adapted during the process of translating from the emerged context to the adopted one? What makes a success/failure of transferring low carbon development model into a new geographic, social, political, economic, cultural context?

This study explores a theoretical tool drawn from the literature of knowledge mobility and transition studies, and further investigates the translating process of Passive House concept from Germany and Europe to China.

2. Conceptual Framework

The knowledge circulation process is conceptualized in the literature of policy mobility from international development experience. The conceptual framework drawn from the policy mobility literature helps to understand how policy ideas flow transnationally, interacting with the local actors and adapting into a new context [7, 8, 9]. It addresses the “struggles involved as particular ideas are drawn into—localized—in new situations” [11]. The result is co-evolving of the ideas as they travel into the new social, cultural, institutional, and economic situations [10]. It brings up the questions of the actual impact by disseminating the “best practices” or sustainable development models. It highlights the traveling process as the processes of disseminating, translating and adapting [12], addressing the driving forces from both idea lending and receiving contexts [13]. It interprets the process of policy/knowledge transferring with the notion of mutual learning [14]. The green innovation is subject to a re-combination with pre-existing on-site knowledge that can lead to further innovations [15].

Recently, the growing interest in green innovation, climate change and sustainable development has been drawn on transition studies, which focus on interaction of social and technological changes [15]. The discussions help to identify the drivers and barriers of low-carbon sustainable transitions in the urban system, particularly on the topics of transport, energy and building sector [15, 16, 17, 18]. The transition process is conceptualized by the multi-level perspective model (Figure 1, [19]). It identifies three hierarchic and co-evolutionary levels to analyse the complexity of changes in socio-technical systems: 1. A micro-level of niches, where innovations occur e.g. experimental projects or policies, inventions, and community initiatives; 2. A socio-technical regime where the dominant standards, norms, structures, institutions or market rules are stabilised over time; 3. A socio-technical landscape level, where changes usually take place slowly in this wider context including cultural norms, values, demographic trends or political strategies [19].

Experiments can trigger social change. Experimental niches are protected from the normal rules, for example pilot projects or special subsidy programs. These niches are tested and developed. Successful ones can be translated to the regime level and formulate new regular conditions. The ones who cannot trigger aligning changes at regime and landscape level will fail. The three levels are co-evolving and subject to external driving forces [15, 19, 20]. For example, the oil crisis and Chernobyl nuclear disaster triggered the transformative power for the Energiewende (German energy transition).

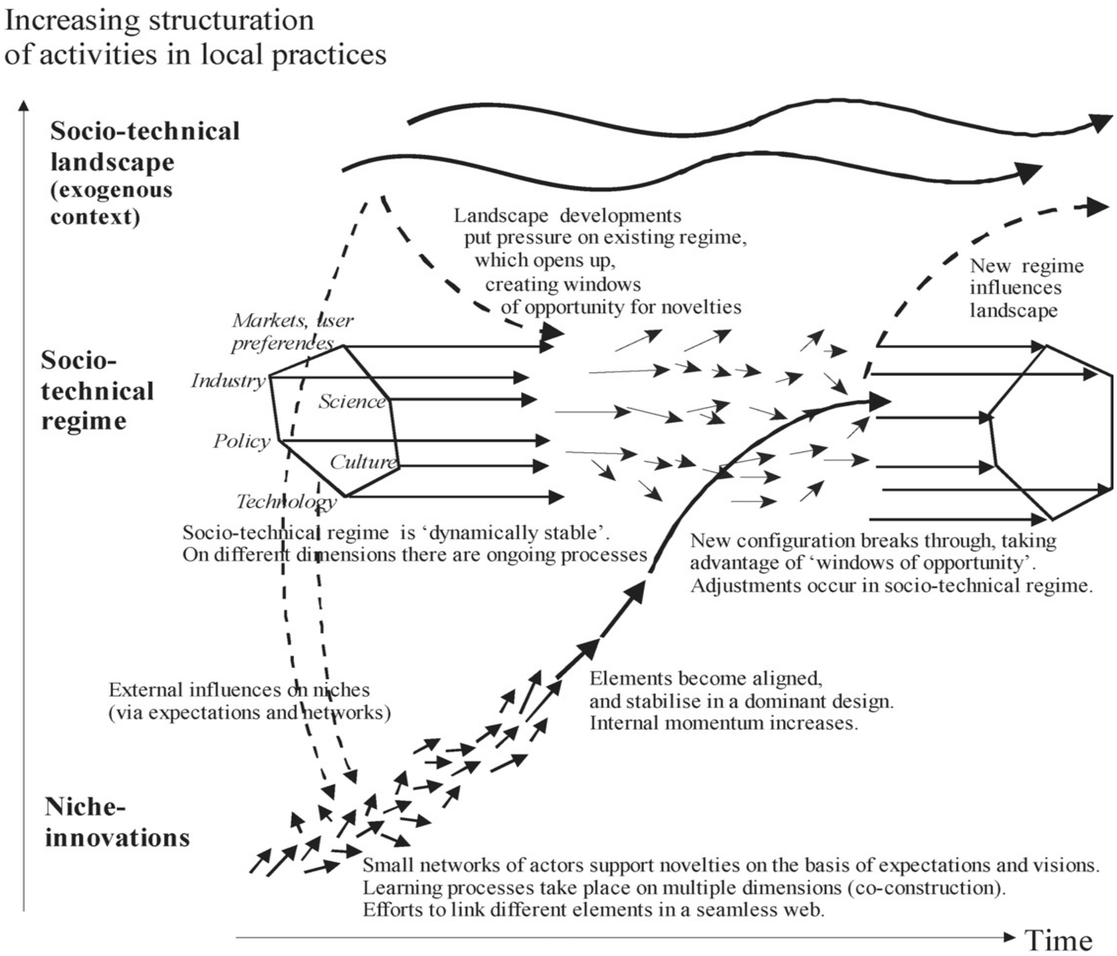

Figure 1. Multi-level perspective on transitions (source: [20])

Affolderbach and Schulz (2016) further explored the synergies of the transitions and policy mobility framework by proposing the concept of "mobile transitions". Transition studies focus on the impact of local experimental niches on the local or national socio-technical regime, which lead to transformation. Policy/knowledge mobility framework offers better understanding of the traveling process of ideas cross-locally or transnationally. Combining the transition with mobility frameworks can provide a better understanding of overall process of cross-local knowledge translation [15].

Based on the conceptual framework of policy mobility and transition studies, this paper examines the case of European low-energy building experiment of the Passive House, and its translation into Chinese context. The data sources include design documents, technical reports, policy documents, academic publications, conference presentations, websites and media articles.

3. Passive House in Germany: From Experiment to Standard

The Passive House concept was developed in 1980s when the oil crisis triggered economic depression and environmental social movements in Germany and Europe. Nationwide, there was growing concern on energy security and climate change. The civil society, policy, and culture were synchronously moving towards an ecological modernisation [21, 22]. The strategy underlying the Passive House experiments was to create a low energy, low emissions, resource efficient building through strict heat conservation: thermal protection and heat recovery. While some of the passive house principles have been applied over the world in vernacular buildings and research projects, the Passive House concept is considered being created by Professor Bo Adamson of Lund University (Sweden), and Dr. Wolfgang Feist of the Institute for Housing and the Environment (Germany) in 1988 [23]. The approaches of Passive House are excellent insulation, prevention of thermal bridges, airtightness, insulated glazing and heat recovery ventilation. The concept is designed to fit central European climate with no necessity for active heating facilities [24].

The concept was materialised in 1991 in the city of Darmstadt to the result of passive house feasibility research funded by the Hessian ministry for economics and technology. A Passive House Developers Society composed of four families, with Dr. Feist's among them, was formed in the city quarter of Kranichstein and commissioned the architects Bott, Ridder and Westermeyer to build a row of four family houses. Each of the 156m² apartment was designed with perfect thermal features in roof, exterior wall (275mm EPS), basement ceiling and windows (triple-pane low-e glazing), together with heat recovery ventilation, ground heat exchanger for preheating the fresh cold air and solar collectors for hot water supply. The maximum heating loads in Kranichstein passive house was 10 kWh/(m²a), which saved 90% energy than conventionally built houses [24].

Although there was local political support from Hessen state and Darmstadt city government, established policies and funding incentives to support this development did not pre-exist, until later in 1990 KfW bank began to provide low-interest loan to encourage energy saving projects [24]. There was reluctance from the private owners to invest into such buildings: the price is relatively high although 50% of the building cost was covered by the state of Hessen; energy was not so expensive as it is today; there was no mandatory regulation for such low-energy building [26].

In 1996, Passive House Institute (PHI) was found to further research, develop and promote the Passive House model. The technical and economical practicality of implementing Passive House standard was tested through the European sponsored research project - Cost Efficient Passive Houses as European Standards (CEPHEUS). In 1997, European Commission funded 262 passive houses projects in Austria, Switzerland, Germany, France and Sweden, and to present the result in the Expo 2000 in Hannover. The passive house built by PHI is located in Kronsberg district of Hannover, beside the site of EXPO 2000. Through the CEPHEUS project, the Passive House concept demonstrated itself to be technically and economically feasible across Europe [27, 28].

Since then, the Passive House concept was "traveling" widely, applied not only in buildings but also in urban districts, for example the Bahnstadt residential area in Heidelberg [29]. Currently there are approximately 25,000 passive houses in the world and 80% of the projects published by PHI are built in Germany and Austria [30].

The Passive House concept includes three formulations: Passive House standard, Passive House Planning Package (PHPP) design tool and the certifications to buildings and components. The framework also supports the policy goal of energy efficiency. In Germany, KfW bank provides funding support for the passive house construction and retrofit [31]. The international consultants, academics, NGOs began to introduce Passive House as a good practice toward low-energy, low carbon sustainable urban development to other places around the world [32, 33, 34, 35, 36].

Passive House developed as a traveling concept, was evolving as the result of interacting with the local and global actors. At the beginning, the Passive House standard is designed to fit central European climate and the requirements are on space heating demand ≤ 15kWh/(m²a), primary energy demand (for all energy services) ≤ 120 kWh/(m²a), and airtightness (Ionescu et al., 2015). Later the cooling demand requirement of ≤ 15 kWh/(m²a) was read in the Passive House standard, responding to the hot climate zones. In 2010, European Union issued updated Energy Performance in Building Directive [37], which introduce the nearly-Zero-Energy Building (nZEB) as goal for all new buildings by 2021 and for new public building by 2019. Meanwhile, the energy efficient innovations in construction industry further developed, for example the Plus-Energy-Building concept [23, 38]. In 2014 PH standard is re-classified as PH Classic, PH Plus, PH Premium, and EnerPHit for retrofitting exiting buildings [39]. In the new rating system, the primary energy demand is replaced by PER (Primary Energy Renewable) to support the energy transition agenda in Germany and worldwide. The PER calculates energy demand in detail through PHPP, responding to each of climate zone globally. The component requirements are correspondingly adapted to the climate zone and cost efficiently optimised for the applied zone [40].

Passive House was developed as a nearly zero energy building model. The experiment was driven by engineering pioneers to test the technical principles, design options, design tools and to develop the cost-effective solutions, which could be promoted and adapted in a wider socio-technical context [24].

4. Passive House in China: Disseminating, Translating and Adapting

China has ratified the Paris Agreement and is engaged in its post-2020 nationally determined contributions (NDCs) to mitigate and adapt to climate change. In China, the building sector accounts for 28% of the energy consumption, and the number is rising due to the growing population, rapid urbanisation and industrialisation [41]. The resource and energy security concerns brought China's growing emphasis on energy efficiency in the 11th, 12th and the current 13th National Five-Year Plan. From 1986 to 2015, China issued about 44 building energy efficiency-related standards [42], and since 2002 initiated series of energy efficient and green building pilot projects [43]. Policy implementation, financial incentives, accelerated approval processes, and priority of land allocation boosted the investors' interest in developing energy-efficient profile properties and therefore increasing their competitiveness [43, 44].

Additionally, the Chinese government considered the energy efficient and green building technologies as pathways to modernise Chinese building industry [45, 46, 47]. Energy efficient and green profile projects also helped to attract international financial and technical support and increase attraction for foreign business and investment [45]. Moreover, solar and wind energy had rapidly development in China thanks to the policies and subsidy programs [48]. The launching of emissions trading system in 2017 and potentially later carbon tax helps to trigger greater demand for renewable energy and energy efficient technologies [49], [50]. Passive House's suitability to adopt renewable energy [51] aligns with China's strategy to increase the market demand for energy-efficient and renewable energy products and services.

The first passive house in China was the Hamburg House built by Hamburg city in Shanghai World Expo 2010. The 2,094 m^2 exhibition centre was designed to meet the German Passive House Standard and Hamburg HafenCity Environmental Standard, aiming to promote the best practice of the "European Green Capital 2011" [51]. During the Expo, the dissemination of passive house concept was facilitated through relative events and mass media attention. But translating the idea into Chinese context confronted difficulties due to its requirement to transform local existing regulations, construction process and production. After the Expo, the Hamburg city government did not further fortify the translation process on Passive House [52].

The translating process was greatly facilitated through the "German-Chinese Working Group for the Promotion of Energy-Efficient Building" partnered by the Ministry of Housing and Urban-Rural Development of China (MoHURD) and the German Energy Agency (dena) established in 2006. Dena worked directly with the socio-technical system through political dialogue, knowledge transfer and strategic market development [53], with benefit from the long-term political support and national branding programs such as "Sustainability - Made in Germany", "GreenTech – Made in Germany", and "Energy Efficiency – Made in Germany" [54, 55, 56]. Under this partnership, dena and the Science Technology and Industrialization Development Center (CSTC), an affiliation of MoHURD, jointly developed pilot projects with low-energy and passive house approaches. in 2012, a 6718m^2 high-rise residential building in Qinhuangdao city of Hebei province was built as the first pilot Passive Ultra-Low-Energy Building [57]. Thermal performance of the building envelope is excellent with passive design approaches such as thermal-bridge-free well-insulated (220 mm EPS) exterior wall, triple glazing low-e windows, air-tightness, and energy recovery ventilation system. The energy demand for heating and cooling is 16 kWh/m^2a, primary energy demand is 102 kWh/m^2a. The project was nation-wide promoted as a show-case of successful knowledge transfer on German energy-efficient technologies, products and construction processes with potential to proliferate on the large scale in China [52]. Subsequently Hebei province released the first voluntary passive building standard guideline based on German passive house standard: Design Standard for Energy Efficiency of Passive Low-Energy Residential Buildings in 2015 [57, 58]. Later that year, based on the passive house experiment through transnational cooperation e.g. with Germany and US, MoHURD issued trial version of Technical Guidelines for Passive Ultra-Low-Energy Green Residential Buildings [59]. At provincial level, policies, financial incentives and standards are developed in Beijing city, Hebei, Shandong, Henan, Heilongjiang, Jiangsu and Jiangxi provinces [52].

In 2016, the concept of passive house appeared in the Guidelines on Urban Planning and Development released by Communist Party of China Central Committee and the State Council [60]. Regulations released by State Council set the tone of rules, standards, plans and financial incentives released by ministries, for example MoHURD and Ministry of Finance [61]. Thus, this policy document is considered as an evidence to mainstream the Passive House concept in energy efficient buildings in China.

In 2017 MoHURD issued 13th Five-Year Plan for the Building Energy Efficiency and Green Building Development [62]. Referring to the international narratives, the nearly-Zero-Energy Building (nZEB) has become a crucial concept, targeting on building over 10 billion m^2 pilot nZEBs by 2020. Recently, MoHURD is developing the National Technical Standard of Nearly-Zero Energy Building. The framework directly referred to the experiments of Passive House pilot projects. For example, the airtight building envelope is required although it is still new to Chinese construction process and no Chinese standard on air tight construction exists yet [63, 64, 65].

Nationwide, there are more than 100 projects built through passive house approach. Some are awarded certificates based on different standards, namely the Passive House Certificate, Sino-German Energy-Efficient Buildings and CPBA Certificate (Table 1). The Passive House concept can be adapted to the rich Chinese vernacular architectural styles and different climates. Although most of the certificated passive low-energy buildings are in severe cold and cold climate zones, there are also trial adaptions to the hot summer-cold winter and hot summer-mild winter climate zones. Passive House approaches have been adapted to local context and are moving towards creating a new socio-technical regime.

Table 1 Certificated passive low energy building in China by 2017

Certification	Quantity	Awarded by	Standard	Description
Passive House Certificate	20	Passive House Institute, Germany	Passive House Standard	Category: office building, residential building, industrial building, exhibition enter, health centre, and kindergarten in China's 4 climate zones
Sino-German Energy-Efficient Buildings – Passive Low-Energy Building Quality Certificate	30	Dena and Science Technology and Industrialization Development Centre (CSTC) (affiliated to MoHURD)	Sino – German Energy Efficiency Standard	Category: office building, residential building, exhibition centre, school in China's 4 climate zones
China Passive Ultra-Low-Energy Buildings - CPBA Certificate	34	China Passive Build ing Alliance (affiliated to China Association of Building Energy Efficiency)	Technical Guidelines for Passive Ultra-Low-Energy Green Residential Buildings (MoHURD)	Category: office building, residential building, exhibition centres, health centre and kindergarten, covering 4 climate zones in China

(Source: [66, 53, 52])

The recent Passive House urban district development in Gaobeidian, which locates 100km south of Beijing, tests the practicality of proliferating the Passive House principles in China at large scale.

Bearing the same name after the German Passive House district Bahnstadt in Heidelberg, the Bahnstadt Gaobeidian includes 30 high-rise buildings, several multi-story and single-family buildings in over 1,000,000m^2 [67]. Implementing the world's largest Passive House settlement project in China requires to overcome the discrepancy between PH standard and Chinese construction routines, to develop construction knowledge and capacities to apply PH technology in large scale projects, and to formulate economically feasible solutions, which are by no mean guaranteed through the knowledge gained from successfully implemented small pilot projects [68].

The adaption of the Passive House approaches to the Chinese context was supported greatly by active dialogues with the local actors (local administrators, professionals, construction supervisors and component producers) through seminars, conferences, training programs and study tours, facilitated by German consultants, academics, NGOs and development agencies [53, 69, 70, 71, 72]. It encouraged to foster a context-oriented passive house development model and nurtured the mutual learning process.

The Passive House's process of translating into local context also confronted difficulties. For example, the current regulation on floor area calculation doesn't allow the extra insulation thickness to be deducted from floor area, which can be discouraging to the private energy efficient property development [52]; Evidenced by documents, experts are holding different arguments if the passive house concept is suitable to be adapted in Chinese climate zones with hot summer, and there exist few closely monitored and proven evidences in China; Both construction and industrial production capacity is increasing but slowly [73]; The Chinese culture is not yet co-evolving with the technical change. For example, 20 out of the 21 Chinese passive houses published by PHI are consulted by planners, architects and engineers with German background. To the most of Chinese developers, the Passive House is merely "a mirror image of German Passive House technology in China" [74].

5. Discussion and Conclusions

The Passive House concept developed from the experiments in Germany and Europe successfully disseminated and translated into Chinese practice. The standard criteria are smooth to be circulated with its simple and concise narrative character, which merely requires control for heating, cooling, primary energy and airtightness. The challenges are on implementation which inform the existing routines, regulations and culture of building industry. However, the provided design tool (PHPP) to support the design choices, educational and networking programs facilitating the planning decision making, and PH certification for incentives and promotion significantly increase the capability of the Passive House to be translated and inhabited into the new context. It shows that the translatable knowledge distilled from an experiment needs to be clearly defined and succinct. Its form should be able to overcome the context (socio-technical regime and landscape) from which the knowledge emerged and re-align with the context into which it is translated.

The narrative of Passive House appears to be evolving, on account of changing climate and energy policy narratives, market trends, knowledge transferring actors, and practice evidences. Through the translating process the Passive House framework interacts with the socio-technical regime on the recipient side. For the transnational practitioners, it presents the necessity to recognise this eco-evolving nature throughout the translation process. In the cross-local practice, the contexts (socio-technical regime, landscape and their driving forces) from both knowledge supplying and demanding sides should be full addressed and understood, if improved outcomes are to be achieved.

Combining mobility with a transition conceptual framework is very useful to clarify the overall translating process of knowledge distilled from experiments in the original socio-technical context into a new one. It extends the notion of "adaptation" and "mutation" in the mobility conceptual framework. This study is limited to the documentary evidence on general base. Further endeavour should be to develop a clearer conceptual model to better articulate the translating process. Detailed case studies based on stakeholder interviews and document reviews should be conducted on the translating process of Passive House from German and Europe to China, in order to examine the theoretical framework with detailed empirical evidence.

Strategies for a sustainable energy transition: the case of the housing sector in Graz, Austria

Hohmann B

University of Graz, Institute of Geography and Regional Science, Heinrichstrae 36, 8010 Graz

bernhard.hohmann@uni-graz.at

Abstract. To facilitate a sustainable energy transition, the housing sector needs to be considered as a whole. Consequently, buildings as well as spatial structures have to be sustainable. Buildings, new and existing, need to be energy efficient, low carbon, considering diverse demands, while also providing a healthy indoor environment and a high quality of life. Spatial structures have to be efficient through compact development, supporting the transition to a post fossil society and mobility regime, that also provide high quality public spaces. In a transdisciplinary approach, strategies and policies, relevant for the case of Graz, Austria, were analyzed. Challenges and potential solution approaches were identified in a theory discussion, considering spatial development and construction aspects. A resulting set of measures to support the necessary sustainability transition is evaluated and iteratively enhanced by qualitative expert interviews with relevant stakeholders, i.e., researchers, practitioners and the administration. The aim of this research is to come up with a set of policy recommendations for decision makers. First results of this work in progress are already available and presented in this paper.

1. Introduction

In order to avert drastic consequences of climate change, the 2 °C target, also embraced by the Paris Agreement [1], needs to be met. This is only possible if GHG emissions are significantly reduced to achieve the energy transition to 100% renewables. Participating countries have set themselves individual goals, which will be hard to attain, but still even need to become more ambitious. Furthermore, climate change is not the only challenge that needs to be tackled. Brand argues, that the situation can be rather described as a multiple crisis, which requires a profound social change [2]. The Sustainable Development Goals (SDGs) [3] are a key global governance approach, that tries to tackle this complex situation comprehensively, covering not only climate action, but all kinds of social aspects as well. The SDG 11 *Sustainable Cities and Communities* is of special importance, as buildings are a major contributor of GHG emissions due to their high energy consumption.

According to the Energy Efficiency Plan of the EU [4], buildings account for 40% of the total final energy consumption in the EU. More than 80% of this energy demand is caused by heating and domestic hot water. In addition, construction and renovation processes also contribute to energy demand. Moreover, the location of a building indirectly also influences the amount of emissions, as it impacts mobility patterns of occupants and infrastructure extent.

As a result, buildings in loosely populated suburbia are generally responsible for a significantly higher energy consumption, due to less efficient mobility patterns than homes in urban areas. Furthermore, considerably more resources have to be spent (energy and money) on the construction and maintenance of the necessary infrastructure in dispersed areas. Therefore, it is crucial to consider the spatial dimension of the housing sector, to decrease its impact on energy consumption. Consequently, it is favorable to promote measures that lead to denser structures, which can also be socially beneficial and integrative.

Individual buildings, on the other hand, raise questions, such as, how they should be built, heated, cooled or ventilated, in order to facilitate a switch to renewable energy supply, to increase their energy efficiency and to decrease energy and resource consumption. Moreover, a distinction is necessary between new constructions, with significantly more degrees of freedom, and existing buildings that need to be refurbished, insulated or adapted. All these discussions must not neglect the social dimension of sustainability and thus, consider the needs of and impacts on the residents, providing a high quality of life.

Graz, as a medium sized European city, serves as a case study for this research. Until 2030, the city is expected to grow dynamically within the city limits by 18% (based on 2014), i.e., approximately 48,000 additional inhabitants with an according need for new housing [5]. Furthermore, the historic center of Graz is an UNESCO World Heritage site, which limits growth and redensification options in the downtown area, as well as energy efficiency measures.

The aim of this research is to generate a set of strategic principles and specific measures that can guide the housing sector in Graz on a path of a sustainable energy transition. The suggestions consist of top down measures (i.e., legislation, tax or subsidies), but also consider bottom-up approaches, such as the strategic enforcement of increased participation. The generation process of this set of recommendations, as well as the whole research design and methodology is outlined in Section 2. A system model describing the relations of stakeholders and the connection to the research process is presented in Section 3. The preliminary set of recommendations is discussed in Section 4, while the current state of this research in progress, next steps and future work, will conclude this paper in Section 5.

2. Research Design

The underlying hypothesis of this research is that: strategies, regulations and incentives, concerning the housing sector in Graz, have to be significantly improved to promote a sustainable energy transition. This leads to the research question: how to adapt strategies, regulations and incentives (subsidies and tax), to enforce the right measures to promote a sustainable energy transition? To answer this question, a transdisciplinary approach was chosen, as discussed in Section 2.1. The applied mixed methods multi actor process is presented in Section 2.2.

2.1. Transdisciplinary Approach

As stated by Stiess et. al. [6], few fields of action are as complex as the area of housing and construction. Ecologic, economic, social and institutional dynamics are interconnected in numerous ways, causing interacting and overlapping effects. Therefore, an adaption of the building stock requires the consideration of a multitude of actors of different fields and contexts. In addition, various professional perspectives and conflicting goals need to be incorporated. According to Stiess et. al. this integration effort can only be tackled by applying a transdisciplinary approach. First, disciplinary knowledge of fields, such as construction, architecture or urban planning need to be analyzed and combined to a coherent concept. Second also the relevant actors for an according implementation of the proposed measures need to be included in the research process [6].

Consequently, a transdisciplinary approach is chosen to answer the present research question. Moreover, this work has the aspiration to not only analyze this complex field, but also to trigger change to make the current situation more sustainable. It is hence based in the field of critical geography, which traces back to Max Horkheimer's critical theory and assumes, that everything that influences human life is man-made and thus changeable [7]. This connects to the realm of the transformative paradigm, as outlined by Creswell [8]. It is based on the critical theory and underlines the self-conception of researchers who feel to have a responsibility to dedicate their work to serve aims of social justice and sustainability. Within this worldview, research is commonly collaborative, based in political domains and power and justice-oriented. Most importantly, however, it is change-oriented which implies a transdisciplinary approach, including multiple actors from politics and society into the research process.

As discussed by Jahn and Keil [9], the transdisciplinary research process is not a clearly defined procedure. Within the field, different discourses focus on more science or more practice focused branches. In general, transdisciplinary research aims on generating scientific solutions for societal issues. This can appear in the form of an intervention in public discourses or an increased expert knowledge. On the other hand, also scientific results are created, e.g., new transdisciplinary models or detailed problem descriptions. The transdisciplinary integration describes the process from the constituted societal problem to an elaborate societal solution. For the necessary sustainable solutions, segmented disciplinary and common knowledge are not sufficient. Therefore, a reflected synthesis of the different solution approaches is necessary and leads to a systemic problem solution of the societal problem. In addition, this synthesis of different knowledge creates a new comprehensive theoretical structure [9]. A general model of a transdisciplinary research process, differentiates three stages [9].

(i) A common object of research has to be constituted by combining different disciplinary knowledge with practical issues, commonly involving the relevant actors. This leads to the research questions.

(ii) Relevant disciplinary knowledge is generated and integrated.

(iii) In the transdisciplinary integration, practical solutions are generated and a new transdisciplinary knowledge base is created. This stage summarizes the results of the previous stage and verifies the validity and relevance of the proposed solution approaches, by, e.g., conducting expert interviews with the relevant stakeholders. This creates strongly integrated objects, e.g., strategies or specific measures. Thus, added value is generated for each involved actor and beyond by creating a base for potential future cooperation and research.

In this research disciplinary knowledge from the fields of architecture, construction engineering, geography and spatial planning are integrated to take a broad perspective on the role of the housing sector in Graz, in a sustainable energy transition. This scientific knowledge is combined with the practical experience of relevant stakeholders (i.e., experts) to generate a new transdisciplinary knowledge base and come up with a set of possible measures to transform the status quo sustainably. The process of this multi actor mixed methods approach is discussed in Section 2.2.

2.2. Methodology

In accordance with the transdisciplinary research approach discussed in Section 2.1, the methodology follows a three stage process.

1.) First, an analysis of global challenges and possible solution approaches was conducted in which the goal of a sustainable energy transition was focused on the housing sector. In combination with feedback from exploratory interviews with researchers of the respective disciplines and practitioners, this lead to the research question.

2.) Against the backdrop of the theory discussion, a qualitative analysis of strategies and policies, concerning the national, the provincial and the local level of administration, relating to the housing sector in general or concerning the spatial development dimension, was conducted. The documents were processed and coded using MAXQDA [10] to systematically identify relevant text passages, by using different sets of search strings. Out of these relevant text passages, challenges and possible solution approaches were extracted. This process lead to a first set of specific measures, as well as, more general strategic recommendations. Scientific experts of the fields of architecture, civil engineering and spatial planning were asked for their opinion on these proposals. In these semi-structured qualitative expert interviews, the suggestions were discussed and graded to identify the most relevant measures.

3.) This reduced set is currently being evaluated in interviews with practical experts, i.e., developers, cooperative housing associations, architects or civil engineers. In the next step, feedback from administration officials is obtained. Finally, the resulting set of recommended strategic principles and specific measures is presented to political decision makers.

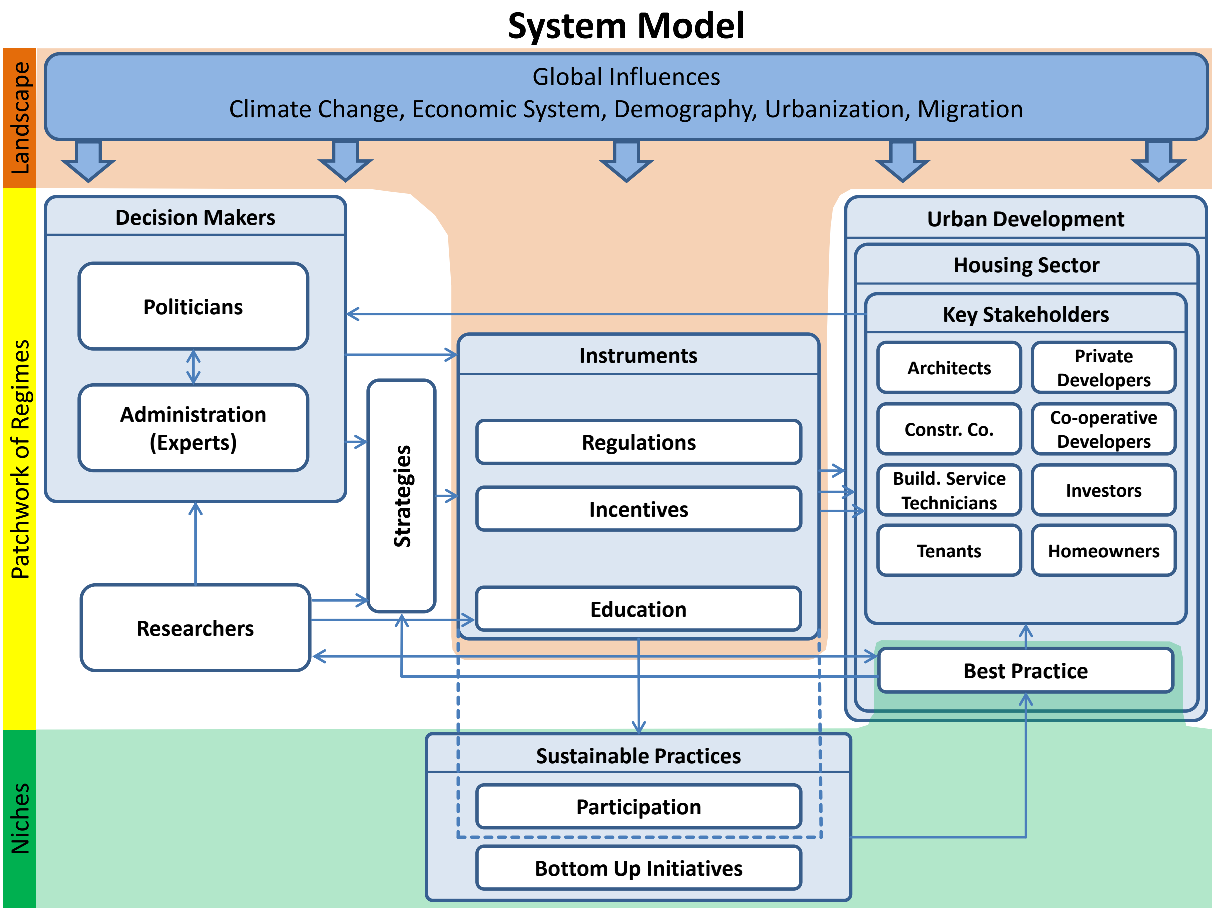

Figure 1. System Model visualizing the relations of the relevant stakeholders and instruments to promote a sustainable transition of the housing sector. The tiering on the left side corresponds to the multi level perspective (cf. Section 3). Source: own design.

3. System Model

To visualize the relations of the relevant stakeholders and instruments to influence the transition, a system model was iteratively developed and validated in cooperation with scientific experts. The system model depicted in Figure 1 also connects this research with the multi level perspective (MLP), introduced by Geels [11]. The MLP, is a model to describe socio-technical transitions which differentiates three levels. In this broad framework, a so called *patchwork of socio-technical regimes* is influenced by *niche innovations* and an *exogenous landscape*. Socio-technical regimes propose, that process technologies, practices and scientific knowledge are socially embedded in a network of actors, institutional structures and infrastructures. Niches are sources of radical change, located at the micro-level, that can lead to incremental or substantial regime change. The exogenous landscape represents external factors which can not be controlled by individual actors, but influence the regime level. Pressure from the landscape can open a window of opportunity in the patchwork of regimes, in which niche innovations have the potential to establish themselves as alternative paths within the system. In contrast, the current regime will try to resist fundamental changes [12]. Therefore, attention has to be focused on how to destabilize current regimes, as the system needs to be transformed towards sustainability.

In the present case the exogenous landscape is, on the one hand, represented by global influences that can not be altered by the patchwork of regimes, i.e., climate change, the economic system, demography, urbanization or migration. On the other hand, the landscape can be interpreted as to additionally include regulations, incentives and education. These instruments, which can be influenced and altered by key stakeholders, can put pressure on the regimes of the housing sector or urban development. This way, sustainable practices, which represent the niches in the MLP, can potentially establish themselves in a window of opportunity in the current patchwork of regimes. These sustainable practices can be participatory processes that respect actual needs of occupants, or bottom up initiatives that try to trigger change to establish sustainable practices. In part these sustainable practices already materialized as best practice examples, which are part of the current patchwork of regimes, but still represent niches.

The system model includes the relevant stakeholders identified in this research process. The instruments, which can be utilized to put pressure on the system to initiate a sustainable transition, are determined by politicians and administration officials who decide and prepare new legislation. These decision makers can be influenced by scientific expert opinions of researchers. Both stakeholder groups influence strategies, which serve as principal guidelines of how the instruments should gradually develop. Moreover, researchers have a direct influence on education, but only indirectly on regulations or incentives. The instruments, are interpreted as part of the landscape environment for the housing sector and urban development, that influences the behavior of the key stakeholders within these regimes, i.e., homeowners, tenants, investors or practitioners, such as architects, construction companies, building service technicians or developers.

Consequently, this system model also refers to the research design and the three stage methodology, as described in Section 2. 1.) Global challenges and influences are analyzed, which represent the exogenous landscape. 2.) The instruments are analyzed to identify challenges and potential improvements, to put pressure on the system to trigger the opportunity for a change towards sustainability. The identified ameliorations (i.e., strategic principles and specific measures) are evaluated and enhanced by the relevant scientific experts. 3.) Next, practitioners commit their perspective on the reduced set of suggestions. In the final step, the resulting set of measures is presented and discussed with administration officials and political decision makers to initiate this process of a sustainable transition.

4. Strategies and Policies for a Sustainable Energy Transition

As discussed before in Sections 2 and 3, the research process generates a set of recommended strategic principles and specific measures. In this section preliminary results are presented. The qualitative analysis of strategy and policy documents (39 relating to the housing sector in general and 24 concerning spatial development), resulted in a first set of 96 recommendations and additional general challenges. These were discussed and iteratively improved in qualitative interviews with scientific experts, who also graded the specific measures and strategic principles. This way the vast amount of suggestions was reduced to a set of 50 most important recommendations (stage 2). Currently, this set is evaluated by practical experts, i.e., developers, cooperative housing associations, architects or civil engineers and in a next step, feedback from administration officials and political decision makers will be obtained (stage 3). The preliminary recommendations are summarized and structured in regulations, incentives, measures concerning education and strategic principles (in correspondence with the system model in Figure 1).

4.1. Regulations

Regulations are a key instrument to secure sustainable development in a top-down manner. For a long term sustainable development, the mandatory use of LCAs in the construction of buildings, is a key requirement. Furthermore, immediate bans on fossil energy sources for the supply of new buildings, obligations to implement passive cooling (shading) on all new buildings or an immediate total ban on split system air conditioning devices in new constructions are important measures to avoid long-term lock-in effects. Another relevant measure would be the mandatory implementation of low-temperature radiant heating and cooling with thermal component activation in new constructions. To ensure a healthy indoor environment and to prevent rebound effects the introduction of mandatory training offers (e.g., the correct use of heating or ventilation systems) by developers for occupants in new highly energy efficient buildings could be a beneficial measure. In addition, mandatory post occupancy evaluations in new apartment buildings and evaluation of the results by the facility management could also improve the actual performance of buildings.

Another key topic to increase sustainability is the promotion of reuse instead of demolition and replacement. This could be supported, if in case of a replacement, the gray energy of the demolished building would be added to the LCA or the energy performance certificate (EPC) of the succeeding building. In case of historically important buildings, reuse also implies the preservation of building culture. In case of willful neglect of such buildings, it could be beneficial to introduce a confiscation option for the community (with compensation). The densification of urban spaces to promote compact development could be fostered by allowing developers to exceed the maximum density in refurbishments as well as new constructions, if a green building certificate is obtained to prove compliance with sustainability criteria.

In order to foster inclusive and collaborative planning, it is suggested to specifically dedicating a certain share of building land in new developments (e.g., in land-use plans), for co-housing initiatives, as it is practiced for instance in Vienna. Moreover, obligatory additional community areas in new housing projects could help to support social integration. The rate of sustainable refurbishments could be increased by the introduction of mandatory higher rates for the creation of reserves (in condominiums), dedicated to the sustainable implementation of a refurbishment, respecting construction methods, materials or a well-considered decision process (proved by a LCA). Furthermore, it would be helpful to adapt the apartment property law (*Wohnungseigentumsgesetz*) in a way to prevent that one owner can block the implementation of a refurbishment. A reform of the tenancy law to create equal conditions for all tenants, or an adaption of rents in social housing, depending on income with periodic updates, to avoid that wealthy tenants occupy needed social housing, could lead to a more just space and cost distribution in the housing sector.

For a sustainable spatial development, a mobility transition to a post-fossil society is necessary. Thus, restrictions for motorized individual transport are necessary, i.e., no subsidies for still individual car based e-mobility, reduction of the number of public car parking spaces and of public investments in road infrastructure. In addition, a reduction of mandatory minimum numbers for the construction of car parking spaces for new buildings, and introduction of upper limits would be beneficial. At the same time, the mandatory minimum number of bicycle parking spaces for new constructions, with a focus on roofed parking, also considering bicycle trailers and cargo bicycles, need to be increased. The introduction of a separate *location factor* for buildings or an extension of the EPC by spatial factors (e.g., proximity of public transport or local suppliers) could raise awareness about the benefits of centrality. A stricter enforcement of the demand of the construction law, that the design of a building has to fit the present street-, town- and landscape, could help to make the urban environment also visually more attractive. Moreover, sprawl could be reduced by mandatory mixed-use multi-story developments on supermarkets and the introduction of tight maximum absolute limits of the plot size for new single family homes, corresponding to the local settlement structure.

4.2. Incentives

In contrast to regulations, incentives (which can be alternative or complementary measures) can help to softly promote a sustainable transition. New incentives, promoting innovative participatory housing approaches, e.g., co-housing, could be introduced as a part of the housing subsidies of the province. The subsidies for reuse and refurbishments could be extended to also cover community areas. In turn, the support for new detached single family homes in urban areas could be scrapped to reduce space consumption. Furthermore, a mandatory consideration of the embedding in the neighborhood and the surrounding public space should be tied to the granting of subsidies.

In order to increase the number of sustainable refurbishments, further investment incentives for owners (subsidies or tax reliefs) to refurbish sustainably (proved by a LCA) should be created. The introduction of specific subsidies for an accompanying process in refurbishments of condominiums, could increase participation and raise awareness, facilitating a more sustainable implementation.

Another suggestion is the coupling of interest rates of building savings contracts (*Bausparvertrag*) and correspondent loans to the gained CO_2 emission savings of a refurbishment. Generally it is suggested to establish more incentives on all levels of administration to facilitate reuse rather than demolition and replacement, as well as the introduction of distinct incentives to promote densification in the process of a refurbishment. Incentives for extensive greening of roofs, on the other hand, could alleviate some of the negative effects of higher densities.

The transition to renewable energies could be accelerated by the introduction of a tax on CO_2 emissions in combination with an eco-social tax reform. Specifically targeting heating systems, a tax on these CO_2 emissions, which is progressively increasing over time, could motivate users to switch their heating system. In addition, subsidies for heating systems with thermal component activation that can be used also for cooling (thermo-active ceilings) potentially raise awareness and avert the further increase of the number of inefficient cooling devices.

To make the space and cost distribution more fair, incentives and suitable general conditions could be created to motivate older people to give up unneeded space (e.g., move to a smaller, more convenient flat or share the house). Moreover, a vacancy tax in urban areas could help to activate vacant flats. In order to promote central living and make it more affordable than the suburban, a progressive tax on land, as a function of the utilization ratio of land and the quality of the location (e.g., centrality) could be introduced. Another beneficial measure would be, the introduction of cost transparency in the construction and maintenance of public infrastructure and a splitting of costs according to the principle that the responsible party has to pay.

4.3. Education

Educational measures aim at raising awareness and the dissemination of professional knowledge, in this context. These measures also positively influence the *Sustainable Practices* addressed in the system model in Section 3. In order to spread knowledge about the latest innovations, best practice and lessons learned on housing among professionals, including relevant research results of other fields (e.g., sociology, psychology, ethnology or geography), it is suggested to establish a suitable medium for that purpose. Additional awareness raising campaigns to promote energy efficient behavior would be beneficial. Likewise the rate of sustainable refurbishments could be increased through, e.g., information about saving potentials in connection with the issuing of energy performance certificates, under the condition that issuers are continuously trained on up-to-date sustainable solutions. An introduction of a summary in construction processes, listing all materials used in a construction process, including their components, properties and impacts on health and the environment, could potentially help to establish awareness about the impact of construction.

4.4. Strategic Principles

In addition to the specific measures that can be attributed to regulations, incentives and educational measures, also more general strategic principles have resulted from the research process. The fostering of the implementation of flexible floor plans of flats in combination with a participatory planning process can help to promote a more just space and cost distribution, as people are more flexible to give up unneeded space, without the need to move. Rebound effects in new highly energy efficient buildings could be averted by a good facility management that monitors energy consumption and contacts occupants in case of irregularities. A general strategic preference of low-tech solutions in construction could significantly help to save resources. For a sustainable spatial development, car free cities with spacious pedestrian zones and high quality public spaces have to be fostered. Furthermore, the increased consideration of local waste heat potentials (e.g., for district heating or local heat supply) needs to receive more attention to promote a sustainable energy transition.

5. Conclusion

So far, the underlying hypothesis, that strategies and policies, concerning the housing sector in Graz have to be significantly improved to promote a sustainable energy transition (cf. Section 2) was acknowledged by all scientific experts. The preliminary results presented in Section 4 are currently under evaluation by practitioners. In the next step they will be discussed with administration officials of the local and provincial government. After this, it will be possible to answer the research question more comprehensively, with the final set of recommendations. Moreover, it will be possible to analyze a second research question, i.e., whether there is a knowledge gap of what is sustainable, among the relevant stakeholders (i.e., architects, developers, construction companies, investors, building service companies, home owners, tenants politicians or administration) and, if yes, how to improve this situation.

The results of this work are specifically concerning the case of the city of Graz. The general approach of the applied research design (cf. Section 2) and the iteratively developed system model (cf. Section 3), could also be transfered to other cases beyond Graz. 1.) The general research question can be directly transfered and possibly adapted to another local context. 2.) A basis for such a transdisciplinary research process can be created by the combination of an analysis of the relevant local policy documents and a state of the art theory discussion. The identified challenges and possible solution approaches are evaluated together with according scientific experts. 3.) Also the expertise of local practitioners and decision makers needs to be included, to produce a set of recommended specific measures tailored to the particular situation. Consequently, this approach can be utilized to support a sustainable transition of the housing sector, also in other local contexts.

Planned future work is to present the final results of this research to local decision makers, to support the targeted transition process. The establishment of an urban lab to acquire deeper insights, to come up with new research results and to foster a dialog among relevant stakeholders, is also planned.

Acknowledgments

Energy transition and technical energy regulations in the building sector

Knoeri C, Schwarz M, Nakhle C

ETH Zürich, Group for Sustainability & Technology, Weinbergstrasse 56, 8092 Zürich

cknoeri@ethz.ch

Abstract. Energy demand from buildings accounts for about 31% of global final energy demand and 23% of global energy-related carbon emissions. Technical energy regulations or building energy codes - policies that set minimum requirements for energy in buildings – have proven effective and efficient in decarbonizing the building sector. However, despite their long history and success, policymakers increasingly recognise that TERs in their current design have reached a point of diminishing returns. This study evaluates five countries with innovative building energy codes – Denmark, France, England, Switzerland, and Sweden – through reviewing legal documents and conducting expert interviews with researchers, practitioners, and regulators. Our results highlight the implementation challenges of innovative building energy codes and we provide learnings in form of six design principles.

1. Introduction

The building sector accounts for about 31% of global final energy demand and 23% of global energy-related carbon emissions [1]. While buildings provide a remarkable potential for energy savings and carbon emission reduction [2], many energy-efficient opportunities are not realized despite being economically superior compared to their carbon-intensive alternatives. Technical energy regulations or building energy codes (BEC), which set minimum requirements for energy in buildings, have proven effective and efficient in reducing energy demand and carbon emissions in the past – for example, up to 22% energy savings in Europe [3] and China [4].

However, despite their success and long history, BECs in their current design have reached a point of diminishing returns [5]. Literature outlines the following five reasons: First, BECs traditionally focused on prescriptive requirements such as minimum U-values. Second, current BECs regulate the energy demand during the use phase of buildings, and thus neglect embodied energy (i.e., energy used to produce construction materials). While this is appropriate for conventional buildings with up to 90% of their lifecycle energy use during their operational phase, net-zero energy buildings have up to one-third of their energy use, and up to half of their carbon emissions embodied in their materials [6]. Third, most BECs still allow fossil heating systems, which are subsequently still the prevalent technology in many industrial countries, despite economically superior renewable alternatives. Fourth, most BECs regulate building design and construction based on calculated energy use but not measured energy use, despite an average difference between calculated and measured energy use at 34% [7] – termed as 'performance gap'. Fifth, while stipulating requirements for retrofits, with retrofitting rates below 1% per year in many countries [8], a fast decarbonization of the entire building stock is unlikely.

Although literature highlights these challenges of current BECs, it lacks providing a comprehensive analysis of how to overcome these challenges and thus achieve a low-carbon building sector. Further, due to being mandatory for the entire sector, BECs' implementation has been outlined as a key issue [9]. This study aims to address this gap by evaluating how policymakers can design and implement innovative BECs that address challenges of their predecessors. To do so, we first elaborate on the five challenges of current BECs –in the following termed 'key leverage points'. We then review five countries with innovative building energy codes – Denmark, France, England, Switzerland, and Sweden – applying archival data and expert interviews with academia, industry, and regulators.

2. Methodology

We aim to increase our understand on how policymakers can design and implement innovative BECs that address key leverage points in three parts

Part 1 - Key leverage points: We first analyzed the few existing review studies on BECs, which mention several limitations current BEC designs have. We then consolidated and extended the findings from the review paper with a forward and backward search from the review literature and an independent keyword search.

Part 2 – State-of-the-art of building energy codes: First, we identified and selected innovative BECs that address key leverage points. To do so, we collected innovative BECs in a 'long list'. We then applied two selection criteria: BECs are already in the process of their implementation and in countries that have similar climatic conditions. The former is required as most challenges of BECs disclose during their implementation – for example, politicians might set ambitious targets and introduce new laws but fail to implement them. The latter is required as climatic conditions influence the sources of energy demand that regulation needs to address. We ultimately selected Denmark, France, England, Switzerland, and Sweden. Second, to understand selected innovative BECs, we scanned through the relevant legal documents for building regulation (707 pages) and validated our understanding with secondary literature. For comparing BECs, we developed a categorization framework that covers the essentials of previous, prevailing, and innovative BECs (in total 63 indicators). We validated the filled framework concerning comprehensiveness and correctness in several rounds with building and energy experts.

Part 3 - Implementation challenges of innovative BECs: To discuss the challenges that disclose during their implementation, we conducted 18 semi-structured interviews (Table 1). To account for different perspectives, we conducted interviews with researchers, practitioners, and regulators. We selected the interview partners through targeted snowball sampling. In the first round, we identified experts by drawing on secondary data of BECs, industry reports, and academic publications in this field. In the second round, we then asked interviewed experts for recommendations for other experts. We conducted the interviews between March 2018 and January 2019. The response rate was 24% (researchers 33%, practitioners 20%, regulators 22%). We validated our findings by asking the interviewed experts to check their interview summary and the final case summaries, including the statements of the other experts.

3. Results

3.1. Part 1 - Key Leverage Points

In the following, we will briefly summarize the five identified key leverage points for decarbonizing the building sector:

(i) In many countries, BECs have been effective in '*Improving Energy Efficiency*' in buildings [10]. Historically, most energy-efficiency gains came from mandating better thermal insulation of the building envelope and installing energy-efficient building technologies for heating. While this was achieved mainly by increasing the stringency of prescriptive requirements, there are limits to which this approach can achieve energy savings, resulting in diminishing returns for each incremental improvement. For example, adding insulation material to an uninsulated wall reduces heat loss by about 75%, while adding the same amount of insulation material again only results in 11% more reduction [5]. In turn, a shift from a traditional focus on prescriptive requirements for individual building parts (e.g., U-Value) to performance metrics for the entire building energy (e.g., primary energy demand) is necessary. Besides performance and prescriptive requirements, BECs can also limit service capacities such as maximum electricity or natural gas supply [11].

(ii) Current BECs neglect '*Considering Embodied Energy*' while concentrating on energy consumption during the use phase of buildings and thus neglect embodied energy. While this might be appropriate for conventional buildings with up to 90% of their lifecycle energy use during their use phase, net-zero energy buildings have up to one-third of their energy use, and up to half of their lifecycle carbon emissions embodied in their materials [12]. Further, energy-efficient buildings often use many energy-intensive materials [13]. Also, the transport of materials significantly affects the amount of embodied energy; for example, while timber originating from sustainable forestry is almost carbon-neutral, due to its energy-intensive transport, the embodied energy varies drastically depending on its destination [14]. Further, the recyclability of building materials contributes to the overall reduction of a building's embodied energy [14]. BECs can help to reduce the embodied energy and carbon by taking a lifecycle perspective for performance metrics, thereby providing a more holistic picture of a building's energy consumption.

(iii) A complete decarbonization of the building stock requires '*Integrating more Renewable Energy*'. While some BECs already prescribe the use of renewable energy, most still allow fossil heating systems, which are the prevalent technology in the building stock [15], despite energy-efficient alternatives are available. BECs could increase the share of renewables in four different ways: First, increasing the stringency of performance metrics that are based on primary energy demand or carbon emissions. Such a performance metric could also be extended to neighborhoods and districts, which facilitates the cost-effective integration of renewables. Second, prescriptive requirements can directly stipulate the use of renewable energy, indirectly increase the share of renewable energy – for example, through mandatory feasibility assessments of renewables – or directly ban fossil fuel technologies such as gas and oil boilers.

(iv) While on paper new buildings are increasingly energy-efficient, '*Closing the Performance Gap*' – the difference between the calculated and the measured energy use – is crucial as this gap amounts to 34% on average [7] but can even increase up to 300% [16]. Causes of this gap are manifold, for example, wrong estimates of the energy-use behavior of occupants, deviations to as-planned building properties such as insulation and air permeability, rebound effects, and unfamiliarity of occupants with complex energy efficient technologies. BECs can contribute to close the performance gap by, first, improving the compliance check through additional testing of the constructed building (e.g., blower-door test) or checking compliance based on measured energy performance. Second, BECs can stipulate training and tools for building developers and owners.

(v) With retrofitting rates below 1% per year in many industrialized countries [8], many of today's existing buildings will also exist in 2050 and beyond, making a fast decarbonization of the entire building stock challenging; BECs should therefore particularly focus on '*Accelerating Retrofits*'. Besides less stringent requirements for retrofits compared to new constructions, BECs can accelerate retrofitting by, first, stipulating retrofitting of buildings during a change of ownership or occupant – during such special occasions energy efficiency measures are typically more profitable – and, second, providing a long-term perspective on minimum energy requirements that existing buildings have to meet. Such a long-term perspective would serve as a roadmap, making it easier for building owners to make retrofitting decisions involving time horizons of a decade or more.

3.2. Part 2 – State-of-the-Art of Building Energy Codes

In this second part we briefly outline the common denominator – or state-of-the-art – in BECs in the selected countries adressing the five key leverage points outlined above (Table 2).

(i) To improve energy efficiency, all selected cases implemented a performance metric, mostly considering primary energy demand. Further, all cases kept prescriptive requirements for the envelope efficiency or a second performance metric for total heating demand. Such a 'double metric' allows the countries to, first, minimize building energy demand and, second, minimize the use of resources or carbon emissions to cover the remaining building energy demand. England and Switzerland add requirements for individual building technologies and Switzerland and Sweden limit the capacity for heating power. Only France includes a requirement for summer comfort – the temperature on the hottest five days is not allowed to exceed a certain threshold – and only Denmark pre-announces future energy efficiency requirements.

***Table 2**: Overview of the state of the art in the topic of technical energy regulations.*

		Denmark	France	England	Switzerland	Sweden
Improving Energy Efficiency	Performance	Yes	Yes	Yes	Yes	Yes
	Prescriptive	Yes	Yes	Yes	Yes	Yes
	Capacity	-	-	-	Yes	Yes
Considering Embodied Energy	Performance	-	Yes (pilot)	-	-	-
Integrating more Renewable Energy	Performance	Yes	Yes	Yes	Yes	-
	Prescriptive (direct)	Yes	Yes	-	Yes	-
	Prescriptive (indirect)	Yes	-	Yes	-	-
	Prescriptive (ban)	Yes	-	-	Yes	-
Closing the Performance Gap	Compliance Check	Yes	Yes	Yes	Yes	Yes
Accelerating Retrofits	when retrofitting	Yes	Yes	Yes	Yes	Yes
	to retrofit	-	Yes	-	-	-

(ii) So far, no country considers embodied energy in their BECs. However, France announced to include embodied energy to be part of the next regulation in 2020. This regulation will include embodied energy in the existing primary energy metric and will put an additional focus on embodied carbon.

(iii) To integrate more renewable energy in buildings, all selected countries adopted a performance metric that supports the use of on-site and off-site renewables. While all other countries focus on primary energy demand, England adopted a performance metric based on carbon emissions. Also, all countries except Sweden adopted additional prescriptive requirements for the use of renewable energy. Denmark, France, and Switzerland directly stipulate the use of renewable energy. Further, Denmark and Switzerland include technology bans and Denmark only restricted the extension of their distribution network of fossil fuels. Also, Denmark and England take an indirect approach by stipulating an assessment of renewables in regards to their technological and economic feasibility.

(iv) To close the performance gap, all selected countries check compliance with the technical energy regulations before the start of the construction as part of the building permit process and directly after the construction as part of the building decommissioning. Further, all countries except Switzerland also conduct an airtightness test. Further, England requires building owners to provide occupants with a set of operating & maintenance instructions, and Sweden includes a compliance check based on measured data after two years of occupation.

(v) To accelerate retrofits, all selected countries except Sweden include less stringent requirements for retrofits compared to new constructions and allow buildings that are retrofitted to opt for compliance based on prescriptive requirements. Both less stringent requirements and the option for prescriptive requirements reduce costs for retrofitting buildings. Besides such requirements that aim at buildings that undergo a retrofit, France follows a unique approach and pushes for mandatory retrofitting of buildings. So far, they prohibit the sale of social housing with high-energy demand, thus hoping for an increase in the retrofitting rate of social houses.

3.3. Part 3 – Innovative Building Energy Codes and their implementation challenges

In this final part of the results we look at innovative BEC approaches in the five countries and what have been the challenges when implementing them.

Denmark - Increasing energy efficiency through pre-announcing energy standards: Denmark reduced the energy use of buildings drastically by pre-announcing future BECs, thus providing long-term regulatory certainty for the building industry. The building industry perceived the pre-announcing as a strong signal that drives innovation and cost reductions, and therefore, advocated for it. Knowing that a voluntary energy standard will become mandatory, companies had time to develop and exploit investments in new technologies, materials, and construction methods. Ambitious building owners, too, advocated for the announcement of future regulation as it provides a target to aim at. However, Denmark stopped making BECs even more stringent as the requirements did not prove to be cost-effective; yet, concerning building sustainability, they might again pre-announce regulations in the future.

France – Considering embodied energy in central performance metric & Accelerating retrofits through situational retrofitting obligations: France will include embodied energy in the next update of the thermal regulations for buildings. However, the introduction of embodied energy is challenging, requiring extensive prior testing and continuous learning. Further, integrating a lifecycle perspective of buildings' energy use is expected to transform the French construction industry. Besides embodied energy, another target of French policymakers is to accelerate retrofitting the existing building stock, for example, by mandating all private residential buildings to achieve steadily increasing energy levels over the next decades. However, while ambitious targets and laws exist, decrees to turn the targets into specific policy measures are lacking because the retrofitting obligation causes additional upfront costs for building owners and is premised on the French Energy Performance Certificate, which is perceived as unreliable by the population.

England – Increasing the share of renewables through adopting a carbon emissions metric: England adopted a CO_2 performance metric to align requirements for buildings with national targets and international commitments. As a result, carbon-friendly technologies have been heavily adopted; shortly, the decarbonization of the electricity mix will pronounce this technology impact. However, the carbon emission metric is perceived increasingly critical because, first, reducing carbon emissions does not necessarily result in energy-efficient buildings and, second, primary energy factors are more stable than carbon emission factors. England is likely to shift towards a primary energy metric, also because the EU pushes the use of primary energy as part of its harmonization efforts.

Switzerland – Increasing the share of renewables through prescriptive requirements: Switzerland increases the share of renewables in buildings through two specific requirements: One requires new buildings to produce a certain amount of electricity on-site, the other requires residential buildings that have an oil or gas boiler to install a heating system based on at least 10% renewable energy in case of a boiler replacement. Both requirements – despited perceived to be very effective in pushing more renewables into buildings – are heavily debated. Mandatory on-site electricity production is perceived as technology specific and as challenging to achieve in the case of compact buildings. Renewable heating might result in high investments costs for homeowners.

Sweden – Closing the performance gap through compliance based on measured buildings' performance: Sweden aims to close the performance gap by checking compliance based on the measured building's performance two years after its occupation. This compliance path is viewed differently by building developers, owners, and municipalities. Larger actors seem to prefer the measured over the calculated compliance check, while for smaller actors, this is typically vice versa. This might be because, first, the available and required measurements are often different; the smaller the building, the less precise the measurements and, in turn, the larger this difference. Second, sanctioning the building owner in case of non-compliance two years after the building's occupation is a delicate task for smaller municipalities; keeping the file open for two years requires more personnel capacities. Sweden plans to address the second challenge by, first, shifting the authority for the final compliance control from local municipalities to the regulator and, second, combining the compliance check with the issuing of the energy performance certificate, which has already previously done by the regulator's energy experts.

4. Discussion

In the following, we synthesize the key findings across the five case studies. We derive six policy design principles from the challenges regulators were facing across our selected case studies when implementing innovative BEC designs. Despite the broad variety in innovative approaches addressing very different aspects of buildings' energy use, the challenges faced showed a surprisingly similar pattern. Table 3 lists the six key learnings – or policy design principles – derived and illustrates them with examples from the cases.

(1) To keep the additional burden for building owners at bay, policymakers should design BECs as cost-effective as possible, thus only mandating what is economically beneficial – e.g. being net present value positive – to consumers but fails to diffuse in the market. This is especially important as many of

the mandated efficiency technologies require comparable high upfront investment compared to their fossil counterparts.

(2) Creating long-term regulatory certainty – e.g. through preannouncing of regulatory changes – provides a fair planning horizon for the building industry, in turn, spurs innovation, drives down technology costs and, ultimately, allows for stricter BECs.

(3) Avoiding technology-specific requirements allows all buildings to comply. However, even de facto not technology-specific regulations – such as a requirement for onsite electricity generation – might leave homeowners with very limited choice given the current technology landscape.

(4) Anticipating the impact on various actors the adoption of new BECs might have is crucial for a broad acceptance of the regulatory change; regulatory change is often particularly challenging for small actors. This has been observed across the board from small construction firms via homeowners to small municipalities struggling with the implementation.

(5) Ensuring sufficient knowledge about the regulatory innovation before implementing it, helps policymakers to improve its design (e.g., identify cost-effective stringency levels) and to justify its implementation (e.g., refer to front-runners who prove cost-effectiveness).

***Table 3**: Overview BEC Design Principles and Design Recommendations*

Design Principle	BEC Design Examples
Keep additional burden for building owners at bay	▪ Include technical feasibility & cost-effectiveness tests ▪ Combine BEC with additional policies such as zero-interest financing to lower the burden of upfront investment cost.
Create long-term regulatory certainty	▪ Align BEC with national energy & climate targets ▪ Pre-announce next BECs ▪ Integrate continuous improvement process
Avoid technology-specificity	▪ Ensure multiple technology options are available when increasing stringency levels ▪ Set performance based targets for retrofits
Anticipate the impact new regulations have on actors	▪ Support the building industry through reducing unnecessary soft costs ▪ Support building owners decision-making through providing information ▪ Support authorities through disburdening them from capacity-intensive compliance control
Ensure sufficient knowledge about innovative design	▪ Pre-announce next BECs ▪ Conduct multi-stage test programs ▪ Build upon voluntary labels ▪ Learn from frontrunner legislation
Integrate BECs in the local context	▪ Leverage the existing infrastructure ▪ Consider the level and pace of ongoing grid decarbonization ▪ Leverage domestic resources ▪ Consider the quality of domestic building industry ▪ Check political feasibility

(6) While learning from frontrunner firms and legislation helps to design BECs that enjoy broader acceptance, policymakers have to adapt these learnings to the local context, which includes existing infrastructure, level and pace of grid decarbonization, domestic resources, quality of domestic building industry, and current politics.

In summary we can say that the mandatory nature of BECs as a policy instrument seems to directly lead to the first four design principles derived, which all ensure that the broad range of actors in the sector are able to cope with the new regulation. With increasing distance from the traditional regulations – e.g. when including embedded energy – extensive testing becomes crucial. Further, despite the general findings, adapting an innovative approach to the context of the local building industry, infrastructure, electricity grid, and political system has been found challenging in all cases. Finally and beyond this study, BECs are only one of a mix of policy instruments (e.g. labels, subsidies, tax incentives etc.) which all have to work in concert to achieve a most efficient and effective transformation of the building stock.

Achieving net zero status in South Africa

Terblanche R

School of Construction Economics and Management
University of Witwatersrand, 1 Jan Smuts Avenue, Johannesburg, 2000, South Africa

rolien.labuschagne@wits.ac.za

Abstract. The purpose of this research is to determine how net zero buildings in South Africa can achieve net zero status. Net zero buildings are defined as energy efficient buildings with energy supply from renewable sources on-/ or off-site or through offsets. The Green Building Council South Africa launched and certified the first four buildings in South Africa under its Net Zero Pilot Certification scheme in October 2017. Net zero status can be achieved in waste, water, carbon and ecology respectively. The concept of net zero buildings is thus new to South Africa and certain barriers needs to be overcome. A semi-structured questionnaire was sent out to developers in order to establish the perceived barriers by developers. Net zero buildings still needs to be commercially justified in South Africa. Cost and lack of incentives are definite barriers. The National Building Regulations of South Africa is a barrier to the development of net zero buildings as is does not require buildings to aim for net zero status. Requirements from national authorities could greatly impact changes in the approach to developments. There is a knowledge gap in the construction industry of sustainable and net zero buildings in South Africa regarding the benefits, implementation thereof as well as the actual costs.

1. Introduction

The United Nations Environment Programme (UNEP) reports that the built environment contributes approximately 40% to global energy consumption and approximately 36% in greenhouse gas emissions [1]. Recently, developing countries, such as South Africa, has become known for rapid urbanisation. [2]. Urban areas not only see an increase in the carbon dioxide emission but also see a decrease in biodiversity and the effects of the Urban Heat Island effects [3]. Johannesburg, a metropole in South Africa, has been ranked as one of the most polluted cities in the world. This is due the heat island trapping dust from mining and other pollutants. According to the World Health Organisation, Pretoria is the second most polluted city in South Africa, followed by Cape Town and Durban [4]. Internationally, the growth of cities, known as urbanisation, establishes by means of high rises, inward compacting and or outward expansion. [5]. Nonetheless, urbanisation in African cities manifests as uncontrolled spatial expansion, known as urban sprawl. Recent studies on African cities found that urban sprawl subsequently causes unsustainable land use, and often consumes bordering urban areas and converts non-urban land, primarily agricultural lands, into urban developments [6]. As such, it is imperative that African countries, such as South Africa, re-evaluate development strategies by introducing sustainability.

Some sustainability strategies, for example greenery systems, have been around for centuries to reduce and mitigate the negative effects of the built environment on the surrounding environment and biodiversity [7]. Although they have been around for centuries, green infrastructure systems is relatively new to the South African industry [8], and adaptation to sustainable strategies are slow. The latest sustainable strategy is net zero developments. Understanding if and how net zero developments are introduced in South Africa, and knowing how South Africans can achieve net zero status developments, could inform and encourage the industry. The objectives of this study is thus to define net zero developments, determine the status quo of net zero developments in South Africa, the involvement of building regulations of the latter and to determine the difficulties that South Africans face with the implementation thereof. As such, the main aim is to understand how developments in South Africa can reach net zero status.

2. Building regulations in South Africa

The national building regulations of South Africa does not include any reference to vegetation, greenery or net zero energy usage [9]. As such, it is not compulsory by national regulations to develop sustainable or net zero buildings in South Africa. Nonetheless, South African cities have influence over building energy usage, and thus energy-related emissions, through the building plan approval process, building inspectorate and regulatory functions. Local authorities in South Africa introduce their own by-laws regarding green and sustainable buildings. A range of options regarding the minimising of energy usage by buildings are being explored. These include by-laws that are more stringent than the national building regulations on building energy efficiency. Stringency would increase in order to meet the net zero or low-carbon target by 2030/2050. Incentives for developing more energy efficient buildings are also being considered. Four of South Africa's metros (Johannesburg, eThekwini, Tshwane and Cape Town) are aiming to implement innovative programmes and certain policies that strive towards net zero carbon emissions from newly-developed buildings by 2050 [10]. The City of Johannesburg has a Built Environment Guideline which will be simplified and reused for awareness-raising. eThekwini (Durban) aims to incentivise green developments. City of Cape Town wants to update their Resource Efficiency Criteria for Development guideline and incorporate low-carbon conditions. The City of Tshwane (Pretoria) requires that all new city-owned buildings must achieve at least a five star Green Star rating and their Green Building By-law document will be updated to incorporate a zero carbon target [11]. In South Africa, the Green Building Council of South Africa (GBCSA) is the main driver of green developing principles [12].

3. Green Building Council South Africa

The GBCSA is a member of the World Green Building Council and was founded in 2007. The aim of the GBCSA is to develop green building solutions to drive the revolution of the South African developing industry towards sustainability. In addition, the GBCSA and focus on green building training and certification. The GBCSA certified the first four buildings in South Africa under its Net Zero Pilot Certification scheme in October 2017 [13]. In the pilot programme, four developments were awarded a net zero certificate. These four developments are the first and only net zero certified buildings in South Africa currently. The developments are the Estuaries Plaza in Century City situated in Cape Town, which received a net zero water certification, the Vodafone Site Solution Innovation Centre in Midrand situated in Johannesburg, which received a net zero certificate in both carbon and ecology, Greenfields Industrial Park in Cape Town and Two Dam Sustainable in Montagu, which both received a net zero carbon certificate [14].

The GBCSA categorizes net zero buildings into the following four categories: carbon, water, waste and ecology. Each categories has its own definition. A net zero carbon building is defined as: "A building that is highly energy-efficient, and the remaining energy use is from renewable energy, preferably on-site but also off-site where absolutely necessary, so that there are zero net carbon emissions on an annual basis." A net zero water building is defined as: "A building that is designed, constructed and operated to greatly reduce total water consumption, and then use harvested, recycled and reused water such that the amounts of water consumed is the same as the amounts of water that is produced." A net zero waste building is defined as: "A building that reduces, reuses, and recovers its waste streams to convert them to valuable resources with zero solid waste sent to landfills over the course of the year." A net zero ecology building is defined as: "A building that does not reduce the ecological value of the site during development for Greenfield sites [15]."

4. Comparing definitions of net zero across the world

Various definitions and understandings of net zero buildings emerged worldwide. Net zero as defined by Europe, The United States, Brazil and the World Green Building Council will be compared.

4.1 Europe

According to Article 2(2) of the Energy Performance of Buildings Directive (EPBD) of Europe a nearly zero-energy building (NZEB) is defined as "a building that has a very high energy performance, as determined in accordance with Annex I which translates to the nearly zero or very low amount of energy required should be covered to a very significant extent by energy from renewable sources, including energy from renewable sources produced on-site or nearby". Each European country, as part of the EPBD recast into national legislation, can adopt a unique national definition of NZEB. Subsequently, variances exist among the NZEB definitions within the European Union, the calculation methods as well as the type and level of requirements [16].

4.2 The United States

The National Institute of Building Sciences in the United States defined "a zero energy building (ZEB) as an energy-efficient building where, on a source energy basis, the actual annual delivered energy is less than or equal to the on-site renewable exported energy" [17].

4.3 Brazil

The Green Building Council of Brazil defines a net zero energy building as a development that proves that the consumer site of the annual operating energy is reset by a combination of high energy efficacy and energy generation from renewable sources [18].

4.4 World Green Building Council

The World Green Building Council (WGBC) defines "a net zero carbon building as a building that is highly energy efficient and fully powered from on-site and/or off-site renewable energy sources". Canada, Brazil, Australia and South Africa launched the net zero initiatives in 2017 [19].

4.5 Comparison

South Africa is on par with some developed countries regarding the implementation of net zero buildings. It is however, still a fairly new initiation in South Africa. The definitions as given by Europe, United States, Brazil and the Green Building Council all comes down to buildings that are energy efficient and that uses renewable energy resources, where the energy used by the building does not exceed the energy generated by the renewable resources. The GBCSA, however, created four separate categories for net zero status: water, waste, carbon, and ecology. The carbon category relates to the definitions given by Europe, United States, Brazil and the Green Building Council. The water, waste and ecology categories are other means for South African developers to achieve the net zero status.

5. Barriers and solutions to the implementation of net zero buildings in South Africa

Although various benefits have been identified for sustainable buildings, stakeholders, particularly in Africa, have not yet realised the claims as such [20]. Barriers to implement net zero buildings in South Africa includes the perception of costs being higher than it is in reality as well as the lack of incentives [21]. South Africa has a water shortage problem and could be considered a barrier when it comes to developing green buildings, as green building are often seen as rich in vegetation [22]. While African urbanisation has mostly been criticised extensively for its apparent failure to contribute to a sustainable built environment [23], inadequate guidance is accessible to African governments, policy creators and planning institutions, in respect of how best to deal with these concerns [24].

The average premium cost to build a four star Green Star SA rated building is 5.5% on the total building cost and 6.6% for a five star Green Star SA rated building [25]. The average premium costs for developing a net zero building in either of the four categories given by GBCSA (carbon, water, waste and ecology) has yet to be researched.

If a sustainable industry has not been established, a premium cost exist to overbridge the unknowns and lack of technology available. For example, retrofitting buildings with greenery systems in South Africa. Van der Walt [26] did a cost benefit Analysis for retrofitting an existing building with a green roof system excluding any external incentives or policies i.e. the "do nothing" approach. He found that a retrofitted green roof system will not be feasible in South Africa, as the owner of the building will never be able to recover these expenses. The same cost benefit analysis was done, however incentives and benefits were taken into consideration. The results indicated that a retrofitted building only becomes feasible with the following incentives and polices: if the green roof system reduces the building's energy consumption by not less than 3%; the municipality subsidise 80% of the green roof's installation costs and; there is a reduction of property tax by 2% during the green roof's lifespan. Given these circumstances, a building owner will have a repayment period of 7 years [26]. As such, South African developments are currently relaying on the change of policies and the availability of incentives in order to develop feasible sustainable buildings. That being said, local governments in South Africa are presently dealing with the concept of local economic development (LED), which is perceived as a tool that can support the development of sustainable buildings. LED are progressively becoming a centralised tool while local governments are faced with the challenge of developing sustainable housing that will succeed in improving the quality of lives, economic growth and provision of local needs. [28]. Therefor there is movement towards sustainability in South Africa. The solution provided by Holliday Schmidheiny and Watts is to drive markets in favour of sustainability, leveraging the power of innovation and global markets for the benefits of everyone – including developing countries [29].

The primary reasons for introducing environmentally friendly measures in hotels in South Africa, found by Ismail and Rogerson, were to lessen the hotel's carbon footprint, to decrease costs and to boost the image of their brand [27]. Hence we see that there are motives for South African developments to follow sustainable strategies.

6. Research Methodology

A mixed method approach was used in order to gather perspectives [28] of developers. A semi-structured questionnaire was emailed to ten developers. The ten developers where selected on a non-probability basis. Five developers responded. The respondents have between 12 and 30 years of experience as developers. Their input is thus deemed as valid and reliable.

7. Analysis of semi-structured questionnaire

The respondents were asked if they have ever developed a net zero building as defined by the GBCSA. None of the respondents have developed a net zero building before. The perceived barriers as set out by the respondents were the following: The 4 Star green star rating is commercially justified; cost, (both the cost of implementation as well as the price sensitivity of the market), scarcity of resources and technology, client's perception of value, lack of incentive/encouragement from the local authorities to promote/include this at the planning phase; completely unfamiliar to net zero developments. The literature review indicated that the barriers of implementing net zero buildings in South Africa includes: lack of incentives; lack of knowledge regarding net zero buildings by the developer, lack of knowledge regarding net zero buildings by the construction professionals; the perception of cost related to the development of net zero buildings; the actual cost for the development of net zero buildings; water shortage in South Africa; maintenance cost and the National Building Regulations. The respondents were asked to rate barriers given on a Likert scale of one to five, where one is seen as not a barrier at all and five is perceived as a major barrier. The bar graph below shows the extent to which a barrier is involved.

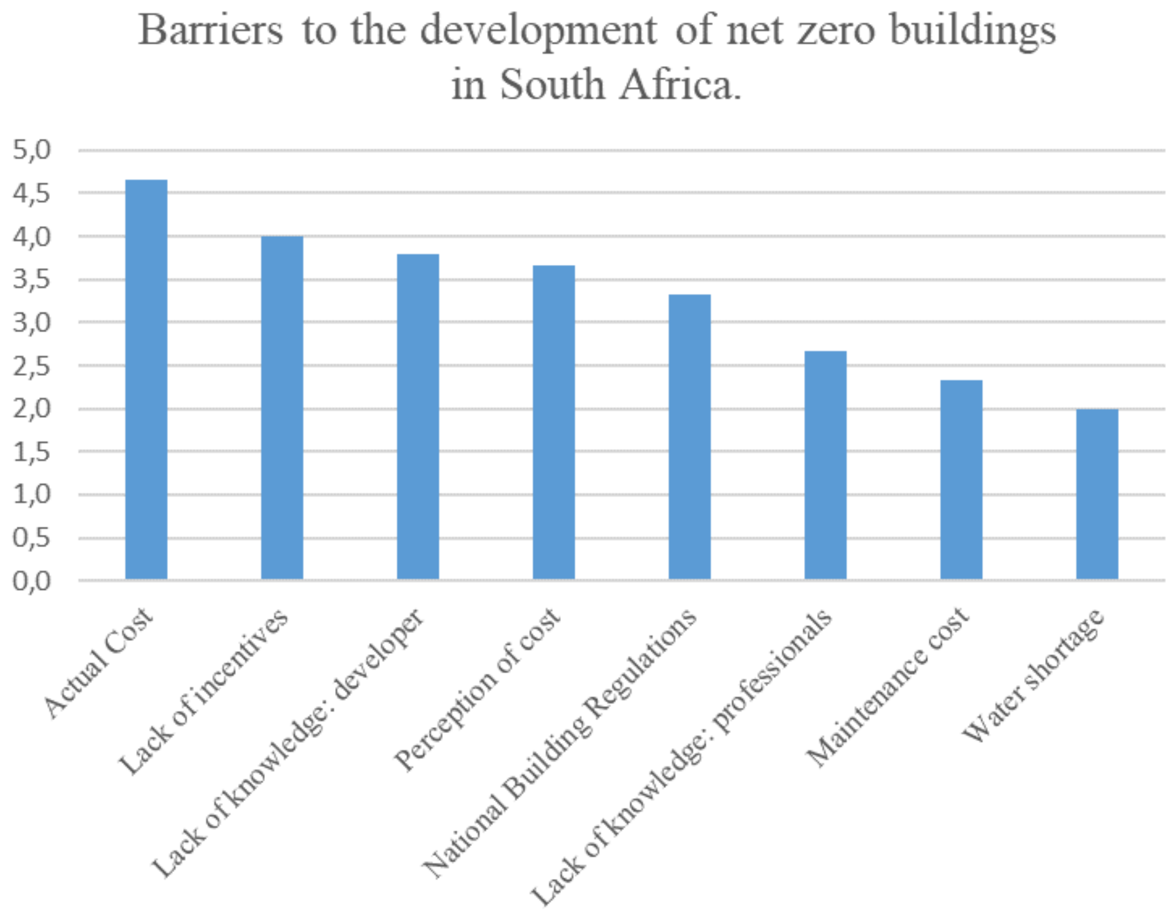

Figure 1: Barriers to overcome in order to achieve net zero status in South Africa

South African developers considers the cost of developing a net zero buildings as the major barrier. Lack of incentives is ranked as the second highest barrier. The third and fourth highest barriers are seen as the lack of knowledge by developers and the perception of costs respectively. The national building regulations and the lack of knowledge by professionals are both perceived as a moderate barriers. Maintenance cost is perceived as small barrier, which means if the design is done correctly, the maintenance could be kept to a minimum. Water shortage in South Africa is not a barrier to the development of net zero buildings in South Africa.

8. Conclusion

Cities, especially African cities, are in need of sustainable developments and the net zero criteria is providing the opportunity thereof. The national building regulations of South Africa does not include any reference to vegetation, greenery or net zero energy usage, however, local authorities introduce their own by-laws regarding sustainable development. Four of South Africa's metros (Johannesburg, eThekwini, Cape Town and Tshwane) are working towards the implementation of policies regarding sustainable development. The GBCSA is a members of the World Green Building Council and has awarded the net zero status to four buildings to date. The definitions as given by Europe, United States, Brazil and the Green Building Council all comes down to buildings that are energy efficient and that uses renewable energy resources, where the energy used by the building does not exceed the energy generated by the renewable resources. The GBCSA, however, created four separate categories for net zero status: carbon, water, waste and ecology. The carbon category relates to the definitions given by Europe, United States, Brazil and the Green Building Council.

Net zero buildings still needs to be commercially justified in South Africa. Cost is a definite barrier for the development of net zero buildings, thus incentives could increase the interest thereof significantly. The National Building Regulations of South Africa is a barrier to the development of net zero buildings as is does not require buildings to aim for net zero status and it is recommended that the National Building Regulations are adjusted accordingly. Requirements from national authorities could greatly impact changes in the approach to developments. The knowledge gap in the construction industry of sustainable and net zero buildings needs to be closed in South Africa regarding the benefits, implementation thereof as well as the actual costs. If installations are done with minimum maintenance in mind, then the maintenance barrier could become redundant. South Africa faces the above mentioned barriers and solutions as a developing country. The same barriers could be issues in other developing countries and the same solutions could be of help to other developing countries.

This research is limited to South Africa and is limited by the small amount of feedback received. It is recommended that more interviews or semi-structured questionnaires are gathered for an in depth and comprehensive conclusion. The research is also limited by the lack of previous research done on net zero buildings in South Africa and further research in this general area in South Africa is recommended. Further research on the premium costs of net zero carbon, water, waste and ecology in South Africa should be done. Future research could also focus on South African credit institutions, fund companies and insurance companies which can possibly acknowledge net zero building developments for sustainable financing instruments, sustainable fund management or insurance offers and support their development with incentives.

Abstract. Climate change mitigation requires the construction of low/zero-carbon buildings, and this is a challenge for designers. The use of Life Cycle Assessment (LCA) provides useful information to support eco-efficiency improvements and therefore, to reduce the climate impacts of building designs. However, it does not provide information about whether a proposed design aligns with achieving the global climate target of limiting global warming to below 1.5°C or 2°C. This study, therefore, introduces an LCA-based top-down approach for setting climate targets for the whole life cycle of buildings in terms of greenhouse gas emissions. It involves assigning a share of the 2°C global carbon budget for 2018-2050 to a country, to the construction sector of the country, and finally to a building. The approach includes a stock model that accounts for the projected growth in the number of buildings and associated climate impacts in a country up to 2050. The proposed approach was applied to a detached house in New Zealand, the most common residential building type in the country; it was found that the climate target of a New Zealand detached house over a 90-year lifetime is 71 tCO_2eq. This modelling approach has potential to guide designers and other interested stakeholders in development of building designs enabling the building sector to operate within a selected global climate target (such as the 1.5°C or 2°C target).

1. Introduction

The construction sector fulfils several human needs (e.g. provision of housing, hospitals, schools and transport infrastructure), but mostly at the cost of a range of environmental impacts including climate change [1, 2]. For example, the sector uses 40% of global energy and therefore contributes around 30% of global greenhouse gas (GHG) emissions annually [1]. At the same time, due to the growing population and economic activities, the demand for construction is rapidly increasing globally and this will lead to more climate impacts in the future. Thus, it is timely to consider the issue of climate change mitigation for the construction sector.

Efforts to mitigate climate impacts from this sector in the past have tended to focus on the use phase of buildings. However, as energy use in the operation of buildings becomes more efficient and there is greater uptake of renewable energies, researchers are becoming more interested in opportunities to reduce the so-called “embodied GHG emissions” associated with the manufacturing of construction materials and to the construction, maintenance and end-of-life of buildings [3]. This requires analysis of the climate impacts associated with buildings (including materials and elements) throughout the complete life cycle [4, 5]. Life Cycle Assessment (LCA) accounts for all inputs, outputs and flows within the complete life cycle of a building and can be used for this type of analysis [6, 7]. Evaluating the climate impacts of a building using LCA is, however, not sufficient to mitigate climate change globally [3, 8], as LCA only provides information about the climate impacts of a building relative to another building and does not provide information about the building's performance in terms of any global climate target (or threshold) [9-13]. For example, building X may be considered better than building Y if it emits less GHG emissions over its lifetime; however, it may be that neither of them can be considered sustainable if their GHG emissions are more than their assigned shares of the global carbon budget. This insight has led researchers to focus on the development of benchmarks using a top-down approach [3-5, 14, 15]. A top-down benchmark, in general, aims to cascade global climate targets down to sub-global levels [5].

Some researchers have already calculated top-down benchmarks for buildings. For example, Zimmermann et al. [4] suggested that the climate impacts of a global citizen should be limited to 1 tonne carbon dioxide equivalent per capita per annum [$tCO_2eq/(c.a)$] by 2050 to stay within the 2 degree Celsius (°C) climate target, according to the *2000 Watt society vision* [16]. They subsequently set a climate target for a Swiss single-family house based on the relative share of household expenditure for residential buildings in Switzerland, following the sharing principle of *final consumption expenditure* [17]. Following this method, the climate target of a Swiss single-family house was 370 kilogram $CO_2eq/(c{\cdot}a)$ [$kgCO_2eq/(c{\cdot}a)$]. Another similar top-down approach, also based on the 2000 Watt society vision [16], was recently developed for Switzerland [3]. However, when assigning a share of the carbon budget (of 1 $tCO_2eq/(c.a)$ in 2050) to a residential building, Hollberg et al. [3] rather used the *grandfathering* sharing principle [13, 17], which assigned a share of the carbon budget to the residential sector based on its relative contribution to the national GHG emissions. According to this approach, the climate target of a Swiss single-family house was 360 $kgCO_2eq/(c{\cdot}a)$.

In another study, Brejnrod et al. [8] defined climate targets for a single-family house in Denmark (for the year 2010). They calculated the carbon budget available for a global citizen in 2010 (985 $kgCO_2eq/(c{\cdot}a)$ for 2°C and 522 $kgCO_2eq/(c{\cdot}a)$ for 1 Watts per square meter [Wm^{-2}] targets), and assigned a share of it to a Danish single-family house using the sharing principle of final consumption expenditure (i.e. the relative share of household expenditure for housing), as was previously done in [4]. Following this method, the climate targets of a Danish single-family house were 110 $kgCO_2eq/(c{\cdot}a)$ and 58 $kgCO_2eq/(c{\cdot}a)$ for 2°C and $1Wm^{-2}$ respectively. Given the aim of the study was only to calculate GHG emissions reduction targets for existing buildings (in the year 2010), no climate targets for future buildings were recommended. Similar efforts to propose climate targets for commercial buildings exist [e.g. 5, 14]. For example, Russell-Smith et al. [14] estimated a target of 2.29 tCO_2eq/m^2 for the whole life cycle of a commercial building in the USA, considering a 50-year lifetime. The target was based on the GHG emissions projections in the IPCC Fourth Assessment Report [18], which recommended a 70-80% GHG emissions reduction below 1990 levels by 2050 in order for buildings to operate within the 2°C climate target. Likewise, using a similar approach of Zimmermann et al. [4], Hoxha et al. [5] proposed climate targets for a set of commercial buildings in 2050, including offices (14 $kgCO_2eq$ per square metre floor area per annum [$kgCO_2eq/(m^2{\cdot}a)$]), restaurants (20.3 $kgCO_2eq/(m^2{\cdot}a)$), food stores (19.8 $kgCO_2eq/(m^2{\cdot}a)$) and hotels (11.7 $kgCO_2eq/(m^2{\cdot}a)$).

Overall, although studies defining climate targets using a top-down approach for both residential and commercial buildings in different countries exist [e.g. 3, 4, 8, 15], no similar study is available for New Zealand. The climate targets proposed in other studies are not generalizable given the large variations in the construction materials, climate conditions and energy mix in different parts of the world. Moreover, the existing studies are limited in several aspects. In particular, while all the existing studies have considered population growth when setting climate targets for buildings in 2050, none of them has modelled the growth in the number and size (i.e. floor area) of buildings nationally and/or globally (through to 2050). However, temporal aspects such as the growth in the number and size of buildings are critical in determining the available share of the global carbon budget of a building, and should be addressed when setting climate targets for future buildings. Also, many of the studies have proposed a single climate target value for the whole life cycle of a building, and it would be challenging for building designers to use the proposed target as a guide in the design process given the lack of transparency regarding environmental hotspots. This study, therefore, developed an LCA-based top-down approach to propose a climate target for the whole life cycle of a building in any country that also accounts for future construction of buildings up to 2050, and provides a breakdown of this target into individual life cycle stages. The proposed approach was subsequently applied to a detached house in New Zealand, which is the most common type of residential building in the country, representing almost 80% of residential buildings [19].

2. Methods

2.1. Overview of the top-down approach

The procedure for calculating the climate target for a building was:

- Determine the maximum acceptable amount of GHG emissions that can be emitted while respecting the chosen global climate target during a chosen time period (referred to as the global carbon budget).
- Assign a share of the global carbon budget to a country based on population projections.
- Assign a share of the country's carbon budget to the country's construction sector based on the relative contribution of the sector to the country's total climate impacts in a reference year (or period).
- Calculate the climate target for different building categories by assigning the construction sector carbon budget to the different building types based on the LCA climate impact of each type of building and the projected number of those buildings, both pre-existing and built in the chosen time period. Note that this means that, for example, buildings constructed in 2030 will only include 20 years of utilisation if the chosen time period extends to 2050.

The following sub-sections describe the proposed top-down approach in detail, illustrated for a case study of the New Zealand detached house (see Figure 1). In this study, the term 'detached house building sector' refers to the total number of detached houses in New Zealand.

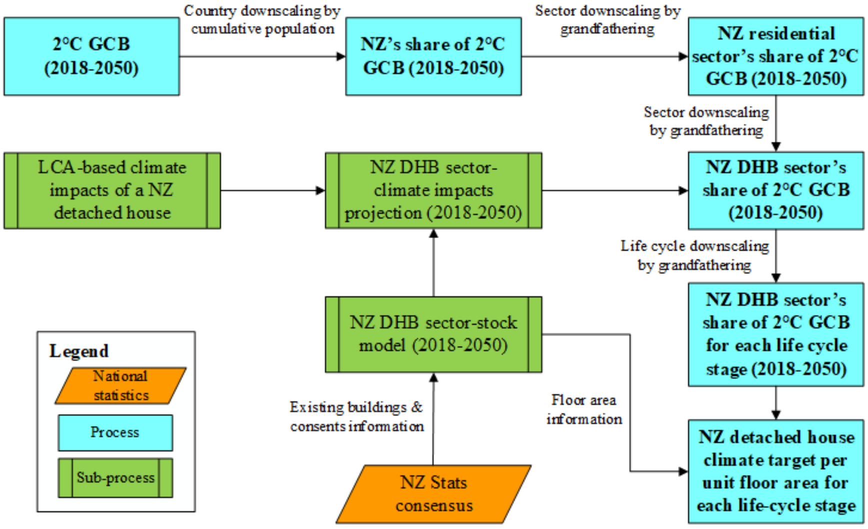

Figure 1. Proposed top-down approach to set a GHG emissions target for New Zealand (NZ) detached house. GCB= global carbon budget; and DHB= detached house building.

2.2. Global climate target and carbon budget

In this study, 2°C was chosen as the global climate target i.e. the maximum amount of GHG emissions that can be emitted and still limit average global warming to below 2°C above pre-industrial levels. The chosen global climate target was subsequently translated into a global carbon budget of 1110 $GtCO_2eq$ for the period of 2018-2050 ($CB_{Glo,2018\text{-}2050}$), using the approach proposed by Rogelj et al. [20]. The year 2018 was chosen as the starting point due to the accessibility of good quality data developed as part of BRANZ's New Zealand whole-building whole-of-life framework research [21]; data were modelled up to 2050, the year chosen for the target year of many on-going climate change negotiations, including the New Zealand Zero Carbon Act [22].

2.3. Carbon budget of New Zealand

To assign a share of the 2°C global carbon budget to New Zealand, the so-called sharing principle of *cumulative impacts per capita* was applied. The principle focuses on achieving equality in terms of the cumulative climate impacts of different populations [23]. This means that, if the people of New Zealand emit more GHG emissions today than the global average per capita, future people of New Zealand should be restricted to emit a smaller proportion of GHG emissions in future based on the global carbon budget. And people in less-developed regions who may emit less GHG emissions today than the global average per capita, will be entitled to emit a higher proportion of GHG emissions in future based on the global carbon budget. The cumulative carbon budget available for New Zealand for 2018-2050 was calculated as follows:

$$CB_{NZ,2018\text{-}2050} = \frac{POP_{NZ,2018\text{-}2050}}{POP_{Glo,2018\text{-}2050}} \times CB_{Glo,2018\text{-}2050} \quad (1)$$

where:

$CB_{NZ,2018\text{-}2050}$ - the share of the global carbon budget available for New Zealand for 2018-2050
$POP_{NZ,2018\text{-}2050}$ - the cumulative population of New Zealand for 2018-2050
$POP_{Glo,2018\text{-}2050}$ - the cumulative population of the world for 2018-2050
$CB_{Glo,2018\text{-}2050}$ - the global carbon budget for 2018-2050.

2.4. Carbon budget of New Zealand detached house building sector

The *grandfathering* sharing principle was used to assign a share of New Zealand's carbon budget to the New Zealand detached house building sector (as previously applied in [3, 8]). The grandfathering principle assigns a carbon budget share to the chosen sector based on its relative contribution to New Zealand's climate impacts in a reference year (or period), as represented in Equation 2. Ideally, this year should have been 2017, which is the year prior to the period under analysis. However, due to data limitations, the year 2012 was selected and it was assumed that the relative contribution of the detached house building sector to New Zealand's consumption-based climate impacts remained unchanged during the period 2012-2050.

$$CB_{NZ,DHB,2018\text{-}2050} = \frac{GHG_{NZ,DHB,2012}}{GHG_{NZ,2012}} \times CB_{NZ,2018\text{-}2050} \quad (2)$$

where:

$CB_{NZ,DHB,2018\text{-}2050}$ - the share of the global carbon budget available for the New Zealand detached house building sector for 2018-2050
$GHG_{NZ,DHB,2012}$ - the GHG emissions of the New Zealand detached house building sector in 2012
$GHG_{NZ,2012}$ - the consumption-based GHG emissions of New Zealand in 2012
$CB_{NZ,2018\text{-}2050}$ - the share of the global carbon budget available for New Zealand for 2018-2050.

2.5. Stock model of New Zealand detached house building sector

In order to estimate the climate impacts of the New Zealand detached house building sector, a stock model developed by BRANZ was used, which was based on several assumptions including socio-economic growth in different regions of New Zealand, net floor area of a (future) detached house and demolition rate [R Jaques, personal communication, Dec 21, 2018].The model consisted of two components: one projected the growth in the number and net floor area of detached houses up to 2050 and the other estimated the associated climate impacts. Firstly, the total number and the net floor area of detached houses that existed at the end of 2017 were modelled. Next, the number and net floor area of detached houses for 2018-2050 were projected based on the long-term trend in building consents, considering the anticipated changes in building regulations [R Jaques, personal communication, Dec 21, 2018]. Finally, using the climate impacts of a typical New Zealand detached house [D Dowdell, personal communication, Jan 11, 2019], the LCA climate impacts of the complete detached house building sector (both existing and future detached houses) for 2018-2050 were estimated.

2.6. *Climate target of New Zealand detached house*

The carbon budget share of the detached house building sector for 2018-2050 ($CB_{NZ,DHB,2018\text{-}2050}$) was shared between the existing and future stock using the grandfathering principle (see Section 2.4). Similarly, using the same principle, $CB_{NZ,DHB,2018\text{-}2050}$ was shared between different life cycle stages. Then, for each life cycle stage, the associated total floor area of the detached house building sector was calculated. By dividing the available carbon budget for each life cycle stage by the associated total floor area of the sector, climate targets per unit floor area for individual life cycle stages were determined. Finally, to determine the climate target for the whole detached house: (i) the climate targets per unit floor area for product life cycle stages, construction process life cycle stages and end-of-life stages were multiplied by the projected floor area of a detached house; (ii) the climate targets per unit floor area per annum for maintenance and replacement, total operational energy use, and operational water use stages were multiplied by the floor area and the time period of utilisation; (iii) and then, the two values were summed.

3. Results and Discussion

3.1. *Climate target of New Zealand detached house*

Using the proposed top-down approach, the climate target for the whole life cycle of the New Zealand detached house over a 90-year lifetime was calculated as 71 tCO_2eq. This was equivalent to a climate target of 292 $kgCO_2eq/(c.a)$ when normalized, given the average household size in New Zealand is 2.7 [24]. A breakdown of the climate target in terms of individual life cycle stages is presented in Table 1. The largest share of the climate target was assigned to total operational energy use (42%) followed by operational water use (22%), product life cycle stages (15%), maintenance and replacement (13%), end-of-life stages (7%) and construction process life cycle stages (2%). These results, which have a relatively higher proportion of the carbon target assigned to the use phase compared with a conventional LCA study of a building, can be explained by the sharing principle (i.e. grandfathering) applied to assign a share of the New Zealand detached house building sector's carbon budget to individual life cycle stages. This principle assigned a carbon budget share based on the GHG emissions contribution of each life cycle stage to the GHG emissions of the New Zealand detached house building sector during 2018-2050. Thus, the percent-wise GHG emissions contributions of different life cycle stages to the New Zealand detached house building sector were comparable to the percent-wise shares of the climate target of the detached house, as represented in Table 1.

3.2. *Comparison with other studies*

Direct comparisons between the climate targets of this study and previous work [3, 4, 8] were not possible due to the significant differences in the top-down approaches and underlying assumptions. To understand the uncertainties associated with the choice of top-down approach for setting climate targets, both with and without consideration of future building projections, the approaches available in the literature were applied in the context of a New Zealand detached house without accounting for the growth in the detached house building sector (see Section 1 for the details of the approaches). As observed from Figure 2, when the approach of Zimmermann et al. [4] (i.e. based on the final consumption expenditure principle) was applied to New Zealand detached house, the climate target of the detached house reduced to 260 $kgCO_2eq/(c{\cdot}a)$. This was due to the low household expenditure share of New Zealand (26%, [25]) compared with the household expenditure share of Switzerland for housing (37%, [4]). Similarly, when the approach of Hollberg et al. [3] was applied (i.e. based on the grandfathering principle), the climate target of the New Zealand detached house was further reduced to 57 $kgCO_2eq/(c{\cdot}a)$. This significant reduction was due to the low contribution of the New Zealand detached house building sector to the national GHG emissions (approximately 6%, according to this study) compared with the Swiss residential sector (36%, [3]). Furthermore, according to the top-down approach developed by Brejnrod et al. [8] (i.e. based on the final consumption expenditure principle), the climate target of New Zealand detached house was 256 $kgCO_2eq/(c{\cdot}a)$. This was because the share of household expenditure of New Zealand (26%, [25]) was more than twice the share of household expenditure of Denmark for housing (11%, [8]).

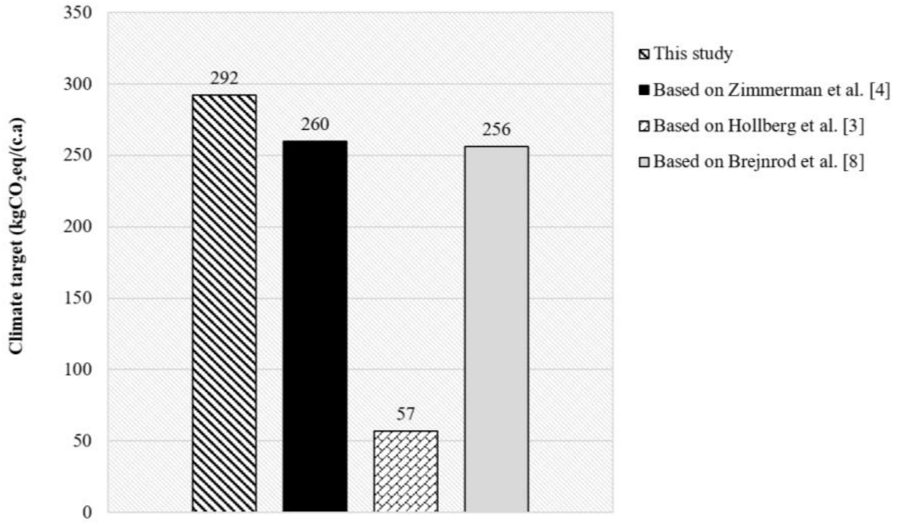

Figure 2. Comparison of climate targets of the New Zealand detached house calculated using the top-down approaches available in the literature.

4. Conclusion

This study introduces a new top-down approach for setting a climate target for the whole life cycle of a building and a breakdown in terms of individual life cycle stages. This approach, for the first time, includes a stock model that accounts for the projected growth in the number (and size) of buildings and associated climate impacts in a country up to 2050. The proposed approach was applied to a detached house in New Zealand to define a climate target. The study has highlighted the importance of accounting for the temporal aspect when setting climate targets for future buildings, which includes the selection of time period and the projected number of future buildings. On the other hand, it should also be noted that the approach and climate targets are associated with a large amount of uncertainty. For example, when assigning a share of the New Zealand carbon budget to the detached house building sector, the grandfathering principle was applied but other sharing principles could be used instead (such as the final consumption expenditure principle). Likewise, to estimate the climate impacts of the New Zealand detached house building sector, the stock model developed by BRANZ was used [R Jaques, personal communication, Dec 21, 2018] which was based on several assumptions including socio-economic growth in different regions of New Zealand, building regulations, net floor area of a (future) detached house and demolition rate. These assumptions, of course, are also associated with a significant amount of uncertainty. Further research is, therefore, necessary to quantify the uncertainty associated with these aspects. However, overall, the proposed approach and climate target provide an approach that can potentially support designers and other interested stakeholders (including architects, civil engineers, scientists and investors) in aligning their building designs with global climate targets such as the 2°C climate target.

Table 1. Results of the application of the top-down approach to New Zealand detached house.

Life cycle stage [a]	LCA impacts- detached house over a 90-year lifetime [b] (ktCO₂eq)	LCA impacts- detached house building sector (2018-2050) ($MtCO_2eq$)			Carbon budget - detached house building sector (2018-2050) ($MtCO_2eq$)	Net floor area- detached house building sector (2018-2050) ($10^6 \times m^2$)	Climate target per unit floor area ($kgCO_2eq/m^2$)	Climate target- detached house over a 90-year lifetime [e] (tCO_2eq)
		Existing	Future	Total				
Product life cycle stages	33	-	18	18 (18%)	5	109	50	10 (15%)
Construction process life cycle stages	5	-	3	3 (3%)	0.9	109	8	2 (2%)
Maintenance & replacement	29	10	3	13 (13%)	4	8,272 [c]	0.5 [d]	9 (13%)
Total operational energy use	71	35	8	42 (43%)	13	8,272 [c]	1.6 [d]	30 (42%)
Operational water use	38	18	4	22 (22%)	7	8,272 [c]	0.8 [d]	15 (22%)
End-of-life stages	15	-	0.6	0.6 (1%)	0.2	8	23	5 (7%)
Whole life cycle	**191** [f]	**-**	**-**	**98** [f]	**31** [f]	**-**	**-**	**71** [f]

[a] The LCA was conducted following the EN 15978:2011 standard [26].
[b] The LCA climate impacts were from [D Dowdell, personal communication, Jan 11, 2019].
[c] Since the net floor area of this life cycle stage is a function of area and time the unit is square meter annum ($m^2 \cdot a$).
[d] The unit is $kgCO_2eq/(m^2 \cdot a)$.
[e] The projected average floor area of a (future) detached house is 207 m^2.
[f] Column totals may not add up due to rounding.

Abstract. The EU building stock is relatively old with 40% of it built before 1960. In Albania the building sector accounts for 26, 9% of final energy consumption, offering high energy saving potentials due to the great number of old residential buildings. Intervention is not always possible and, in order to achieve significant environmental savings, the national action plans cannot rely only on the physical improvement of existing buildings. This paper proposes a probabilistic LCA and LCC evaluation model using MC simulation, for the prediction of intervention options in existing buildings. The potential environmental and economic impacts of three intervention options: standard, ambitious retrofitting and new construction during the whole life cycle of a building are analysed. A framework is defined, with the purpose of estimating the value of a building in a specific time during its life cycle. Comparing the generated values of potential environmental impacts and associating them with the changes on the buildings value enables the process of deciding upon the most desirable and/or agreed combination. The results of the SLED Study 2015 on Albanian building typology are used, while the new construction model is defined according to German EnEV2014 requirements. The GWP values from the LCA/ LCC assessment of the intervention scenarios, done through the SBS tool of Fraunhofer IBP, are used to create a prediction model for future alternative solutions especially in early planning phase. Decision-making through this model can encourage a sustainability strategy for energy efficiency improvement in the building sector of Albania.

1. Introduction

In the EU building sector, the replacement rate of old buildings by new build is around 1% a year, while the renovation rate goes up to 1-2% per year. Considering that more than 90% of the existing building stock in the EU was built before 1990, the renovation of old buildings holds major significance in employing energy efficiency strategies [1].

As the obligation to accomplish CO_2 emissions reduction by 2050 becomes more urgent, the responsibility of acting upon this goal cannot be directed only towards EU countries, rather it requires a joint pursuit in global scale. That is why non EU countries, as part of the Energy Community Treaty, have to be actively engaged and, as growing economies, their contribution on European energy efficiency improvement cannot be neglected. With regard to this, several studies have been carried out in non EU area in order to investigate current trends and encourage new politics and more attention to environmental issues. Among them, in Balkan region, SLED Study (Support for Low-Emission Development in South Eastern Europe) reported for instance that the energy costs will be 47% lower in comparison to the costs of the BAU (business-as-usual) intervention scenario, if the ambitious retrofit is applied in 2030 [2].

Even if meaningful, the results provided by SLED study do not consider the environmental impact of the buildings during their whole life cycle, including renovations work because of building parts obsolescence, and neither do they consider the difference of the GWP values between different intervention scenarios. This is actually a methodological issue, which is largely debated within the sustainability assessment of products use phase and leads to new approaches which can derive more results and can be better related to external factors as well. Standard LCA and LCC methodologies, which are widely applied for the assessment of products environmental and economic sustainability, could represent the basis for a comparison study, but considering the complexity of the building sector and the different factors that are known to affect such decisions during a building's lifespan [3], the necessity arises for a more complex processing of the environmental-economic results. For this purpose, some statistical instruments such as Monte Carlo Simulation have been recently introduced into "probabilistic approaches", which can integrate parameters associated to specific economic and environmental boundaries and can provide results within the whole building's lifespan in a more comprehensive form.

In this paper the environmental impact of different intervention scenarios for the building sector in a non-EU country is analyzed in order to generate relevant results for a non EU economic and environmental reality including a comparison between a static standard approach and a more dynamic probabilistic one.

2. LCA – LCC analyses for renovation measures: state of art

With the increasing attention to the existing building stock, new measures supported by new techniques and innovative materials lead to a richer terminology: classical terms, recovery and rehabilitation, have been recently accompanied by new words, such as retrofit and refurbishment. Such measures have overlying meanings, which very often leads to lack of clarity. In fact, while refurbishment process is a general improvement of the building by cleaning, decoration and re-equipping and includes energy efficient and sustainable activities, a retrofit measure is more specifically a provision of a component of feature not fitted during manufacture or addition of something that the building did not have when first constructed. The term derives in fact from the crasis of "retroactive" and "refit" (reassemble, repair). It conveys an addition of elements (surfaces, volumes, etc.) which were not provided during the object production, in order to extend its service life [4]. Among the variety of solutions, an aware choice has to be carried out in order to provide an indication about the pay-off time of the selected measure [5]. Nevertheless, the need for a change into more energy efficient systems has exposed the necessity of a more accurate investigation of such solutions in order to ensure a significant global enhancement of performance with awareness of the environmental impacts. In conclusion, the economic analysis cannot be anymore solely the instrument for decision-making, but it should be accompanied by an environmental assessment of the considered measures.

Life Cycle Assessment (LCA) is a standardized methodology which has been applied for decades in the building sector, especially as basis for the building certification labelling systems. LCA considers the entire life cycle of a product from raw material extraction and acquisition through energy and material production and manufacturing, to use phase and end-of-life treatment and final disposal. Through such a systematic overview and perspective, the shifting of a potential environmental burden between life cycle stages or individual processes can be identified and possibly avoided. For such reasons, LCA results can be included in the decision process by considering natural science, framework and principles according to the international standards ISO 14040 and ISO 14044 [6].

The consideration of retrofitting and further measures on existing buildings can be seen as new challenge by LCA point of view. In fact, the selection of refurbishment technologies and the success of a retrofit project cannot be indicated with complete certainty due to aspects and factors related to humans' behavior and choices [7]. For these reasons, quite recently LCA investigations focused on uncertainties associated to this methodology. Such uncertainties are due to insufficient and incomplete information (e.g. lack of data on construction materials, geometry of the building, etc.), inaccuracies of models and available software unpredictability of future events (e.g. change of use, service life duration, unexpected seismic events, etc.) and, considering the wide building lifespan (50 years) can be relevant for the final evaluation. With the regard to the building carbon embodied emissions can be distinguished [8]:

- uncertainty about the current embodied carbon of construction materials, components and whole buildings;
- uncertainty about the future embodied carbon of construction materials and components, including technological innovation;
- uncertainty about future events in the service life of built assets, including length of component life, component replacement or substitution, changes of use, end of life;
- Uncertainty about system boundaries and methods of measurement.

With regard to handling of uncertainties, many applications in literature are carried out with probabilistic approaches by using statistical instruments such as Monte Carlo Simulation (MCS). The basic idea of such approach is using randomness to solve problems that might be deterministic in principle and is the most useful when it is difficult or impossible to use other probabilistic approaches. In the field of LCA, MC Simulation performs risk analysis by building models of possible results by substituting a range of values – a probability distribution – for any factor that has inherent uncertainty [9].

3. **Method**

Taking into account that there are several possibilities of interventions able to render satisfying results with regards to energy efficiency and environmental improvement in the building sector, the involved actors face the existence of different decision strategies during a building's life cycle (50years) [8]. The decision making process considers:

- the possibility of allowing the building to continue its life cycle in its existing state until it has reached its end of life
- the possibility of refurbishment/ retrofit and further local and global intervention during its life cycle, which can extend the nominal building service life as well
- the possibility of rebuilding, with demolition of existing building, in a given moment in time during the building's life cycle, in order to build a new

3.1. Economic issues in the final decisions

Decisions about existing building interventions are influenced by several factors associated to technical aspects, such as available technologies, material and engineering/ architects knowledge, as well as economical and financial limitations (i.e. -long payback periods, willingness of building owners to pay for retrofits with missing public financial instruments) [10]. On the other hand, the environmental evaluation of different intervention options, if accompanied by an economic analysis which facilitates the comparison among alternative refurbishment measures, can provide an indication of whether the alternatives are energy efficient and cost- effective.

As depicted here the economic factor is at the moment probably the most important one: especially for developing economies, such as non EU countries. For this reason, even if the main objective of this study is linked to the environmental assessment of retrofit/refurbishment measures, economical matters cannot be neglected in the decision making part of the methods.

3.2. Probabilistic LCA with MC Simulation: determined framework

In this paper a probabilistic LCA with application of MC Simulation has been carried out. For the assessment of the total GWP (kg CO_2-eq/ m² year) of an existing building subjected to renovation works, the LCA analysis considers a cradle to grave system boundary (A1-A3, B4-B6, C+D phases). The study takes into account a 50 years period for the building's life cycle, with 2018 as start of investigation.

The GWP values extracted from the environmental assessment of the building represent the data input. The reference building has been analyzed and probability values have been established by considering previous studies for each intervention alternative (existing, refurbishment, rebuild) [11]. The real age of the existing building type is assumed to be 40 years; hence, the start intervention probability on year 2018 is calculated to be 33, 7 %. Decision about an intervention option is fixed in a 5 year period, where a random value Rv (x) impacts the behavior of the rest of the parameters. The first decision in the system regards only two possibilities: *0 - no intervention*, the building is assumed to continue the rest of its life cycle in its existing state; *1- intervention*, it is determined that the building is suitable for a change, but the specific intervention method is not yet defined. The generated random value is then compared with the given intervention probability functions. If the probability of intervention in a given moment in time *(t=x)* exceeds the random value *(Rv)*, then an intervention occurs; otherwise the building will not be subjected to any renovation work (See 3.1).

$$R_v=\begin{cases} \geq P(I) \text{ No intervention Dec=0} \\ < P(I) \text{ Renovation measure Dec =1} \end{cases} \quad (3.1)$$

Where: *P(I)* – probability of intervention in a specific point in time

The next decision regards the type of intervention. The economic data are used as input values in this phase, where the decision for refurbishment *(Intrv. 1)* or rebuild *(Intrv. 2)* depends on the relation between the respective costs (3.2):

$$C_{t+p}=\begin{cases} \geq 75\%{*}C(Reb)\rightarrow \text{Rebuilding Dec = Intrv.2} \\ < 75\%{*}C(Reb)\rightarrow \text{Refurbishment Dec=Intrv.1} \end{cases} \quad (3.2)$$

Where: *Ct+p*- total costs of refurbishment; *C(Reb)* – costs of rebuild

The total GWP after a study of 50 years is calculated by adding contribution due to production, use phase (due to total energy demand) and end-of-life of the building system. Since whatever intervention enhances the global energy performance of the buildings, the energy demand depends on the achieved quality of the building (3.3).

$$GWP_{tot}=\sum_{y=1}^{50} GWP_{prod,\,y}+GWP_{use,\,y}+GWP_{EoL} \quad (3.3)$$

With regards to the GWP due to retrofit and rebuilding interventions, as suggested by previous works [12], the environmental impacts are adapted through a decarbonisation rate. Such value expresses the potential development of technologies and processes in order to reach better environmental quality, as required by international agreements (i.e. Paris COP31) (3.4).

$$GWP_{prod,\,y}= GWP_{prod,\,y-1}\cdot(1-c_r) \quad (3.4)$$

Costs are analogously discounted by considering a price increase rate and a discount rate as defined below (3.5).

$$C_y= C_{y-1}\cdot\frac{(1-p_i)}{(1-d_r)} \quad (3.5)$$

The total time frame in which a series of decisions takes place: a 50 year period is considered for the building's life cycle. The sum of GWP values is calculated for the intervention strategy that takes place during the life cycle of the building. The distribution of most likely GWP values in the MC simulation is measured by the standard deviation with larger values indicating higher probability of occurrence.

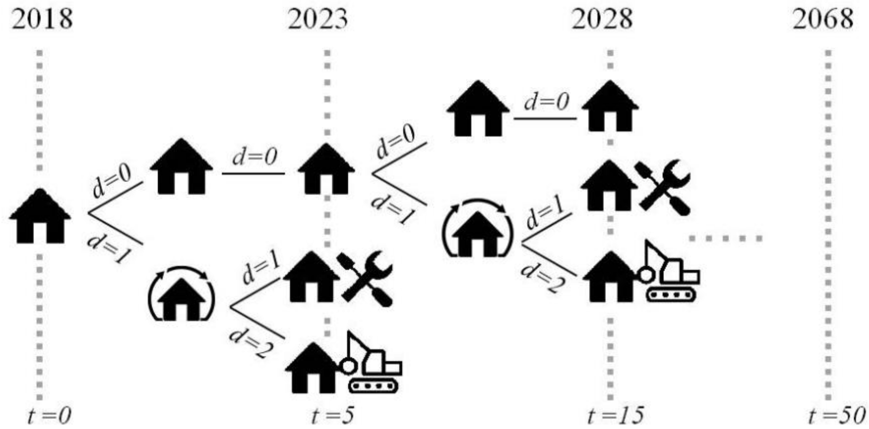

Figure 1. Time-based decision process

4. Case study

The provided model analyses three intervention alternatives for the building stock. The evaluation model is applied in one building type taken as a case study from the Albanian building stock typology system, to show preliminary results, but it is considered relevant for the whole building sector.

This requires first of all a mapping of the Albanian existing building stock: a good overview has been provided by the CENSUS 2011 study, used to establish a building classification which consists of 20 building types based on use type, construction periods, size of buildings and number of floors. According to the INSTAT'11 statistical data, the greatest part of the building stock has been constructed during 1991-2000 with 21% of the whole building stock [13] and surveys carried out in 2009 about the comfort conditions on the Albanian households, ascertained that approx. 85% of them are in bad conditions [14].

Hence, the energy improvement of the building sector in Albania represents a necessity and at the same time a great challenge due to the high amount of required investments and the shortage of public funding. In addition to that, private investments are restricted by further economic obstacles, such as insufficiently funded EE (energy efficiency) units, depressed energy pricing and norm-based billing for heating, data incompliance, unreliable municipalities and homeowner associations, etc. [15].

Regarding climate characteristics and considering the Albanian zoning, 48% of the building stock belongs in Climate Zone B (hilly Mediterranean area) [14] [16]. The most common energy source was wood (57, 5%), followed by LPG (20, 8%) and electricity (15, 4%), while solar heating and other energy sources are irrelevant. Altogether, according to AKBN (The National Agency of Natural Resources) in 2008 electricity covered most of the energy demand (65%), followed by LPG (18%) and fuel wood (15%) [17].

In a second phase, retrofit solution have been investigated: based on the typology system for the Albanian building stock proposed on the SLED Study of the Regional Environmental Centre for Central and Eastern Europe (REC) in 2015, only the "ambitious retrofit" (improvement 2) option proposed is analyzed. The alternative of "standard retrofit" (improvement 1) in fact considers only changes in the envelope of the building but does not include energy use systems. The intervention case of "rebuild" assumes the substitution of an existing building type after demolishing it, with a new building that has same geometry, and energy standard compliant to EnEV2014 requirements.

As a case study the building type, B1 from the typology system is selected. This type is assumed to be the representative for the group of buildings that share same building function, material construction, building period and similar surface area. The B1 type represents detached houses built in the period 1961-1980.

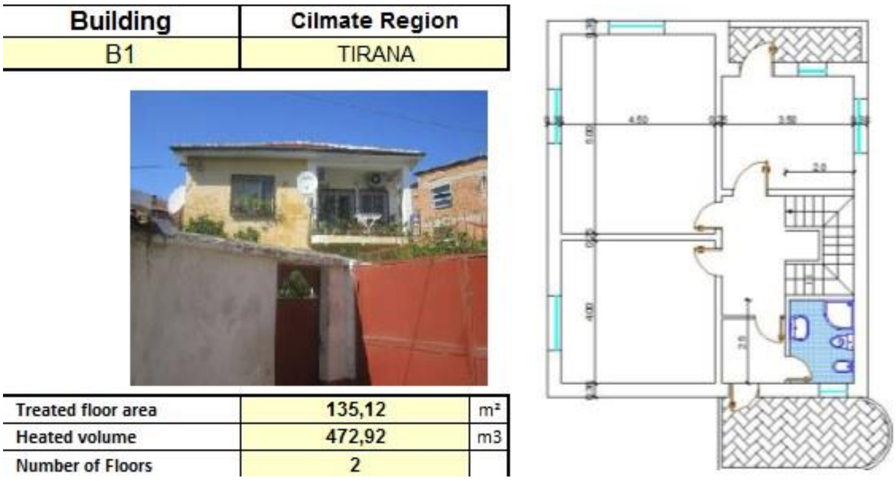

Figure 2. Geometry data on B1 type of building [2] [14]

The building's construction characteristics are shown below (Table 1)

Table 1. Information applied for the life cycle assessment of the building

Building type B1	1961-1980	Type	Features	Figures
General information	Detached house			
	Construction elements	Exterior wall	Solid red brick	208,4 m²
		Roof/Ceiling	Roof with red tiles	67,6 m²
		Floor slab	Concrete floor	67,6 m²
		Window	Single glazed, wooden frame	17,3 m², 4,92 W/m²K
		Exterior door	Wooden door	7,2 m², 3,0 W/m²K
	Energy supply system	National net of electricity supply (Hydropower energy generation) Multi-split AC Pellet boiler		
	Energy demand			275,32 kWh/m²a
	Envelope surface		**368,0 m²**	
	User surface area		**135,12m²**	

GWP results are then calculated for the existing building model with the SBS Building Sustainability Tool in compliance with the LCA methodology for the ambitious retrofit (Refurbishment), as well as the "Rebuild" case [18]. Characteristics of the refurbishment measures and rebuild construction defined according to EnEV standards are shown in Table 2 and LCA/ LCC results of the life cycle and costs analysis for the three cases of intervention are reported in Table 3 [19]:

Table 2 Differences in construction of two intervention options taken into analysis

Construction	Refurbishment measures	Rebuild characteristics
Exterior wall	Red brick, Polyst. EPS 10cm, U-Value=0.29 W/(m²·K)]	Limestone, EPS, Plaster, U-Value=0.24 W/(m²·K)]

Roof/Ceiling	Roof with red tiles, Polyst. EPS 12cm, U-Value=0.27 W/(m^2·K)]	Plasterboard, Therm. insulation EPS, Wood constr., MDF-plates, Roof tiles, U-Value=0.176 W/(m^2·K)] cement, Insulation EPS, PVC-P, reinforced concrete, mineral-wool, gips, U-Value=0.14 W/(m^2·K)]
Floor slab	Concrete floor, Polyst. EPS 5cm, U-Value=0.54 W/(m^2·K)]	=
Window	Triple thermal insulation glass, 90% Plastic frame, U-Value =0.65 W/(m^2·K)]	
Exterior door	Plastic door, U-Value =0.75 W/(m^2·K)]	=
Energy supply system	Electricity (Hydropower) Pellet boiler 25% energy Low temperature gas system 10% energy Multisplit-clima unit 65% energy	Energy supply based on electricity based systems Electricity from Hydropower 100%
Energy demand	9.410,5 kWh/y. En. for electricity 27.785,9 kWh/y. heat energy demand	16.079,3 kWh/year

Table 3 GWP and costs results. Life Cycle Assessment and Life Cycle Costing

Building type B1	**A1-A3**		**B6**		**C1-C4**	**C3+D**
	(kg CO_2-eq./m^2)	**(€/m^2)**	**(kg CO_2-eq./m^2)**	**(€/m^2)**	**(kg CO_2-eq./m^2)**	**(€/m^2)**
Existing state	-	-	1737,85	-	39,9	120,00
Standard retrofit	15,9		794,6	-	72,4	
Ambitious retrofit	29,25		436,96		95,5	
Refurbishment		175,00		-		-
New building/ Rebuild	242	257,38	35,25		-	-

For the economic analysis the information about investment costs on refurbishment are obtained from SLED Study, while for rebuild are obtained from the Albanian National Housing Authority [20]. According to OBC-Transeuropa, a trustworthy discount rate of 5.7% is applied to all the costs and price increase rate of 1, 5 % considered [21]. Discount rate does not consider any risk prices, in order to obtain a conservative estimation and price increase rate due to the Albanian inflation rate.

4.1 Results

The Monte Carlo simulation is modelled in a first screening to identify the range of results generated through 200 runs. In the first instance maximal, minimal and average values are obtained. The GWP results are afterwards divided in 7 ranges and for each of them the probability of occurrence has been determined. The distribution of such probabilities shows that most of intervention scenarios for a 50 year time frame fall in the range of 1300-1600 kg CO_2-eq. / m^2 year.

GWP (kg CO2-E./m² year)	
MAX	4448,29
MIN	1052,57
Avarage	1398,97
Standard deviation	256,34

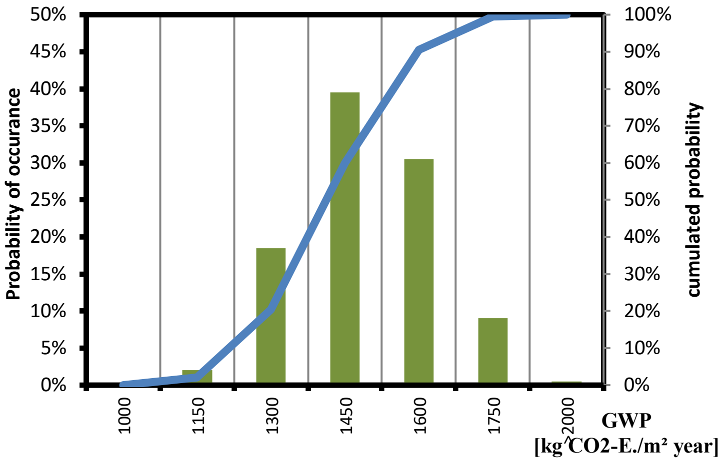

Figure 3. Graph showing cumulative probability distribution for the GWP value of three intervention scenarios for the Building type B1

In a second instance a significant mean value of 1495 kg CO2-eq. / m²year has been established. Here the mean value is the one which reaches a cumulative probability of 80%, namely 20% probability of exceedance. The total number of refurbishment interventions in one simulation run is 547, while for the rebuild intervention it counts 66 times. According to the results, in a costs-based simulation of possible scenarios, refurbishment is most preferred than rebuild. This justifies the high values of GWP which come from the impact due to the use phase of a refurbished building.

5. Discussion and outlook

This paper proposes a probabilistic LCA approach for intervention cases in the Albanian building stock and illustrates the effectiveness through a building type case study undergoing three scenarios of intervention.

The results of this research show how different LCA approaches determine different final decisions. In fact, from the perspective of a static LCA, a rebuilding for the analyzed case study may be advantageous: the emissions during the use phase are in fact strongly reduced, thanks to the low yearly energy demand. On the contrary, the results of the probabilistic LCA, show that the refurbishment solution has been preferred the most: this is due to the included economic factors, which dictate strongly the final decision.

It is necessary to underline that refurbishment interventions alone are not advantageous in the long term: in fact, while they can improve the energy performance of the building, further issues, e.g. structural vulnerabilities, may not be solved. As shown in the case study of this paper, the building has almost exhausted its nominal service life and therefore a global integrated intervention may be required, rebuild included. On the other hand, the rebuild process requires a long time, high investments and the demolition of the previous construction produces huge quantities of waste destined to landfill [22]: in this sense, a rebuilding is not the optimal solution for both environmental and economic points of view. Hence, innovative technology options for eco-efficient buildings have been investigated: those can restart the service life of the building and improve the whole structural and energy performance. With awareness of the material choice, a good recycling rate can be guaranteed and total costs may be limited [23].

With regard to the LCA methodology, a static LCA approach would not reflect the likewise way of making a decision. On the other hand, this is possible by carrying out a probabilistic analysis: even if it represents a more complex procedure, it can handle the uncertainties due to variations or intervention during its operating phase. As further advantage of the probabilistic LCA with MC simulation, the methodology can be easily modified, depending on the economic and environmental conditions, and can take into account the remaining value of a newly constructed building after the 50 years of considered lifetime, which in this case is not included.

Towards conceptual understanding for the adoption of building environmental sustainability assessment methods in the UAE built environment

Shibeika A, Abdel Raheem T, Hittini B

Architectural Engineering Department, United Arab Emirates University, Al Ain, Abu Dhabi, UAE

a.shibeika@uaeu.ac.ae

Abstract. The UAE is witnessing increased interest for sustainable development which poses challenges on the development processes for the large amount of built environment projects taking place in this emerging economy. While, great attention has been given to the development of tools and methods to measure and assess the performance of buildings to meet specific environmental sustainability targets, however, less is known about the effect of these assessment methods on the built environment development process itself. This paper addresses this gap through the investigation of the adoption of building environmental sustainability assessment methods for development projects in the UAE. Currently, there are two assessment methods in the UAE; Pearl Building Rating (PBR) and Al Sa'fat systems. Background study revealed that both systems: are developed in parallel to the development of building codes, adopt performance-based approach for assessment methods, and their adoption for development projects is basically mandatory. This paper draws from diffusion of innovations theory and growing literature in the adoption of similar assessment methods in projects, with the objective of proposing a conceptual framework that conceptualizes PBR and Al Sa'fat methods as innovations and the development projects as the social system for adoption, while focusing on the adoption process dynamics rather than the decision to adopt or not. The proposed framework captures specific conceptual themes, providing the foundation for further empirical investigation. As such, this paper contributes to the growing literature on the adoption of global energy assessment tools and specifically addresses the UAE's sustainable development policy and regulation.

1. Introduction

Sustainable development is important for emerging economies such as the UAE, which has been witnessing rapid development in buildings and infrastructure for the last 30 years or so, propelled by an oil-rich economy. As the country aspires to couple economic development with social and environmental development [1], and to confirm its commitment to the sustainable development goals (SDGs) set out by the United Nations for 2030 [2], numerous federal and local policies and strategies has started to converge to enable the realization of sustainable development goals. Examples of these are: UAE Vision 2020, the UAE Centennial 2071, and the UAE Energy Strategy 2050. This sustainability discourse which is increasingly emerging and diffusing from policy into practice has great effect on construction work and firms specially that construction and building sector contributed 8.40% of the UAE GDP in 2017 [3]. Hence, the broad focus of this research is the sustainable development for the UAE built environment.

A lot of attention has been given to the development of tools and methods to measure and assess the performance of buildings to meet specific environmental sustainability targets. While, assessment methods have been considered as *market transformation tool,* which not only provide objective evaluation of environmental performance but also enable green design guidance and encourage communication within sustainable project teams [4], less is known about the effect of these assessment methods on the built environment development process itself. A growing literature has started to address this gap and found that while these methods provide opportunities for innovation, it also has the potential to stifle innovation by prescribing specific solutions and promoting a tick-boxing approach to meet required regulations instead of adopting sustainable design and construction practices [5] [6]. Drawing on Diffusion of Innovations (DOI) theory, this paper contributes to this growing literature by proposing a conceptual framework for understanding of the adoption of Building Environmental Sustainability Assessment Methods by the UAE built environment projects, this framework serves as the foundation for further empirical investigation of the UAE construction industry.

The paper is organised as follows: The following section introduces the UAE context for environmental sustainability of the built environment. That is then followed by conceptual framework for understanding the adoption of assessment methods by development projects based on the analysis of relevant literature in light of DOI theory. Finally, the paper concludes with a discussion of the planned empirical investigation through case studies of UAE sustainable projects as the next step for this research.

2. The UAE context for environmental sustainability of the built environment

The UAE has started to adopt a pro-active approach towards sustainable development of the built environment from the mid-nineties. In 1996, the Environmental Agency-Abu Dhabi (EAD) was established with the aim to protect biodiversity; provide cleaner environment and sustainable development; and decrease energy and water use, waste and carbon footprint. The focus of EAD is on 6 themes, which are: air and climate change, water, marine, energy, biodiversity and waste [7]. In 2006, the Emirates Green Building Council (EmiratesGBC) was established, also, work has started on Masdar city, which is a carbon-neutral, zero-waste city in Abu Dhabi. Masdar city sheds the light on Abu Dhabi as a technology developer instead of being an importer [8]. The UAE places attention on increasing sustainability literacy through launching pioneer projects such as Masdar, as well as setting clear guidance for performance and methods for assessment of buildings, this could be attributed to its nature as a wealthy emerging economy opposite to other developed countries which focus on subsidising energy cost or providing tax reduction for sustainable products and services.

The use of assessment methods to promote sustainable practices for the built environment has started in the UAE through the adoption of two adaptations for the main two international assessment methods of LEED and BREEAM in 2007 and 2008, respectively. To meet the specific requirements of the UAE environmental resources, both methods gave special attention to the issue of water, hence, Emirates LEED has three more total scoring points compared to LEED for giving a higher weight to water conservation according to the region's climate. This increased emphasis on water conservation is exemplified in the fact that UAE buildings could not be certified unless potable water is reduced by 20% regardless of the points achieved in any other category. Similarly, the weight of the water category in Gulf BREEAM was increased to 30% compared to 6% in BREEAM [9]. This reflect the country's awareness and sensitivity to the adoption of assessment methods that address its specific climatic condition and available resources, which is in line with what has already been established in the literature proving the difficulty in having a set of pre-designed environmental criteria that is prepared for worldwide use without further adjustments [10].

Currently, there are two building environmental assessment methods in the UAE. First, there is Abu Dhabi's Pearl Building Rating (PBR) system which was launched in 2010, PBR systems is based on Estidama program which is a framework for sustainable built environment launched in 2009. Similar to other sustainability frameworks, it addresses the three main pillars of sustainability: environment, economy and society, this is in addition to a fourth pillar "culture" which is unique to Estidama to reflect the local climate and culture of the UAE. Unlike BEEAM and LEED which reference existing national codes and planning guides, PBR system is being developed in parallel to the building codes. PBR assessment method is set to assess the performance of buildings, communities, and villas, establishing separate ratings across the design and construction phases of development projects. The system addresses seven categories - integrated development process, natural systems, liveable communities, building and villas, precious water, resourceful energy, stewarding materials and innovating practice - where there are both mandatory and optional credits. To achieve a 1 Pearl rating, which is mandatory for all new projects, all the mandatory credit requirements must be met. Government funded buildings must achieve a minimum of 2 Pearl rating. To achieve a higher Pearl rating (2-5 Pearls), all the mandatory credit requirements must be met along with a minimum number of credit points.

Second, there is Al Sa'fat building rating system launched in the Emirate of Dubai in 2016, which is a reestablishment of the Dubai Green Building Regulations of 2010. The rating system focuses on building performance, and evaluates all buildings types - residential, commercial, industrial and other facilities- at four stages; planning, design, construction and operation, and is split into four classifications: platinum, gold, silver and bronze. All new buildings are required to achieve bronze rating. It's worth noting that Al Sa'fat in its new form is at the early stages of adoption compared to PBR which hasn't changed since 2010.

This review of building environmental sustainability assessment methods in the UAE shows that both PBR and Al Sa'fat systems are developed in parallel to the development of building codes for each emirate, they both also adopt a performance-based approach for diffusing environmental sustainability practices, as such, they have the potential to improve performance leading to systemic technological change, however, this will only be achieved if these new innovations are adopted following a progressive approach which promotes information sharing and integration among the different parts of the development projects [11]. This raises questions around the processes, people and technology associated with this progressive approach, hence, the aim of this research is to investigate the adoption process of available local UAE assessment methods for development projects.

3. Conceptual framework

3.1 Diffusion of innovations lens and process approach for understanding

Diffusion of innovations theory examines how new ideas move through a particular social system. Diffusion is defined to be *"the process in which an innovation is communicated through certain channels over time among the members of a social system"* [12]. While, innovation is classically seen as both a process to generate new ideas and a new product or service resulting from this generation process [13] [14], innovation adoption is more concerned with the behavior of the adopting unit towards the innovation. In other words, how decisions are made to either adopt or reject the innovation. However, in the case of this research, and as presented above, the adoption of PBR and Al Sa'fat assessment systems in the UAE is basically mandatory for all buildings with opportunities for voluntary adoption for higher ratings, therefore, the focus of this research is on the dynamics of the adoption process rather than the decision itself. The goal of this paper is to develop a framework which will provide the conceptual foundation for further empirical investigation to achieve the research aim.

3.2 Assessment methods as innovation

Classic diffusion of innovations theory claims that there are certain attributes of the innovation that influence adopters' behaviour towards the innovation and subsequently influence the decision and rate of adoption [12]. On one hand, there are attributes which are inherent in the innovation, such as the innovation complexity and trialability. While, Ding argues that the inflexibility, complexity and lack of consideration of a weighting system are still major obstacles to the acceptance of environmental building assessment methods [10], differences between PBR and Al Sa'fat and to other well-known systems such as BREEAM and LEED might lead to different adoption patterns and behavior by projects teams calling for further analysis of the structural characteristics and components of both assessment methods.

On the other hand, there are other attributes which are linked to the adopters and their envisaged use of the innovation (competitive advantage, compatibility and observability). Along this line, construction innovation is found to influence and be influenced by the interdisciplinary and interorganisational nature of development projects [15] [16]. Furthermore, the adoption of BREAAM in projects is found to be influenced by the level of experience of the tool specifically and sustainable design in general among the project team participants, as well as the degree of the assessor's involvement in the project [17]. This argument calls for further investigation of the assessment methods in relation to the development projects to capture project characteristics which influence the assessment process, and the alignment of PBR and Al Sa'fat methods with the development process itself.

3.3 Construction projects as the social system for diffusion

Innovations diffuse into social systems which are defined as "*a set of interrelated units that are engaged in joint problem solving to accomplish a common goal*" [12]. This social system is comprised of two main structures: formal and informal, each represents information that reduces uncertainty and gives regularity and stability to human behavior in the system. Rogers defined structure as "*the patterned arrangements of the units in a system"* [12], and highlighted the ability of the system's norms to facilitate or impede the diffusion of innovation. While, built environment development projects are considered as the social system for innovations such as building environmental sustainability assessment methods, the growing literature highlighted some of the components and dynamics associated with assessment methods in projects. For example; Schweber and Haroglu's investigation of the adoption of BREEAM in eight UK projects highlighted the impact of the assessment process on standard project practices [18], revealed factors influenced the fit of the assessment method to design processes [17], and captured significant design changes in order to meet the rating requirements [19]. Similarly, Thomson and El-Haram presented the findings of four case studies of BREEAM adoption over 15 years period and highlighted four elements associated with the assessment process in projects, these are: sustainability leadership, alignment of assessment method with project management, project culture which promote engagement, and efficient knowledge flow [6].

While, delivery methods such as Design-Build-Operate-Maintain, which integrates the designers, contractors and operation and the maintenance managers under one contract to the owner were suggested as useful methods to integrate sustainability practices in projects [20]. Other scholars have also investigated relevant issues such as the importance of the integration of the project supply chain [21] and stakeholder engagement [22] into the assessment process in order to achieve environmental sustainability goals. Linked to this is the importance of adopting and promoting effective knowledge management and learning mechanisms to ensure knowledge brokering [23], and dynamic flow of sustainability knowledge through codification and personalization [6]. Furthermore, besides sustainability leadership and the involvement of sustainability assessors, sustainability literacy and project team dynamics and communication have received considerable attention as enablers for successful adoption of assessment methods. [16] [24] [6]

The above discussion provides useful points of departure which are summarized in Table 1 below, these will provide conceptual foundations for the empirical investigation of the adoption of assessment methods in the UAE development projects which will be presented in the following final section of the paper.

Table 1. Conceptual themes for empirical investigation.

PBR and Al Sa'fat assessment methods as innovation	1. Structural elements for PBR and Al Sa'fat systems, and their effect on the assessment process. 2. Project characteristics which influence the assessment process and the alignment of PBR and Al Sa'fat methods with the development process	
Development projects as the social system for adoption	Formal structure	Informal structure
	3. Project delivery method and (supply chain management, stakeholder engagement). 4. People issues: leadership, assessors' involvement, sustainability literacy, and culture of engagement. 5. Knowledge management and learning mechanisms for sustainable practices.	

4. Conclusion and future research

The aim was to propose a conceptual framework for understanding the adoption of building environmental assessment methods in development projects in the UAE. This aim was founded on the need to address the emerging discourse for sustainable development of the built environment through policy and implementation of local assessment methods in the UAE. Guided by diffusion of innovations theory, literature review of relevant studies considered the conceptualization of the two current assessment methods in the UAE - PBR and Al Sa'fat – as innovation. The adoption process of this innovation is likely to be influenced by its structural elements and how that effect project work. Furthermore, structures and dynamics of development projects also impact the adoption process; these are focused around issues related to project delivery methods, people, and knowledge management. This conceptual framework is useful because it provides the foundation for further understanding and the starting point for the empirical investigation of the research aim which is set to investigate the adoption process for local assessment methods in development projects in the UAE employing case study approach.

This paper contributes to the growing literature concerned with the effect of assessment methods in the development process by providing focus for environmental sustainability of the built environment in emerging economies, with substantial similarities between the UAE's local assessment methods and those developed by other countries, the core concepts and adoption themes could be generalized for various contexts, hence the proposed framework's applicability in terms of conceptualizing development projects as the social system for the diffusion of rating systems. However, the uniqueness of the UAE's context remains evident due to its climatic, social, cultural, and economic conditions. The paper also contributes to the rising discourse in sustainable development in the UAE and beyond through policy and regulations and has the potential to provide directions for projects and regulation development.

SPECIAL FORA

Transition Towards a Net Zero Carbon Built Environment

SBE19 Graz

SUSTAINABLE BUILT ENVIRONMENT D-A-CH CONFERENCE 2019
Graz, 11–14 September 2019

SPECIAL FORUM

Level(s)[1] *and its place in the tool box for sustainable construction*

Andreas Rietz, Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR), Germany

12 Sept 2019, 11.30am -01.00pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

Systems for describing, assessing and certifying the contribution of individual buildings to sustainable development are important tools for motivating building owners and assisting architects in the design process. So far, they are used in Europe for only a limited number of objects. Potential users fear a high nancial expenditure for the collection of additional data and detailed documentation combined with additional costs for the certification process itself. Thus, the question arises for an additional entry point into the topic through the scope and type of sustainability assessment. Level(s) is a voluntary reporting framework for describing and documenting relevant building features with respect to their sustainability related characteristics.The Special Forum will discuss the role of Level(s) in the overall system of instruments and tools to promote sustainable design, construction and operation, and how interdependencies with other approaches can be shaped.

As part of the Special Forum, four presentations and a detailed discussion with all participants with interactive elements are planned:

Presentation 1	Overview of the Level(s) framework/Results of test applications Josefina Lindblom Ph.D., DG Environment, European Commission
Presentation 2	Level(s) in Austria – 2 case studies Martin Röck & Alexander Passer, TU Graz
Presentation 3	Results of Level(s) testing process in Denmark Harpa Birgisdottir & Kai Kanafani, Danish Building Research Institute
Presentation 4	Demand for building related information to support appraisal and green finance – (how) can Level(s) help? Ursula Hartenberger, Head of Sustainability, RICS
Presentation 5	Job sharing between Level(s) and Sustainability Assessment Systems Andreas Rietz, Head of Division Sustainable Building, BBSR
Moderation	Thomas Lützkendorf, KIT

QUESTIONS AND RESULTS

During the discussion with the participants the following questions will be discussed, among others:

(1) How can obstacles be overcome in the context of a broad application of design process accompanying sustainability assessment systems?;
(2) What new approaches and indicators does Level(s) offer?;
(3) What are the experiences with Level(s) in practical application?;
(4) How can a division of labor between Level(s) and other instruments and tools designed to support sustainable planning, construction and operation?

The results of an interactive opinion-forming and the overall discussion are summarized and made available to the participants of the Special Session, the organizers of the SBE19 Graz and the European Commission.

SUSTAINABLE BUILT ENVIRONMENT D-A-CH CONFERENCE 2019
Graz, 11–14 September 2019

SPECIAL FORUM

„Die 3 Schwestern in der Seestadt Aspern Bauplatz D22“ – Paradebeispiel für nachhaltiges Wohnen

Natürlicher Baustoff Ziegel als ideale Voraussetzung für wohngesundes Bauen und Wohnen

Wienerberger Österreich GmbH
12.09.2019, 11.30-12.45 Uhr | Rechbauerstraße 12, 8010 Graz

Überblick - Vorstellung des Bauprojekts „Die Drei Schwestern“ in der Seestadt Aspern

In der Seestadt Aspern wurde auf dem 5.200 m² großen Baufeld D22 nach den Plänen der Kirsch ZT GmbH gestalteten Architektur die Wohnhausanlage „Die Drei Schwestern“ von der Wohnbauvereinigung für Privatangestellte (WBV-GPA) errichtet. Im Zuge der Planung der Gebäudehülle der drei mehrgeschossigen Baukörper (Bauteil A-NNA, B-ELLA, C-LARA) entschieden sich die Verantwortlichen gezielt für den Wienerberger „Porotherm 50 W.i. Plan“ Ziegel. Aufgrund der durchgängig in mineralischer und einschaliger Bauweise als Niedrigstenergiehaus errichteten Baukörper, wurde ein wesentlicher Beitrag zum Verzicht auf erdölbasierten Vollwärmeschutz geleistet. Das Gebäude erreichte bei der ÖGNB Gebäudezertifizierung 769 von 1000 Punkten und wurde mit klimaaktiv GOLD ausgezeichnet.

Im Zuge des Special Forums sollen die hohen ökologischen, ökonomischen und soziokulturellen Qualitätsansprüche der Planung diskutiert werden. Aspekte der Nachhaltigkeit spiegeln sich beispielsweise in der ökologischen Materialauswahl, Langlebigkeit, Wertbeständigkeit, etc. wider.

Geplanter Aufbau der moderierten Diskussion

Neben einer interaktiven Diskussion sind folgende Impulsvorträge geplant:

- **Vorstellung des Gebäudes durch den Bauträger und Architekt**
  Ing. Franz Pranckl MSc (GPA-PlanungsgesmbH)
  Prok. Ing. Herbert Wolf (HAZET)

- **Erläuterung der beiden Nachhaltigkeitszertifizierungen von ÖGNB und klimaaktiv**
  DI^{in} Franziska Trebut (ÖGUT)
  Robert Lechner (Ökologie-Institut)

- **Informationen über das verwendete Baumaterial**
  Mario Kubista (Wienerberger Österreich GmbH)

- **Round-Table mit Publikumsfragen**

Die Moderation wird von Fachjournalistin Mag. Sabine Müller-Hofstetter geführt.

SPECIAL FORUM

CONDEREFF European project regarding construction & demolition waste

Improve environment and resource efficiency and enhance reuse

Land Steiermark - A14 Abfallwirtschaft und Nachhaltigkeit
12 Sept 2019, 11.30am-01.00pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

In 2015, 10 million tons of construction and demolition waste have been generated in Austria. To foster a move towards circular economy and minimize this high amount, Styria is part of the EU project CONDEREFF. CONDEREFF is an interregional cooperation project, which brings together 8 partners from 7 countries to accelerate their policy work on improving resource efficiency at territorial level.

Furthermore, Styria has developed a guideline for the deconstruction of buildings to enhance the amount of recycled materials. The country aims to increase the volume of reused construction materials.

PRESENTATION

Four presentations are planned, focusing on:

Presentation 1 – CONDEREFF: interregional cooperation project (Construction & demolition waste management policies for improved resource efficiency)

Presentation 2 – Guideline for construction and demolition waste: implementation of reuse

Presentation 3 – Reuse in Styria: state of the art

Presentation 4 – Implementation of recycling in planning phase

DISCUSSION AND INTERACTIVE PARTICIPATION

During the discussion with the participants, following questions will be discussed:

- How to handle the separation duty, hazardous waste, appearing during demolition work, how to carry out the examination of contaminants and undesired substances and how to develop the recovery concept
- Practical problems occurring on-site
- Problem end of waste status and the transfer of construction materials to second parties
- Recycled construction materials/ recycling aggregate production, use and awareness raising activities
- How to implement reuse in public procedures and in regulatory framework
- How to implement reuse already in the planning phase
- Improvement of the construction and demolition waste management policy

SPECIAL FORUM

Implementing BWR 7 „Sustainable Use of Natural Resources“ in Europe

Peter Maydl, Prof.em. Graz University of Technology, Consulting Engineer “Sustainable Engineering”
12 Sept 2019, 02.15pm-03.45pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

In 2013, Construction Products Regulation (CPR) has come into force including the new Basic Work Requirement (BWR) 7 “Sustainable use of natural resources”. Although CPR is well established and BWR 7 is in this context a legal demand, it is not yet common practice to take it into account in most of the member states. One of the reasons may be the current wording, which sometimes lacks in clear definitions (e.g. “environmentally compatible raw materials”). In 2020 CPR will be modified by the EC. This is a good opportunity to create a better wording, to ask for more clarity in the case of targets, assessment rules and ways for communication.

Therefore, it is interesting how member states handle these questions and how they are prepared for. This Special Forum shall give the opportunity to all participants to discuss the present situation and future possibilities, exchange experiences from different member states, experts and involved parties and to develop some suggestions for a more precise concept and wording.

OPENING STATEMENTS / IMPULSE-LECTURES

- Presentation by Manfred Fuchs, DG GROW, European Commission: What European Commissions intends with BWR 7
- Oscar Nieto, Construction Products Europe: Environmental information in CE marking – What can we expect?
- Thomas Lützkendorf, Peter Maydl and Alexander Passer: Handling BWR 7 in practice: obstacles, opportunities and proposals for a new wording within a next generation of CPR
- Robert Jansche, Provincial Government of Styria, OIB – Austrian Institute of Construction Engineering: Implementing BWR 7 from the perspective of a national legislative body

DISCUSSION WITH THE POSSIBILITY OF INTERACTIVE PARTICIPATION

During discussion there will be time to

- analyse EC´s intentions and expectations in terms of implementing BWR 7 in the context of the new CPR
- share experiences made in the member states so far
- discuss proposals for an amended BWR 7
- assess the need for action
- develop recommendations for a change of the current BWR 7

SBE19 Graz

SUSTAINABLE BUILT ENVIRONMENT D-A-CH CONFERENCE 2019
Graz, 11–14 September 2019

SPECIAL FORUM

The role of background databases in the environmental assessments of buildings: what is the way forward?

ecoinvent Association

12 Sept 2019, 02.15pm-03.45pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

The availability of accurate and up to date life cycle inventory (LCI) data is key to support environmental decision making in the construction sector. However, as the data needs of life cycle assessment (LCA) practitioners, including those working in Environmental Product Declaration (EPD), continuously evolve, the role and structure of background LCI databases must also develop to ensure that the needs of users are met. The ecoinvent Association is organising this forum to provide information on and discuss the role of background databases in environmental decision making and EPD creation.

As part of the special forum, the following presentations and discussion will take place:

- Welcome
  Gregor Wernet, ecoinvent Association
- The new impact categories in the amended standard EN15804 and their relevance for the construction sector
  presentation by Karen Allacker, Professor, KU Leuven
- The role of the background database in the framework of the amended EN15804
  presentation by Dimitra Ioannidou, ecoinvent Association
- Software development and the amended EN15804
  presentation by Marisa Vieira, PRé Sustainability, developer of the LCA software SimaPro®
- Presentation of a more policy related perspective on the new standard and on the EPD development in Austria
  presentation by Hanna Schreiber, Environment Agency
- Discussion on the experience with the use of background data in EPDs
  Lars G. F. Tellnes, research scientist, Ostfold Research
  Hildegund Figl, IBO-Österreichisches Institut für Bauen und Ökologie GmbH
- General discussion with participants on the role of background databases related to EPDs.

QUESTIONS TO BE DISCUSSED

The participants are invited to provide their insights and experiences with using background datasets for Environmental Product Declarations or Product Environmental Footprints. Among others, the following questions will be addressed:

- What are the expectations of users in a background database, especially with respect to EPDs?
- What should be the role of a background database in supporting efforts to harmonise different methodological approaches, choices and assumptions used in EPDs and LCA?

ORGANIZER

The ecoinvent association is an internationally active not-for-profit organization devoted to supporting high quality environmental assessments. Its activities currently include publishing and maintaining the ecoinvent database and further leading, or participating in initiatives with the aim of promoting good practice in the creation and use of life cycle inventories around the world.

SPECIAL FORUM

Certified Sustainability: Should the VinylPlus® Product Label be Integrated in Existing Sustainability Label Schemes for Buildings?

Heinz G. Schratt, PlasticsEurope Austria, industry spokesperson for all plastics, representative of VinylPlus®
12 Sept 2019, 02.15pm-05.45pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

Sustainability and PVC may go together well—admittedly not all PVC, and not all applications. Hence, it is the goal of industry to provide a tool for the specifier to discriminate between PVC that fits and supports a sustainable built environment. The PVC value chain demonstrates the thinking and the science behind their new VinylPlus® Product Label and invites participants to discuss the potential of that very label, which is being applied to qualified window frames from May 2018.

Long service time of all construction elements and, consequently, of the entire building is in the core of sustainability. The most common materials in B&C undoubtedly provide such longevity: concrete, steel, glass… but so do certain plastics, particularly PVC, in pipes, window frames, roofing and waterproofing membranes, flooring, and coated fabrics (“textile architecture”).

However, not all PVC is created equal. Process technology and/or formulations (additives) of PVC may vary. It is this state of uncertainty that led many environmentalists to putting PVC, also known as Vinyl, under general suspicion and to discourage the use of PVC. Nevertheless, in the right applications, using PVC might substantially contribute to sustainability.

TOPICS TO BE DISCUSSED

Formal presentations

- The four system conditions of TNS – The Natural Step
  A scientific basis for a sustainable development | *Richard Blume, Senior Consultant, TNS*
- Documentation of „Responsible Sourcing“ as a central requirement for sustainability assessment | *Vincent Stone, Technical & Environmental Affairs Senior Manager, VinylPlus®*
- Presentation of the VinylPlus® Product Label | *Heinz G. Schratt, Secretary General PlasticsEurope Austria*

Audience discussion / panel discussion

- Open questions
- Pros and cons of the VinylPlus® Product Label
- A fundamental paradigm shift inside the PVC industry versus a “marketing smokescreen”?
- Status quo: Does the label make life easier for the sustainability schemes and/or their auditors?
- Should the VinylPlus® Product Label be integrated in existing or future sustainability label schemes for buildings?
- Other topics from the participants
- Conclusions

SPECIAL FORUM

EPD thought through to the end?

Proposals how to deal with the modules C and D in Environmental Product Declarations (EPD)

12 Sept 2019, 04.15pm-05.45pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

A pre-requisite to achieving circular economy as contribution to resource efficiency and environmental relieve is the provision of appropriate information. The amended EN 15804+A2 requires the calculation of environmental impacts during modules C (End-of-Life) and D (recycling potential).

Questions resulting from such requirements will be discussed in this forum. We will show the results of a project funded by the German federal EPA, which essentially describes the involvement of the waste management industry (recycling, recovery, incineration) with the calculation of the environmental performance of construction products.

QUESTIONS TO BE DISCUSSED

- How to deal with Modules C, considering different possibilities of dismantling, recovery processes and national waste management regulations within Europe?
- Companies dealing with waste management or recycling have the relevant experience and access to data needed for the quantification of modules C and D. How can this knowledge be applied in EPD?
- How to model the Lifecycle (focusing on EoL) of complex products, e.g. windows or thermal insulation composite systems (ETICS)?
- Is it possible to include the product category rules for the calculation of the EoL stage in product standards?

IMPULSE-LECTURES

- Who is afraid of module C? New approaches and solutions for EoL in EPD
- Why do the waste industries not participate in developing product category rules for EoL scenarios in EPD?
- Traps to be considered when developing recycling routes.

Possibility of interactive participation in the discussion for all participants

Technical equipment for everybody's participation is provided

Beton als Baustoff - wieviel ist uns Nachhaltigkeit wert?

Bewertung, Kosten und Mehrwert von Stahlbeton für Infrastrukturbauleistungen

Dr. Joachim Juhart, TU Graz, Institut für Materialprüfung und Baustofftechnologie

13.09.2019, 09.30-13.00 Uhr | Rechbauerstraße 12, 8010 Graz

INHALT

Beton bzw. Stahlbeton ist aufgrund seiner hervorragenden Eigenschaften der für Infrastrukturbauwerke weltweit meist verwendete Baustoff. Diesen Baustoff nachhaltig herzustellen – also ressourceneffizient, umweltfreundlich, dauerhaft und wiederverwertbar – ist ein erstrebenswertes Ziel in Zeiten des Klimawandels.

Folgende Themen und Fragen werden in dem Workshop diskutiert:

- Wie wird Nachhaltigkeit speziell in Bezug auf Betonbauwerke spezifiziert?
- Wie können Nachhaltigkeitskriterien der Baustoffe Beton und Betonstahl in Ausschreibung und Vergabe von Bauleistungen berücksichtigt werden?
- Kostet nachhaltiger Beton mehr als Standardbeton oder ist er sogar günstiger?
- Welchen Mehrwert in Bezug auf Umweltfreundlichkeit, Ressourcenschonung etc. bringt nachhaltiger Stahlbeton für die Gesellschaft? In welcher Maßeinheit wird dieser Mehrwert gemessen?
- Wie sind Umweltauswirkungen und die Lebensdauer von Stahlbeton zu monetarisieren?

MODERIERTE DISKUSSION UND INTERAKTIVE TEILNAHME

Impulsvorträge im Rahmen des Forums:

- **Definition von „nachhaltigem Stahlbeton"**
  Umweltwirkungen, Dauerhaftigkeit und Kreislauffähigkeit von Beton; Ökozemente, Ökobetone, Lebensdauer und Performance [J. Juhart, TU Graz]
- **Ökobilanz von Betonstahl - eine Einordnung der Ergebnisse in Österreich**
  [A. Passer, TU Graz]
- **Die Schweizer „Ökobilanzdaten im Baubereich" – Grundlage zur effizienten Umweltbeurteilung von Bauwerken und Baustoffen**
  Datengrundlagen (Ecoinvent etc.) und Bewertung am Beispiel Schweiz
  [R. Frischknecht, treeze Ltd- Life Cycle Assessment]
- **Environmental Cost Indicator: its application in tendering in the Netherlands (MKI („Milieukostenindex") – Ausschreibungspraxis in den Niederlanden)**
  Kosten für Umweltauswirkungen von Umweltindikatoren von Beton [U. Hofstra, SGS Intron]
- **Weiße Wanne plus – ein Standard für nachhaltiges Bauen mit Stahlbeton in Österreich?**
  Bewertung, Kosten und Performance bezüglich Nachhaltigkeitskriterien am Beispiel Weiße Wanne
  [ÖBB bzw. ASFINAG, A. Hüngsberg / M. Kleiser]

Workshop Plastics in Sustainable Building & Living: Protection of Health and the Environment

13 Sept 2019, 09.30am-01.00pm | Rechbauerstraße 12, 8010 Graz

SUBJECT

International Sustainable Chemistry Collaborative Centre (ISC3) is a new international organisation founded by the German environmental ministry with its Headquarters in Bonn. It is aiming at sustainable solutions for chemicals. Among other topics the ISC3 has a workstream Plastics in Sustainable Building & Living. The centre has installed an expert group to prepare a transparent report that will show the innovative fields in the construction sector and provide guidelines for industry, politics and consumers, on how to drive construction products towards sustainability in sense of SDGs. ISC3 is in dialogue with stakeholders from academia, industry, NGOs and international organisations. The fundamental questions in workstream are: How to drive construction products towards sustainability in sense of SDGs? And, what are the most relevant innovative areas and potentials for Sustainable Chemistry in the field of Building, Living and Plastics? The current workshop is devoted to the topic Protection of Human Health and the Environment aiming at Polymers in Building and Living area.

The Goals of the workstream are:

- to transform chemical products in building and living towards Sustainability
- to give impulses for the research and entrepreneurship
- to investigate the innovative fields and set the agenda for the near future
- to show the potentials for the Sustainable Chemistry regarding SDGs

The following questions will be discussed at the workshop:

- Where do plastic materials provide benefits for affordable housing in times of rapid urbanisation without compromising health and the environment?
- Which plastics might be substituted for health and environmental reasons?
- What are alternative solutions for plastic products?
- What properties and special features of plastic products contribute to sustainability?
- How can construction plastics be reused and/or recycled at the end of their lifecycle?
- What plastics are subject for concerns regarding waste and emissions throughout the life-cycle?

At the workshop the following presentations are planned:

Welcome and Introduction:

- Introduction of ISC3 – C.Cinquemani, Director Science & Innovation
- Workstream Plastics in Sustainable Building & Living, O.Ditkovskiy, Workstream Manager
- Preliminary Study Plastics in Construction, Prof. Dr. H. Friege, Leuphana University

Session 1 TBC:

- Presentation: LEVELS Framework – EU Commission, DG Environment (TBC)
- Presentation: Application of Building Physics for Climate Change Mitigation, Czech Technical University (TBC)
- Presentation: Plastics & Environment, President of Think Beyond Plastics (TBC)
- Presentation: Plastics in Building, Plastics Europe (TBC)

Session 2:

- Discussion on the leading questions in a round table with all participants

Was leistet grüne Infrastruktur in stark verdichteten Städten und wie lässt sie sich weiter ausbauen?

Handlungsspielräume zur Erhaltung lebenswerter und kooperativ genutzter Städte

green.LAB Graz Projektkonsortium

13 Sept 2019, 12.00am-03.00pm | Waagner-Biro-Straße 99, 8020 Graz

INHALT – VORSTELLUNG green.LAB GRAZ

Green.LAB Graz ist ein aktuell stattfindendes angewandtes Forschungsprojekt im Smart City Stadtteil in der Waagner-Biro in Graz. Das green.LAB Graz verfolgt das Ziel, Erkenntnisse über grüne Infrastruktur als eine zentrale Klimawandelanpassungsmaßnahme in Städten zu gewinnen und zu vermitteln.

Grüne Infrastruktur kennen lernen, erleben sowie selbst umsetzen und mitgestalten findet innerhalb drei verschiedener Schwerpunkte und Herangehensweisen statt:

- innovative Zwischennutzungen von Brachflächen unter Bezugnahme auf das Thema grüne Infrastruktur und Klimawandelanpassung als strategisches Instrument einer nachhaltigen Stadtteilentwicklung praxisnah und kooperativ umzusetzen
- ein innovatives Demogebäude zu errichten als Weiterentwicklung der „Urban Boxes“ in Richtung transportabler modularer Holzbau in Kombination mit Bauwerksbegrünung, Biodiversität, Stadtteilgarten, Regenwassermanagement, effizienter Energieversorgung und Einsatz erneuerbarer Energiequellen
- Spezifizierung eines technischen Monitoring-Systems inkl. Messgrößen sowie Maßnahmen zur Auswertung des „social impacts“

GEPLANTE INHALTE DER IMPULSVORTRÄGE

- Aufzeigen der Problemstellung und des Bedarfs für das Vorhaben Modulare Bausysteme mit integrierter Begrünung als Elemente nachhaltiger Stadtentwicklung
- Warum macht grüne Infrastruktur für verdichtete Städte und Stadtteile Sinn? Welche Kriterien und Maßnahmen können zur Auswertung des „social impacts“ herangezogen werden?
- Aufzeigen von Zwischennutzung von Brachflächen in Kooperation mit lokalen Initiativen als strategisches Element für eine nachhaltige Stadtentwicklung. Der Frage nachgehen, inwieweit Möglichkeiten der Replizierbarkeit von Zwischennutzungen bestehen.
- Welche Fördermöglichkeiten bestehen für die Umsetzung grüner Infrastruktur in Graz?
- Vorstellung der begrünten Uniqua-Fassade in der Annenstraße in Graz

MODERIERTE DISKUSSION UND TEILNAHME DURCH DAS PUBLIKUM

Begehung des Projektgebiets Smart City und vorstellen der Aktivitäten des green.LAB Graz, Erfahrungsaustausch mit AkteurInnen im Bereich Stadt- und Bauwerksbegrünung und Motivation der TeilnehmerInnen / BesucherInnen zur Umsetzung von Begrünungsmaßnahmen, Bewusstseinsbildung über Kosten und Nutzen von Grünflächen, Vernetzung

Holzbau im urbanen Raum – eine Chance für Städte?

Holzcluster Steiermark

13.09.2019, 13.30 - 15.45 Uhr | Rechbauerstraße 12, 8010 Graz

Stadt gemeinsam entwickeln

Vortragende: Mag. Barbara Hammerl / StadtLABOR GmbH

Die Zukunft der Städte stellt uns vor große Herausforderungen und offenbart gleichzeitig enorme Potentiale für die Stadtentwicklung. Entlang bestehender Infrastrukturen wird, wie beispielsweise in Graz, verdichtet und eine Stadt der kurzen Wege entsteht. Welche Aspekte der nachhaltigen Stadtteilentwicklung werden dabei berücksichtigt? Wie verändert sich das Mobilitätsverhalten der Menschen? Welche Bedeutung bekommt die Gemeinschaft? Wie kann kooperative Planung gelingen?

Urbaner Holzbau – Holzbau 2.0

Vortragende: Univ. Prof. Tom Kaden / Technische Universität Graz

Nur wenige Referenz- und Leuchtturmprojekte wurden bislang im mehrgeschossigen Wohnbau bzw. im Nichtwohnbau (z. B. Büro- und Verwaltungs- oder Industriegebäude) in Holz errichtet. Dies obwohl die technischen und wirtschaftlichen Vorteile des Baustoffs auf der Hand liegen, wenn es darum geht, den wachsenden Bedarf an bezahlbarem Wohnraum in den Städten zu decken. Kurze Bauzeiten, ein geringes Gewicht bei hoher Tragfähigkeit und Flexibilität bei der Aufstockung von Gebäuden oder der Wohnraumerweiterung sind Pluspunkte gerade bei der Nachverdichtung im urbanen Raum.

leanWOOD – Optimierte Planungsprozesse für Gebäude in vorgefertigter Holzbauweise

Vortragende: DI (FH) Sandra Schuster / Technische Universität München

Der moderne Holzbau zeichnet sich durch die Produktion von Bauelementen in der Werkstatt mit hohem Vorfertigungsgrad aus. Die Vorfertigung ist eine Prämisse der Wirtschaftlichkeit sowie der Qualitätssteigerung, erfordert aber eine vertiefte Planung, die die Fertigung der Bauelemente, deren Transportlogistik und die Montage berücksichtigt. Die übliche Projektorganisation mit den separierten Einzelschritten Planung, Ausschreibung, Produktion und Montage stellt für den vorgefertigten Holzbau eine große Erschwernis dar.
Im Rahmen des Forschungsprojekts leanWOOD wurden vor dem Hintergrund innovativer Planungsprozesse und Kooperationsmodelle Organisations- und Prozessmodellen für den vorgefertigten Holzbau entwickelt. »lean« zielt dabei auf die »schlanke« Abwicklung von Prozessen und die effiziente wie effektive Koordination der Akteure.

Moderierte Diskussion und interaktive Teilnahme

Fragestellungen der Diskussion:

- Warum hat der Holzbau eine Schlüsselfunktion in der wachsenden Urbanisierung?
- Wie kann die Leistungsfähigkeit des Holzbaus weiter verbessert und der Einsatz forciert werden?

ADVERTISMENTS

Transition Towards a Net Zero Carbon Built Environment

Eine Steuerung für alle Gewerke.
Integrale, PC-basierte Gebäudeautomation von Beckhoff.
Microsoft Technology Center, Köln:
Die integrale Gebäudeautomatisierung
wurde mit PC- und Ethernet-basierter
Steuerungstechnik von Beckhoff realisiert.
www.beckhoff.at/building
Die offene, PC-basierte Steuerungstechnik von Beckhoff bildet die Grundlage einer integralen Gebäudeautomation, die alle Anforderungen an eine nachhaltige und effiziente Lösung erfüllt. Eine einheitliche Hard- und Softwareplattform steuert alle Gewerke, von der nutzungsgerechten Beleuchtung über die komfortable Raumautomation bis zur hocheffizienten HLK-Regelung. Das Ergebnis: Durch die optimale Abstimmung aller Gewerke werden die Energieeinsparpotenziale über die Energieeffizienzklassen hinaus voll ausgeschöpft. Darüber hinaus reduziert die integrale Gebäudeautomation Hardware-, Software- und Betriebskosten. Für alle Gewerke stehen vordefinierte Softwarebausteine zur Verfügung, die das Engineering enorm vereinfachen. Funktionserweiterungen oder -änderungen sind jederzeit möglich.

klimaaktiv

klimaaktiv Bauen und Sanieren

Mit zukunftsfitten Gebäuden zur #mission2030

© Kurt Hoerbst

Das Programm Bauen und Sanieren ist ein zentraler Baustein von klima**aktiv**, der Klimaschutz-Mitmachbewegung des BMNT. klimaaktiv.at/bauen-sanieren

Die #mission2030, die Klima- und Energiestrategie der Bundesregierung, setzt klare Ziele, um den Weg in eine positive Klimazukunft zu ebnen. Der Gebäudebereich ist dabei ein zentraler Hebel zur Erreichung dieser Ziele. Daher hat das Bundesministerium für Nachhaltigkeit und Tourismus (BMNT) mit dem klima**aktiv** Gebäudestandard ein zukunftsorientiertes Gütesiegel entwickelt.

Qualität und Sicherheit

Der klima**aktiv** Gebäudestandard ist für Wohnbauten und Dienstleistungsgebäude für Neubau und Sanierung verfügbar und gibt Hilfestellung für Immobilienentwickler, Architektur- und Bauschaffende, Wohnbauträger genauso wie für alle, die ein Haus bauen, sanieren oder nutzen.

Das klimaaktiv Bewertungssystem

Energieeffizienz und erneuerbare Energien stehen im klima**aktiv** Bewertungssystem für Gebäude im Mittelpunkt, aber auch viele weitere Aspekte werden berücksichtigt. So spielen Gesundheit und Komfort, die Umweltverträglichkeit der Baustoffe und die Wirtschaft eine wichtige Rolle.

Eine Erfolgsgeschichte

Rund 800 Gebäude wurden bislang nach den Qualitätskriterien errichtet und bewertet. klima**aktiv** ist damit europaweit das erfolgreichste und gleichzeitig anspruchsvollste Gütesiegel für nachhaltiges Bauen und definiert die höchsten Anforderungen im Bereich Energieeffizienz.

Zentrale Anlaufstelle für alle Fragen zum Bauen und Sanieren nach klima**aktiv** Standard ist die ÖGUT GmbH. Das Programm wird in allen Bundesländern von Partnern unterstützt.
E-Mail: klimaaktiv@oegut.at

Mit klimaaktiv nachhaltig Bauen und Sanieren

Energieeffizienz, ökologische Qualität, Komfort und Ausführungsqualität – dafür steht klima**aktiv** Bauen und Sanieren. Ob Neubau oder Gebäudesanierung – beides stellt für BauherrInnen und ArchitektInnen eine große Herausforderung dar. Ganz speziell dann, wenn eine Sanierung höchste Ansprüche erfüllen muss. Der klima**aktiv** Gebäudestandard bietet dabei Orientierung und Unterstützung. Er ist das österreichweite Qualitätszeichen des Bundesministeriums für Nachhaltigkeit und Tourismus für nachhaltige Gebäude mit besonderem Fokus auf Klimaschutz und Energiesparen. Mit klima**aktiv** wird die Einhaltung hochwertiger Standards in folgenden Bereichen garantiert:

- **Niedriger Energieverbrauch:** Der Wärmebedarf wird gegenüber Standardbauten um rund ein Drittel reduziert.
- **Mehr Behaglichkeit:** Durch hochwertige Dämmung wird ein hohes Maß an Behaglichkeit im Sommer und im Winter erreicht.
- **Raumluftqualität und Gesundheit:** Durch das Zusammenspiel von schadstoffarmen Baustoffen mit automatischen Lüftungsanlagen werden höchste Ansprüche bei der Raumluftqualität erfüllt.
- **Ausführung und Wirtschaftlichkeit:** Hohe Qualität bei der Planung und Ausführung sind die Basis für langfristige Wirtschaftlichkeit.

Musterhaft saniert mit neuem Gesicht

Bauten aus den 1950er bis 1980er Jahren bauphysikalisch und energetisch auf Stand zu bringen ist eine herausfordernde Aufgabe. Die Fakultät für Technische Wissenschaften der Universität Innsbruck stammt aus dem Baujahr 1969 und ist nach ihrer Neugestaltung und Sanierung nun Vorbild im Bereich zukunftsorientiertes, klimaschonendes Bauen. Nicht nur was die energetische Performance angeht ist das Passivhaus beispielgebend, sondern auch im Hinblick auf die gelungene Zusammenarbeit vieler Beteiligter. Das Gebäude wurde für den Staatspreis Architektur und Nachhaltigkeit 2017 nominiert und erreicht mit 1.000 Punkten den klima**aktiv** Gold Standard.

klimaaktiv Gebäudestandard sorgt für Qualität und Sicherheit

Der klima**aktiv** Gebäudestandard ist ein idealer Leitfaden, um energieeffizientes, ökologisches und behagliches Wohnen sowie Arbeiten zu garantieren – sei es im Falle eines Neubaus oder einer qualitativ hochwertigen Sanierung. Über 800 Gebäude wurden bislang nach den Qualitätskriterien errichtet und bewertet. Damit kann klima**aktiv** die bei weitem höchste Anzahl an deklarierten Gebäuden sowohl im Neubau als auch in der Sanierung in Österreich aufweisen.

Über klimaaktiv Bauen und Sanieren

Das Programm klima**aktiv** Bauen und Sanieren ist ein zentraler Baustein der Klimaschutz-Mitmachbewegung des Bundesministeriums für Nachhaltigkeit und Tourismus, wenn es um energieeffizienten Neubau oder eine qualitativ hochwertige Sanierung geht.

Mehr Informationen zum Programm finden Sie auf **www.klimaaktiv.at/bauen-sanieren**

Alle Details zur Gebäudebewertung und den Kriterienkatalogen finden Sie auf **www.klimaaktiv.at/bauen-sanieren/gebaeudedeklaration**

Zentrale Anlaufstelle für alle Fragen zu klima**aktiv** Bauen und Sanieren ist die ÖGUT GmbH – Österreichische Gesellschaft für Umwelt und Technik.
