WELCOME TO SBE19 GRAZ

Dear ladies and gentlemen,
Dear colleagues,

we would like to welcome you to the Sustainable Built Environment D-A-CH Conference 2019 (SBE19 Graz) - Transition Towards a Net Zero Carbon Built Environment. Together with other events in the SBE-series, the goal is to prepare for the World Conference in 2020 in Gothenburg (WSBE2020 - Beyond 2020).

The aim of SBE19 Graz is to enable an exchange between scientists, practitioners, politicians and the interested public on matters regarding innovative construction products, sustainable buildings, modern design methods and tools, sustainable urban neighborhoods and future-proof urban development. This includes new business models and instruments on green financing as well as national and regional strategies to implement sustainable development principles in the construction and real estate sector. For the first time, this regional conference has been jointly organized by institutions from Germany, Austria and Switzerland following the "D-A-CH" format.

The 145 international scientific committee members put a lot of effort into the double-blind peer review process of the scientific contributions and selected the best contributions for presentations, which are available as open source, indexed publications. 188 scientific presentations from more than 30 countries highlight the wide scope and complexity of international research activities that address sustainability issues for the built environment. The program is structured accordingly including the following topics organized in six parallel sessions: Buildings, Building Design, Processes, Products, Education & Economy and National Issues.

The matter of climate change has been stated clearly by the IPCC: Every degree of warming counts, every year of delay counts and every decision counts. It is now being increasingly discussed how the demands for climate protection can be translated into concrete design requirements, e.g. in terms of environmental budgets or environmental target values. Swift action is required and the advice of our colleagues in climate and environmental research is becoming ever more urgent. What is needed are general sustainability guidelines as well as practical solutions such as planning and assessment methods, innovative construction products and building solutions.

The role of the construction and real estate industry in developing answers to the current problems is crucial. The construction, maintenance and adaptation of the built environment is a basic prerequisite for social and economic development. On the one hand, these activities require significant amounts of energy and initiate material flows and green house gas emissions that impact the global and local environment not only during construction, but for a long time thereafter – typical lock-in factors. On the other hand buildings, cities and infrastructure are not only affected by climate change but are also expected to protect people from the undesirable effects of climate change. Therefore, the sector has multiple tasks, the most pressing one being to exploit the savings potential of the sector with appropriate support through setting suitable framework conditions and policies. Greenhouse gas emissions must be reduced to 50% by 2030 and industrialized nations must achieve net zero emissions by 2050. That is an enormous challenge, but the stakes are high and the building and related industry sector must and will contribute to the effort.

From a complex analysis perspective, topics other than mitigation should not be neglected - examples are health protection, comfort, durability, adaptability, resilience, decommissioning and recyclability (circular economy) or affordability. Frequently, this not only results in synergies but also in trade-offs, sometimes conflicting goals, which only become recognizable and solvable in an integrated, systemic approach. Methodological approaches such as technology assessment or comprehensive sustainability assessment therefore remain indispensable.

The SBE19 Graz addresses questions with additional complementary formats to the regular scientific presentations. Aspects of climate change (SDG 13) and the role of sustainable cities and municipalities (SDG 11) will be discussed in roundtable events at the pre-conference. In the special fora specific topics will be discussed in a workshop character, for example regarding LEVEL(s), CRP special requirement 7, the further development of EPDs, sustainability performance of construction products (steel, concrete, wood and plastics). Last but not least, a focus will be put on how universities and research institutes can contribute to sustainable development with their own responsibility and their own building stock – where your valuable contribution would be highly appreciated.
The days of exchange and discussion at this conference at Graz University of Technology are also an important signal: inspiring cooperation and scientific exchange across all borders is not only possible but necessary - limiting global change within planetary boundaries.
Our organizing team made a special effort to make this event itself a more sustainable one following Green Events Austria suggestions.
SBE19 Graz provides a special setting to refresh existing contacts and create new partnerships and friendships. We hope that your stay in Styria, the green heart of Austria, will stir active discussion and we are looking forward to hear your thoughts and views to progress the Transition Towards a Net Zero Carbon Built Environment.

With kind regards,

FOREWORDS

Transition Towards a Net Zero Carbon Built Environment

Dear SBE19 Graz participants,

credit: lunghammer

sustainability is one of our most eminent topics. It is a necessity for our dealings with nature and scarce or even infinite resources. A responsibility of pressing urgency for all mankind, it is an obligation we owe to future generations. One of the most important contributions we can make for this so very urgent task is to achieve sustainable construction.

The development of sustainable solutions is not an effort limited to single scientific disciplines as we strive for sustainability. Interdisciplinary approaches are key to effectiveness and success through a broad front and are on high demand. TU Graz fosters multiple concepts and focusses on interlinking them. Our Field of Expertise Sustainable Systems – one out of five internationally outstanding research areas – involves researchers from all our seven faculties and half of our around 100 institutes. Its research topics range from future-oriented urban planning, innovative building technologies and energy systems to the use of renewable energy sources, intelligent energy networks and green mobility.

The topic is well represented in our graduate and continuing education. Furthermore, our students organize sustainability events on a regular basis. Our internationally successful student teams work on projects ranging from lightweight concrete to energy-efficient vehicles.

The initiative UniNEtZ unites Austrian universities and relevant official institutions in contributing to the goals defined and pursued by the United Nations Sustainable Development Agenda. Under the leadership of the TU Graz Sustainability Advisory Board, our university and the University of Graz co-ordinate our universities contributions make to the UN sustainable development goal (SDG) 11 of ensuring sustainable cities and communities. Furthermore, contributions are made to work on quality education (SDG 4), clean water and sanitation (SDG 6), affordable and clean energy (SDG 7), industry, innovation and infrastructure (SDG 9), responsible production and consumption (12) and climate action (13).

This conference will bring valuable contributions and yield practical results for the diverse facets and the assignments of sustainable construction. Experience an inspiring visit to Graz University of Technology while participating in fruitful discussions and gaining new insights.

Yours,

Univ.-Prof. Dipl.-Ing. Dr.techn. Dr.h.c.mult. **Harald Kainz**
Rector of Graz University of Technology, Austria

Dear participants of the SBE19 Graz,

as the President of Karlsruhe Institute of Technology, KIT – The Research University in the Helmholtz Association – it is my great pleasure to send you greetings from the executive board as well as the employees and students.

credit: andrea fabry

In an era of intense struggle to achieve the internationally recognized sustainable development goals, it is particularly important to put scientific knowledge at the service of society and to strengthen international cooperation. This also applies to the subject areas of design, construction, renovation and use of buildings, sustainable urban development and sustainable energy supply. After participating in the preparation of the SB13 in Munich and the SBE16 in Hamburg, KIT is now involved in the implementation of the SBE19 in Graz – for the first time as partners with institutions from Austria and Switzerland in a transnational format. KIT staff have directly participated in the Advisory Board and the immediate organization, as well as making scientific contributions to the conference.

At KIT, around 9.300 employees are working together on a broad disciplinary basis in natural sciences, engineering, economics, humanities and social sciences. KIT offers research-oriented studies to prepare its 25.000 students for responsible tasks in society, economy and science. Our aim is to make significant contributions to global challenges in the fields of energy, mobility and information.

Innovations at KIT bridge the gap between knowledge and application for the benefit of society, economic prosperity and the preservation of our natural resources. According to this mission, knowledge for society and the environment is developed and taught at the research university. Due to its broad profile, KIT's divisions and institutes are able to almost completely map the value added chains of the construction, real estate and energy industries. This approach allows us to develop products, technologies, assessment methods and business models that contribute to sustainable development. Thus, KIT has successfully dealt with these key issues: (1) development and testing of sustainability assessment systems for buildings and neighborhoods; (2) analysis of building-related energy and material flows in regions; (3) development of indicators for assessing energy supply systems.

The organization of scientific disciplines of KIT is purposely structured in five divisions: I: Biology, Chemistry and Process Engineering, II: Informatics, Economics and Society, III: Mechanical and Electrical Engineering and V: Physics and Mathematics, deal with research issues with direct relevance to the topics of construction and energy industry. Division IV provides a center for all topics of the natural and built environment. The creation of three overarching strategic fields: „Energy“, „Mobility“ and „Information“, ensures that targeted research contributions can be expected in the coming years to address current megatrends.

Foundations, principles and solutions for the implementation of sustainable development are an integral part of the education of students and young scientists. An extra-curricular course of studies called „Sustainable Development“ organized by the Centre for Cultural and General Studies (ZAK) is just one example. In 2018, UNESCO designated KIT as a “learning location for sustainable development”. The “Future Campus” department coordinates and promotes sustainable development at our own campus.

I am convinced that the SBE19 in Graz will not only be a showcase of past results and achievements, but also the starting point for an even more intensive cooperation in all relevant fields of research. I wish all participants every success in this regard. Finally, I would like to thank the institutions in Austria and Switzerland for their cooperative spirit and in particular TU Graz for their initiative in connection with the host's role.

Professor Dr.-Ing. **Holger Hanselka**
President of Karlsruhe Institute of Technology, Germany

Dear SBE19 Graz participants,

a continuous increase in the population over the last centuries along with the industrialization and its increasing demand for fossil energy led to a record high CO2 concentration in the atmosphere and further ecological and social challenges. The 17 SDGs (Sustainable Development Goals) proposed by the United Nations give a vision for 2030 and are based on the planetary boundary concept with the goal to avoid further damage to our planet. One of the SGDs, the SDG 11, focusses on **“Making cities and human settlements inclusive, safe, resilient and sustainable”** and directly links to the topic of this conference, a sustainable built environment. Issues like land consumption and its related consequences, the use of construction materials, energy efficiency and production are as well addressed as social implications on how we as human beings want or should live together.

BOKU University of Natural Resources and Life Sciences, Vienna is the University of Sustainability. We do research and offer study programs since 1872 based on the integration of technical, ecological and socio-economic fields. This interdisciplinary approach perfectly addresses the research and educational needs of the sustainable development goals. Not surprisingly that BOKU takes a leading role in the Austrian UniNEtZ-Project, which promotes the implementation of the SDG in Austria.

With this background we are proud to contribute to this conference. We expect new findings and we do hope that you have a successful stay in Graz.

Yours sincerely,

Univ. Prof. Dipl.-Ing.Dr. DDr.h.c. **Hubert Hasenauer**
Rector of University of Natural Resources and Applied Life Sciences, Austria

Dear SBE19 Graz participants,

credit: ETH Zurich

the construction industry accounts for over 40% of all raw materials extraction, as well as 40% of total energy supplied and 16% of annual water consumption worldwide. During the last century, overall global material consumption multiplied approximately tenfold, while consumption of construction minerals multiplied by a factor of 42, showing a positive feedback-loop between socio-technical system evolution and its construction material requirement. Following business-as-usual practices will drive building and infrastructure activities along a dramatic and unsustainable path. But these future challenges can also be turned into opportunities.

Selected building technologies can reduce or even store carbon emissions during construction and in the longer term. They can also be used as depositories of materials to be mined at a later stage. Building renovation can also be a catalyst to re-activate social and economic networks in a neighbourhood. To harness these opportunities, the Swiss Federal Institute of Technology (ETH Zurich) is engaged in research and innovation towards a post carbon environment.

ETH Zurich also wants to play a key role in training a new generation of scientists, engineers and architects. We want them to have the fundamental knowledge to tackle these challenges but also, and most importantly, to exercise critical thinking in order that they can engage in society by developing and designing the appropriate answer to the real needs of future generations.

The conference on the Sustainable Built Environment, SBE 19 in Graz, is part of a major international series of conferences supported by the International Council for Research and Innovation in Building and Construction (CIB), the International Initiative for a Sustainable Built Environment (iiSBE), the Sustainable Building and Climate Initiative (SBCI) of the UN Environment, the International Federation of Consulting Engineers (FIDIC) and the Global Alliance for Buildings and Construction (GABC). The series, now on a three-year cycle, is recognised as the world's preeminent conference series in this important field.

I am delighted to learn about the common initiative from Austrian, German and Swiss universities to co-organise this conference. It is hosted at the Graz University of Technology in collaboration with the University of Natural Resources and Life Sciences in Vienna, Karlsruhe Institute of Technology and ETH Zurich.

I wish you all success for the conference and hope that under this common roof you, as researchers and industry partners, will have exciting and fruitful discussions that will trigger the necessary dynamics for transformation towards a net zero emission built environment.

Yours sincerely,

Prof. Dr. Dr.h.c.mult. **Sarah M. Springman** CBE FREng
Rector of Swiss Federal Institute of Technology Zurich, Switzerland

Dear SBE19 Graz participants,

credit: paul gruber

with the Austrian Climate and Energy Strategy, #mission2030, we heralded the end of the fossil fuel age in our country. We want to reduce greenhouse gas emissions by 36 percent compared to 2005 and aim to produce 100 % of Austria's power consumption from renewables by the year 2030. Presently, we are working to prepare the law on the development of energy from renewable sources; we advance electromobility, ensure new funding options by means of the Green Initiative, and promote the Bioeconomy Strategy.

High-quality refurbishment and renovation of existing buildings and energy-efficient new construction are effective strategies in the fight against climate change. With the help of Austria's Heat Strategy the goals for the building and thermal sector laid down in #mission2030 are to be achieved by 2030. Promoting energy efficiency and renewable energy in buildings also creates important impulses for Austria's economy and offers substantial opportunities on international markets.

In addition to the thermal rehabilitation campaign, the subsidies offered within the framework of domestic environmental subsidisation and the Climate and Energy Fund, my climate protection initiative "klimaaktiv" is setting trailblazing impulses with the building standard, the complex evaluation system in the field of climate protection and energy efficiency.

The fight against climate change is anything but easy, but it also represents a great opportunity. Bearing this in mind, I wish the "Sustainable Built Environment Conference 2019" every success. It is a pleasure for us to offer support to this important event.

Kind regards,

Maria Patek
Federal Minister for Sustainability and Tourism, Austria

Dear SBE19 Graz participants,

credit: johannes zinner

cities and buildings of the future have to provide a major contribution to the national and European climate and energy targets. Therefore, energy driven and sustainable city planning, digitalization in the construction sector as well as renewable energy and building technologies are key to support stakeholders, especially under the requirements of building quality and affordability.

Research can significantly contribute to generate innovative solutions for the future by questioning known patterns. If they succeed, they will be put into practice, and the creation of suitable framework conditions are essential to enable a broad and successful implementation.

As an example, the Austrian Federal Ministry of Transport, Innovation and Technology (BMVIT) is committed to the implementation of plus energy districts as a mission of “City of Tomorrow”. It will do so by funding research and development on urban technologies, technological systems and services, and taking the growing importance of digitalization into account.

The focus lies on innovative technologies and systems for energy generation, distribution, transformation and storage as well as the optimization of the energy consumption in buildings and urban neighbourhoods, in addition to energy efficiency and new building technologies for new constructions and renovations.

For many years, Austria is internationally recognized as a pioneer in the field of building and urban technologies. This role is to be further strengthened by the current initiatives, an objective that can only be achieved with the involvement and cooperation of research, industry, public administration and commercial enterprises.

With this in mind I wish those attending the Sustainable Building Conference 2019 stimulant and exciting discussions!

Yours sincerely,

Andreas Reichhardt
Federal Minister of Transport, Innovation and Technology, Austria

„Architecture is a manifestation of freedom"

credit: lebensressort

Scientific evidence for a global warming and change of the climate system is unequivocal. Climate change impacts thousands of citizens' lives around the globe every day in countless ways. One way in which we are impacted is in our weather patterns: we face periods of enormous heat and extreme thunderstorms followed by particularly frosty winters. As we gradually move from a state of normality to a state of extremes, the call on our nation's leaders has become louder and louder. The call? One for sustainability.

Although it is a fact that climate change does not know any borders, Styria wants to procede as a role model. We know that climate change and its effects do not have touchpoints with just one or two thematic areas. Therefore, the Styrian government has decided not to pass just one single law, but to consider these problems in all of its political activities, ranging from tasks such as spatial planning, funding guidelines and general legislation. For Styria, sustainability is not merely one project or something that gets passed in a couple of laws by Parliament. Rather, sustainability is one lens through which all decisions will pass through.

A major area in which sustainability plays a special role is housing and its funding guidelines. Therefore, we pay particular attention to which building materials are used for construction. Another important criteria for obtaining public funding is the issue of energy efficiency when it comes to constructing or renovating houses. Land Steiermark's course of actions clearly favours buildings that protect the climate by using materials that help the buildings achieve energy efficiency, in accordance with European Union directives.

The issues related to climate change and global warming cannot be solved by a single country, yet it is our duty to make our modest contribution to preserve our liveable environment.

Yours faithfully,

Johann Seitinger

State Councilor for Agriculture and Forestry, Water and Waste Management, Housing and Sustainability, Styria, Austria

Dear SBE19 Graz participants,

credit: freisinger

the topic of sustainability affects a variety of areas in our lives; be it the production and consumption of goods, the volume of traffic or our built environment, which seals large areas of land.
All this presents future generations with ever-increasing challenges. However, it is up to us to keep this negative legacy to a minimum.

The economic efficiency, when it comes to using resources as economically as possible, the developments in economic terms as well as the social aspects of responsibility for the future and global distributive justice should guide our actions.

In the Climate and Energy Strategy Steiermark 2030, an important chapter for sustainable construction methods was opened with a focus on „buildings and settlement structures“ from a holistic perspective. It ranges from energy-optimized settlement structures as an element of energy planning to energy-efficient building technologies and climate-friendly and therefore sustainable building envelopes.

In addition, the Climate and Energy Strategy Steiermark 2030 also addresses the aspects of ecology (such as open spaces and urban climate, water and soil, resource cycles and emissions). For example, the sustainability criteria in the waste and resource industry, the energy supply and distribution and the reduction of the personal carbon footprint of each and everyone of us are essential issues.

Now it is important to suit the action to the word and take concrete measures. The fight against climate change does no longer tolerate a delay.

With this in mind, I wish all involved parties a successful participation. May you be the initiator and driving force for processes for a livable future for our children and grandchildren.

Yours faithfully,

Anton Lang
State Councilor for Finance, Transport, Environmental and Renewable Energies / Climate Protection, Sport and Animal Welfare, Styria, Austria

Ladies and Gentlemen,

credit: marija kanizaj

as the Mayor of Graz, I am particularly pleased that the „Sustainable Built Environment D-A-CH Conference 2019“ is taking place in Graz once again. Graz is growing: about 60,000 more inhabitants since 2003. That also means, we are forecasting another 40,000 new citizens by 2035. In view of this development, urban sustainability strategies, especially in the residential sector, are not „nice to have“, but indispensable.

Since this internationally renowned conference enables encounters between young researchers and established scientists, not only the content but especially the format can be described as particularly sustainable.

I hereby thank all those who have contributed to the preparation and implementation of the conference, as well as all speakers and wish you all informative and enjoyable days in Graz!

Yours faithfully,

Mag. **Siegfried Nagl**
Mayor of the City of Graz, Austria

Dear SBE19 participants,

credit: stadt graz/ fischer

it is a great pleasure for me to welcome you to Graz as the capital of the province of Styria and with nearly 300,000 inhabitants the second largest city of Austria. Graz is very proud to host four universities and two universities of applied sciences with about 50,000 students. This is one main reason to support such important scientific events like SBE19.

Another reason is that knowledge exchange and capacity building – with such a holistic approach – are essential for the public sector to keep pace with rapid technological development and changing societal and environmental framework conditions. The SBE19 Graz conference where internationally renowned experts will present important aspects of sustainable building and construction in numerous talks and lectures is a perfect possibility for practitioners, scientists and administration to learn from each other.

As a strong growing city, Graz is continuously looking for sustainable urban development solutions to preserve and even expand its high quality of life under growing framework conditions.

In this regard the City of Graz has already achieved national and international recognition for its innovative efforts to implement such sustainable solutions under its local umbrella strategy for a Smart City. This can only be achieved through a strong PPP-cooperation with numerous experienced scientific partners such as the University of Technology in Graz, the Provincial Government of Styria and with many other innovative institutions and companies.

Curbing climate change today is one of the biggest challenges facing politics, the economy and society. Sustainable building and renovation concepts are essential instruments of climate protection and important steps towards local energy autonomy. More than one third of our energy consumption results from the private, public and service sector. Hence comprehensive thermal retrofitting of building stock, greater energy efficiency in new buildings and a significant increase in the share of renewable energy can - in addition to more efficient energy use in the transport and producing sector - slow down climate change for the long term. Other important topics for urban areas, which will be addressed during the SBE19-conference, are inter alia cities as temporal carbon and energy storage or circular economy concepts for the built environment.

I wish the Sustainable Built Environment Conference 2019 every success and all participants lots of inspiring discussions, insights and findings for future practical implementation.

Kind regards,

Bertram Werle

Director for urban planning, development and construction
City of Graz, Austria

Dear Participants of the “Sustainable Built Environment D-A-CH Conference 2019”,
Dear Ladies and Gentlemen,

in an increasingly interconnected society, companies worldwide face severe challenges. Consequently, Wienerberger is continuously working to improve and further develop its products as well as system solutions for all fields of application, including the recycling and re-use of our products. The foremost goal of our entrepreneurial activities is to achieve a sustainable growth of the company in accordance with ecological, social and economic principles. To achieve this goal, we have defined a clear strategy focused on organic growth, operational excellence, investments and portfolio optimization. We do our utmost to supply future oriented sustainable building material solutions in the building sector. By providing long-lasting and resource-conserving building materials and energy efficient building and infrastructure concepts we confirm that we are taking our role as a responsible member of society very seriously. All stages of the value chain of the Wienerberger Group are covered by a voluntary commitment to sustainability.

At the SBE19, internationally renowned experts will emphasize all aspects of sustainable construction. We especially welcome the fact that many young people and students in the field of sustainable building solutions will participate in the conference. Wienerberger makes every effort to contribute to the promotion of sustainable buildings which is demonstrated by the certification of the residential construction project “D22” in the Seestadt Aspern (Vienna, Austria). The building achieved 769 of 1000 points in the ÖGNB building certification and was awarded “klimaaktiv GOLD”. Fascinating is the fact that the team opted for Wienerberger Porotherm 50 W.i bricks for the building envelope. For the first time in a long while a subsidized residential building was constructed with monolithic, loadbearing clay blocks without additional external thermal insulation. In our opinion, the project can be seen as a real lighthouse project due to its contribution to the energy efficiency of buildings and to climate protection.

Having this in mind, I wish all attendees of the SBE19 stimulating discussions and very promising results!

Yours,

Heimo Scheuch, Chief Executive Officer
Wienerberger AG, Austria

Dear SBE19 Graz participants,

credit: FV Steine-Keramik/Lukas Lorenz

in recent years new construction methods have been developed (e.g. building component activation) in order to reduce the energy consumption of the building sector. Massive research has been carried out on material components in order to minimise the use of raw materials, optimise designs and at the same time improve quality - and thus longevity. The development has also progressed in terms of circular economy. In the mineral sector, for example, almost all construction waste is recycled. A lot of things have been automated and thus undoubtedly optimized. The goal of reducing energy consumption and emissions during the use and dismantling phases of buildings as well as during the production of the building materials was also achieved.

In this context, conferences such as the SBE19 Graz contribute to discussing forward-looking methods, technologies and processes on the levels of building products, buildings, neighbourhoods and existing buildings. They contribute to pointing out solutions in the sense of resource conservation and environ- mental protection, taking into account social and economic questions.

For this reason the Austrian Association of Building Materials and Ceramic Industries makes special efforts to support various national and European research projects, e.g. in cooperation with Graz University of Technology, and thus makes a contribution to sustainable construction research.

With kind regards,

Dipl.Ing. Dr. **Andreas Pfeiler**
CEO Austrian Association of Building Materials and Ceramic Industries

Dear SBE19 Graz participants,

credit: klimafonds/ ringhofer

the significant reduction of greenhouse gas emissions by 80 to 95 percent by 2050 compared to the reference year 1990 is the primary objective of the Paris Agreement. The building sector, responsible for around a third of the local energy consumption, must therefore be completely free of CO_2 emissions in the medium to long term.

It is important to exploit the great potential in the building sector. Energy savings and the use of energy-efficient technologies help to reduce greenhouse gas emissions. From building materials and the supply with space heating, cooling and hot water to the lighting of buildings and technical equipment, there are numerous starting points for forward-looking technologies and solutions. However not only the individual-building-level shows a great untapped potential, but also the interplay in the urban network.

The Climate and Energy Fund focuses on both areas and has for years been promoting model-rehabilitations, research and technology development in the area of sustainable building. With 84 model-renovations already implemented, we show that our vision of designing the building sector free of emissions is already feasible: The energy requirement of 65 of the 84 flagship projects is 100 percent covered by renewable energies. Ten buildings are even classified as plus-energy houses. These objects act as independent power plants and generate more energy than they consume.
Entire cities are taking actions towards greater efficiency and climate compatibility too, which is an important step towards energy independence. More than 50 Smart Cities throughout Austria are already striking this path.

Austria has a pioneering role in the field of sustainable building in Europe, not least because of our funding programs. As part of this funding programs, we initiate numerous R & D activities in this field of research, focusing on the topics of building insulation, multifunctional façade systems, solar thermal and solar cooling, decentralized power supply with photovoltaics, storage technologies, highly efficient lighting technologies, demand-side management, smart home solutions as well as waste and water saving technologies. Numerous technologies and products have already been brought to industrial production and are marketed internationally.

Yours sincerely,

Theresia Vogel and **Ingmar Höbarth**
Management Austrian Climate and Energy Fund, Austria

Ladies and Gentlemen,
Dear participants of the Sustainable Built Environment D-A-CH Conference 2019,

acting sustainably is a law of our time. The Fridays For Future movement shows impressively how vehemently especially young people demand to take determined action for climate protection in all societal, political and economic areas. Sustainable building as part of the national climate and environmental strategies in Germany as well promotes climate protection. Sustainability in the construction sector, on the one hand, means environmentally suitable and energy-efficient building to minimise negative impacts on the climate. On the other hand, we have to adapt our buildings to the climate change to keep damages to the built infrastructure as low as possible.

As a research institution of the German Federal Government, the Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR) advises and supports the German Federal Ministry of the Interior, Building and Community in a wide spectrum of construction-related issues, including climate protection, energy and resource efficiency, planning quality, cost-effective housing construction and demographic change. A special focus is on interdisciplinary research and development projects. The projects create a bridge between research and construction practice. All measures have the aim to promote a sustainable development in the construction sector as a whole.

With the Guideline for Sustainable Building and the Assessment System for Sustainable Building (BNB), the Federal Building Ministry has developed instruments to put its ambitious climate goals into practice. The goal behind was to realise the Federal Government's construction projects sustainably thus acting as an example to other public owner-builders. The Guideline for Sustainable Building and the BNB pursue an approach combining climate protection and climate change-adapted building in terms of sustainable building. In the context of their „Future Building" research initiative, the Federal Building Ministry and the BBSR have developed many action guidelines for planners and architects or builders.

With an exhibition and various lectures during the Sustainable Built Environment D-A-CH Conference 2019, the BBSR will provide an overview of the Guideline for Sustainable Building and the Assessment System for Sustainable Building (BNB), its supporting instruments as well as of model projects of the Federal Government's construction activities. Our Special Forum "Level(s) and its place in the tool box for sustainable construction" shall enable the discussion about how a division of labour between Level(s) as the European Union's voluntary reporting context and other national assessment systems for sustainable building like the BNB might be realised.

The Conference serves to inform and exchange about sustainable developments in the construction sector. It offers an excellent basis for presenting and discussing research results. I wish the Conference all the best, a lasting success and many interesting conversations and findings.

Yours,

Dr. **Robert Kaltenbrunner**

Deputy Director of the Federal Institute for Research on Building, Urban Affairs and
Spatial Development, Germany

1.5°C Climate Change - What are the Implications for the Built Environment?

Prof. Dr. Diana **ÜRGE-VORSATZ**
Department of Environmental Sciences and Policy at the Central European University, Budapest; Vice Chair of Working Group III of the Intergovernmental Panel on Climate Change (IPCC)

The first keynote speech will guide us from the broad topic of climate change to our specific topic „Transition Towards a Net Zero Carbon Built Environment".
Diana Ürge-Vorsatz will present recent developments from IPPC (especially from Working Group III Mitigation of Climate Change) and will inform us about the implications for the built environment.

Supporting, Challenging, Advising: Building Policy in the Light of Climate Change

MinDirig Dipl.-Ing. Arch. Lothar **FEHN KRESTAS**
Head of the Department of Building, Construction Industry and Federal Buildings at the Federal Ministry of the Interior, Building and Community

Megatrends such as climate change, resource scarcity, demographic change and a shift in values towards a greater sense of responsibility to society and the environment are currently presenting additional challenges to politics at federal and regional level. Taking as an example the need and opportunities for German federal politics to act and support sustainable development in the construction, housing and real estate industries, I will in the following consider how governmental tasks and roles can be generally defined in this context.

One matter which has been a subject of discussion for some time now is whether politics has a key role to play when it comes to environmental and health protection issues and securing the future viability of politics, or whether the task of developing and implementing adequate solutions for promoting sustainable development should be left to market forces. Experience gained in Germany and elsewhere shows that a combination of governmental measures and individual or institutional initiatives holds great potential. Politics is thus called to take responsibility for developing medium- to long-term strategies, for setting the framework and boundary conditions, defining socially justified standards and determining requirements to be made in respect of environmental and health compatibility. These are the guideposts along which market forces can seek and find solutions. It is thus especially important that these requirements be formulated so that they are performance-oriented and do not give preference to any specific technologies. Market players all acknowledge that politics has a particular responsibility when it comes to safeguarding social and economic developments while at the same time protecting the environment and conserving resources in such a way as to safeguard our natural resource base. Increasingly, politics is also coming up against growing expectations on the part of businesses and the general public. These expectations have conflicting underlying objectives, though. One example is the struggle to reconcile the goal of securing a quantitatively and qualitatively adequate supply of affordable housing while at the same time improving the energetic quality of the building stock through wide-ranging modernization measures as a means of contributing to climate protection.

Politics takes on various roles when it comes to the planning, construction and operation of real estate based on sustainable development principles as well as when it comes to improving the current housing stock. Given that it is policymakers who are responsible for legislation, it is they who thus first set the regulatory environment. Simultaneously, policymakers create incentive and support schemes which help get new products on the market or close efficiency gaps. At the same time, though, federal institutions are the builders, owners, operators and users of real property. That opens up the opportunity and the need for them to set an example on the one hand and to test new options themselves on the other. In the following these roles will be briefly outlined in connection with the resulting tasks and possible courses of action.

Federal legislation has for many years now included direct references to sustainable development in the construction sector – from the Building Code (sustainable land use) to the Regulations on Determining Real Estate Market Values (including energy quality when determining a building's value). Sustainability is a cross-cutting issue in the building and real estate industries and thus needs to form part of a whole-of-government strategy.

One aspect which Germany has still not addressed when it comes to developing energy quality standards for buildings is the need to add climate action requirements to resource conservation targets. For the first time the Federal Government's Climate Action Plan 2050 sets sectoral goals for reducing greenhouse gas emissions in the building sector, and these could be interpreted as the remaining CO2-eq. budget for real estate utilization. The task now is to achieve those goals by implementing suitable strategies and packages of measures. At the same time, the Federal Government has adapted its national reporting and statistics in order to be able to record and thus assess the level of achievement of select sustainable development targets. The options available for creating fiscal incentives to reduce greenhouse gas emissions have not yet been fully exhausted – a carbon tax is currently under discussion, for example.

It is up to politics to promote beneficial developments by way of providing financial support, where possible and sensible from a macroeconomic perspective. For many years such funding programmes have been available in the building sector to improve the energy quality of buildings, provide advice and support to clients, put products made from renewable resources on the market and construct accessible buildings. How funding programmes can be adapted and improved to contribute even more to climate action is a current matter of debate in Germany and many other countries. The KfW Development Bank, for instance, is reviewing options for funding various building measures, ranging from green roofs as a means of reducing heat island effects to climate-neutral building designs.

As is the case in Switzerland and Austria, research and development in the field of sustainable planning and building, sustainable neighbourhood and urban development, and the development of products, tools and methods is receiving publicly funded support on a massive scale in Germany. Here, these programmes are coordinated and pooled in the Zukunft Bau (The Future of Building) programme, the outcomes of which will be made available to the public.

Building on the traditions of energy-efficient, healthy, and cost- and space-saving planning and construction, the federal ministry responsible for building tasks began implementing the principles of sustainable development back in 2000. Since 2001, this work has been coordinated with representatives of business and science as part of the Sustainable Building Round Table. The aim is to set an example when it comes to sustainable public procurement. The Round Table has not only produced guidelines and a system for evaluating the sustainability of federal buildings (Bewertungssystem Nachhaltiges Bauen für Bundesbauten, or BNB) and made these an obligatory requirement for building projects, the required data and tools have also been made freely available. In the case of building projects funded by the Federal Government, sustainability requirements must be formulated in the early planning stages and then recorded in a target agreement. Projects have to achieve the "BNB Silver" certificate level, though they often do better. The focus is presently on expanding climate action targets, as well as passing on experience gained at the federal level to the federal states and local authorities. The Federal Government is also enhancing the planning, construction and operator skills of staff in regard to energy-saving, resource-friendly, healthy and cost-effective planning through special training programmes.

It will only be possible to successfully implement sustainable development principles in the building sector if the focus is not only placed on so-called lighthouse projects. That is why one approach which is being resolutely pursued is to provide clients and planners with the necessary methods (BNB), data (oekobau.dat, WECOBIS) and tools (eLCA) free of charge in order to achieve a broad-based impact. These are based on European and international norms. Germany actively brings its positions to bear and puts forward ideas in this regard and – like Austria and Switzerland – is actively involved in improving and harmonizing these foundations. That makes it easier for planners, construction firms and product suppliers to cooperate across borders.

Information about sustainable building in Germany and about free-to-use data and tools is available on the www.nachhaltigesbauen.de platform, for example.

One good example of how common political goals can be pursued at regional level is the Alpine Climate Target System 2050 initiative (see https://www.bmu.de/pressemitteilung/alpenregion-soll-bis-2050-klimaneutral-werden/).

At a time when the real consequences of climate change are already being felt, it is important that policymakers step up the pace when it comes to translating scientific findings into policy action and adapting the framework and boundary conditions. Even though they recognize the particular relevance of this issue, the task remains to direct business and social development across the entire bandwidth of related issues so that a balance can be found. When defining and pursuing ecological, social and economic targets, conflicting goals can be identified and resolved, and the livelihoods of future generations safeguarded. In the truest sense of the word, politics itself must be sustainable, too.

Sustainability Assessment in the Focus of the EU-Taxonomy for Sustainable Finance

Ursula **HARTENBERGER**
Global Head of Sustainability, RICS, Member of the Technical Expert Group on Sustainable Finance, Chair of Buildings Sector Group

While initially the focus of legislative frameworks had been more on technical aspects of sustainable development, over the past few years, policy makers have been actively reaching out to and engaging with the finance community.

In this, COP21 in 2015, the signing of the Paris Agreement proved to be a decisive moment. As part of the agreement, signatories not only committed to climate targets, but also to aligning financial flows with a pathway towards low-carbon and climate-resilient development. No surprise then that sustainable finance has now also become a core element of EU policy initiatives, reflecting a growing awareness that this alignment is crucial for successfully addressing the complex challenges of climate change.

However, large-scale investment is needed for the EU to meet its 2030 climate targets, being clearly beyond the capacity of the public sector alone, especially in view of the short time-scale during which the changes need to be made.

The situation for energy efficiency investments in buildings is not dissimilar. According to the most recent Global Status Report[1] , annually published by the UN-led Global Alliance for Buildings and Construction Global Alliance[2] , the rate of investment flows towards more efficient buildings as a share of total investment when compared to previous growth rates is slowing down.

The financial sector thus has a central role to play in driving investments towards more sustainable businesses, technologies and products, including construction and real estate. But how to assess what is a sustainable business, technology or building?

This is where the EU Action Plan for Sustainable Finance[3] adopted in March 2018 which is setting out a comprehensive strategy to connect finance with sustainability comes into play.

One of the measures within the Sustainable Finance package is a proposal for a unified classification system or “Taxonomy”. The aim behind creating this Taxonomy has been to define what can be considered an environmentally sustainable economic activity.

Economic activities are screened for their contribution to six environmental objectives: (1) climate change mitigation, (2) climate change adaptation, (3) sustainable use and protection of water and marine resources, (4) transition to a circular economy, waste prevention and recycling, (5) pollution prevention and control and (6) protection of healthy ecosystems.

To be Taxonomy-eligible, an economic activity must contribute substantially to at least one of these environmental objectives and do no significant harm to the other five. It also has to meet minimum social

[1] UNEP and IEA, 2018, Towards a zero-emission, efficient and resilient buildings and construction sector, Global Status Report. Available at: https://www.unenvironment.org/resources/report/global-status-report-2018

[2] The Global Alliance for Buildings and Construction (GlobalABC), founded at COP21 in Paris in 2015, is a global platform for governments, the private sector, civil society and intergovernmental and international organizations to increase action towards a zero-emission, efficient and resilient buildings and construction sector. For more information: https://globalabc.org/about-gabc/introduction

[3] European Commission, 2018, Action Plan: Financing Sustainable Growth, available at: https://eur-lex.europa.eu/legal-content/EN/TXT/?uri=CELEX:52018DC0097

safeguards in line with ILO[4] standards.
Climate change mitigation activities are categorised by their level of contribution: (1) activities that are already on a low-carbon trajectory, (2) transition activities and (2) enabling activities.
Within construction and real estate, four economic activities have been included in the Taxonomy: the construction of new energy and resource efficient buildings as a low-carbon activity; the renovation of existing buildings as a transition activity and individual measures, such as the installation of efficient building components, i.e. new boilers, windows, insulation, etc., renewable energy technologies and associated relevant professional services as enabling activities. Criteria for the fourth activity, acquisition and ownership, refer to the low-carbon and transitional activities. The appropriateness of the thresholds set will be periodically reviewed and tightened to ensure getting to net zero carbon by 2050.

Except for buildings used by companies engaged in the extraction, transport and manufacture of fossil fuels, the Taxonomy is very inclusive as it covers virtually all buildings and renovations and. To facilitate smooth market entry, it is closely aligned with EU policy instruments, such as Energy Performance Certificates (EPCs) and nZEBs (nearly Zero Energy Buildings) and corresponding thresholds. These obviously only work in an EU context which is why potential proxies have been identified for application by non-EU investors.

Given the complexity of the sector and the issues at hand, developing the Taxonomy for construction and real estate has not been without challenges. The most significant challenge has doubtless been having to find a compromise between ambition and the desire to avoid so-called “greenwashing” and the need to give consideration to different levels of market readiness across EU Member States in different climate zones. Furthermore, the aim was also to enable already operational or emerging financing tools, such as Green Bonds or the Energy Efficient Mortgage Initiative (EEMI)[5] to continue to flourish.

Workability and acceptance have also guided the thinking behind the transitional approach regarding the choice of metrics. Initially, these are going to be based on annual operational primary energy demand as at present only a small part of the market is working with GHG metrics. In future, this will be extended to include operational GHG emissions and eventually also whole life cycle emissions. While there is consensus about the impact and importance of embodied carbon, at present, the embodied carbon data gaps are making any kind of meaningful benchmarking in this area extremely difficult.

However, regardless of these challenges and the fact that there is still some work to be done until the Taxonomy becomes operational in 2021, for the construction and real estate sector the Taxonomy could represent a quantum leap forward by both rewarding buildings that are already high-performing and by channelling investments to those needing upgrading to improve performance. With 97% of buildings in Europe stock requiring updating to achieve higher performance[6] , particularly in the case renovation, that investment is much needed.

What the EU Taxonomy has achieved is the creation of a common language around sustainable buildings, providing answers to questions that investors, their advisors and developers have been trying to come up with for years: what actually makes a building sustainable and how to assess this? This represents a major milestone for the sector and has a strong signalling function for the whole value chain.
Having a clearly defined set of criteria for sustainability performance characteristics will not only help investors to identify sustainable economic investments, it will also help professionals such as facility managers, valuers and brokers in their daily work and during conversations with investors and financing institutions.

Building Related Environmental Impacts - the Hidden Aspects

Dipl.-Ing. Dr.techn. Peter **HOLZER**
Institute of Building Research & Innovation ZT GmbH

SBE19 gathers an impressive number of most experienced, courageous and enthusiastic experts in the field of sustainable built environment. It does so in a series of international conferences which started back in the year of 2000. This year's conference' headline is nothing less programmatic than "Transition Towards a Net Zero Carbon Built Environment". [1]
Without any doubt this transition is a most urgent imperative on a desirable pathway to a generally sustainable development. It is in line with the Sustainable Development Goal (SDG) 11 – Sustainable Cities and Communities of the UN 2030 Agenda as well as with many other international and national targets. We may agree, that the target of a net zero carbon built environment is both crucial and ambitious. yet, encouraged by significant progress that have been made already, we may even agree that the target is realistically achievable. Still, parallel to consequently making this transition towards Net Zero Carbon happen, we have to be well aware of building related environmental impacts beyond carbon emission. I entitled them, somewhat mysteriously, the 'Hidden Aspects'.
Based on meta studies as well as own research activities I'd like to raise awareness to the impacts of buildings on two more alarming threats of sustainable development, beside climate change: Biodiversity Loss and Land Use Change.
Both trends – biodiversity loss and land use change – together with climate change, have basic qualities in common: They, without any doubt, predominantly result from human activities. They are severely threatening the chance of a civilized and desirable future of mankind. They are highly correlated to each other. Finally, they are significantly influenced by the way we design and operate our built environment.
The secured facts of biodiversity loss and land use change are alarming, the same as they are in case of climate change. There's no time left to address one challenge without and not even before the other. It is dangerous to address one aspect without considering consequences to the others.[2, 3, 4]
As a result of years and decades of collaborative and consistent effort, the assessment of carbon emissions of buildings, amongst many other environmental impact categories, has reached a mature and applicable methodological level, supported by databases, tools and coordinated by international standards. Quite different, biodiversity loss and land use change do not play an adequate, if any, role in the list of practically applied building related environmental impact categories.
This is a dangerous gap. Optimising one aspect (carbon emissions) without having the full picture nor an assessment methodology to consider aspects of equal importance (biodiversity loss and land use change) might lead to dangerously wrong decisions. I will take the chance of the keynote to draw your kind attention to these "Hidden Aspects", presenting learnings from meta studies as well as preliminary results of own research, inviting for further discussion:
In case of biodiversity loss I will present ongoing research towards a methodology to develop a mass-related impact factor, which possibly could be integrated into the existing system of Environmental Product Declarations (EPDs). As an encouraging starting point, the impact category of biodiversity loss is

[1] As a consistent next step, WSBE2020 in Gothenburg, Sweden will address the full mission of "Make Sustainable Cities a Reality".

already mentioned in relevant international standards.[5, 6, 7, 8]
In case of land use and land use change, to our assessment, the consideration of the environmental impact from building activities has to be done on political level in a process of responsible spatial planning, well before the process of responsible building design.[9] Still, one could think of integrating an impact factor such as a site-usage-density. But such a factor would only highlight the usage intensity of a site, without considering spatial or environmental qualities of the specific site.
Summing up: Integrating the qualities of biodiversity loss as well as land use change into environmental assessment of buildings and communities calls for new research efforts in development of methodology, derivation of databases and development of tools. It will necessarily raise complexity of environmental building assessment, but, to our understanding, it is definitely necessary to draw decisions of far-reaching consequences in a complex environment.

SBE19 Graz Highlights

Richard **LORCH**
Editor in Chief Journal Buildings & Cities

This presentation draws together the key themes and ideas that emerged at SBE19 Graz conference. It comments on how the Graz conference may shape future research and policy agendas, particularly for the forthcoming WSBE Conference: Beyond 2020.

From Challenge to Mission - Make Sustainable Cities a Reality

Prof. Dr.-Ing. Holger **WALLBAUM**
Full Professor in Sustainable building, Dep. of Architecture & Civil Engineering, Chalmers University of Technology, Gothenburg, Sweden and host of the World Sustainable Built Environment (WSBE2020) conference in June 2020 entitled BEYOND 2020

At the Earth Summit in Rio de Janeiro in 1992[1], more than 178 countries adopted Agenda 21[2] as a plan of action to build a global partnership for sustainable development to improve human lives and protect the environment. At the Millennium Summit in September 2000, the UN Member States unanimously adopted the Millennium Declaration at UN Headquarters in New York. The Summit led to the elaboration of eight Millennium Development Goals (MDGs)[3] to reduce extreme poverty by 2015. The Johannesburg Declaration on Sustainable Development and the Plan of Implementation, adopted at the World Summit on Sustainable Development in South Africa in 2002, built on the Agenda 21 and the Millennium Declaration and put more emphasis on multilateral partnerships as well. At the United Nations Conference on Sustainable Development (Rio+20) in Rio de Janeiro in 2012, Member States decided to launch a process to develop a set of SDGs to build upon the MDGs. At the UN Sustainable Development Summit in September 2015, the subsequent adoption of the Agenda 2030 for Sustainable Development was decided. As we all know, the 2030 Agenda for Sustainable Development provides a shared blueprint for peace and prosperity for people and the planet, now and into the future. The main contribution of Agenda 2030 has to be seen in the 17 Sustainable Development Goals (SDGs), *"which are an urgent call for action by all countries a global partnership. They recognize that ending poverty and other deprivations must go hand-in-hand with strategies that improve health and education, reduce inequality, and spur economic growth – all while tackling climate change and working to preserve our oceans and forests."* [4] Although the SDGs build on decades of work by countries and the UN, including the UN Department of Economic and Social Affairs, the implementation of the SDGs to real actions remains a challenge. Today, the Division for Sustainable Development Goals (DSDG) in the United Nations Department of Economic and Social Affairs (UNDESA) provides substantive support and capacity-building for the SDGs and their related thematic issues, such as water, energy, climate, oceans, urbanization, transport and plays a key role in the evaluation of UN system-wide implementation of the 2030 Agenda. As stated by the UN, "in order to make the 2030 Agenda a reality, broad ownership of the SDGs must translate into a strong commitment by all stakeholders to implement the global goals."

The built environment is – without any doubts – one of the most relevant sectors for the implementation of the Agenda 2030. With the globally ongoing trend of urbanisation, cities play a major role for more sustainable development. Projections suggest cities will swell at an astonishing pace and it needs to be seen whether that means our salvation or an eco-disaster.It is very obvious that the current trend of planning, constructing and maintaining our cities put even more pressure on the planetary boundaries[5]. Hence, what is needed is a transformational plan on how to achieve "Sustainable cities and communities" in terms of concrete actions.

Fig. 1: SDGs that are strongly connected to SDG 11 Sustainable Cities and Communities selected by BEYOND 2020.

The next version of the World Sustainable Built Environment conference that is entitled BEYOND 2020 will exactly focus on creating clear links between the most relevant UN SDGs and the built environment. Central to our discussion will be achieving UN SDG 11, Sustainable cities and communities by the 2030 deadline but from our perspective, the path towards SDG11 is only possible, if other relevant SDGs are fulfilled (Fig. 1).

Key points to achieve SDG 11 will, e.g.

- How can the building sector contribute towards the creation of Sustainable Cities and Communities (SDG11) of the future?
- What other UN SDGs (see below) should play a role in the pursuit of SDG11 from the built environment perspective?
- How does the role and importance of the UN SDGs (relevant for the built environment differ in various parts of the world?
- What challenges and opportunities result for the building sector from implementing the UN SDGs?

The next edition of the World Sustainable Built Environment conference will work on a transformational plan towards the Agenda 2030. Key elements will be addressed already at the SBE19 in Graz.

FULL PAPER

Transition Towards a Net Zero Carbon Built Environment

Stakeholder related fields of action for process optimization of nearly zero energy and plus energy buildings

Höfler R[1]

r.hoefler@aee.at

Abstract. In order to be able to guarantee a regulated process in the design of nearly zero and plus energy buildings, it is important that all relevant stakeholders are involved from the beginning of the project. This is particularly important because disagreements and lack of communication between the stakeholders often lead to problems, which delay planning and implementation and lead to additional costs. In order to prevent the resulting barriers, it is essential that the previous processes for such an implementation are analysed and the individual steps are optimized to such an extent that a goal-oriented and cost-efficient cooperation is possible. This is focused in the thesis "Stakeholder related fields of action for process optimization of nearly zero energy and plus energy buildings". In this way, an attempt is made to achieve process optimization with the aid of various methods from management consultancy. In order to achieve this, the focus of every construction project, especially nearly zero energy and plus energy buildings, must be on integral planning. The individual action steps must therefore be optimized in such a way that it is clearly defined for all stakeholders when and with which partner to interact.

1. Introduction

As buildings account for almost 40% of total energy consumption and 36% of greenhouse gas emissions in Europe, the European Commission has adopted a directive aimed at reducing the total energy consumption of buildings [1].

By the year 2019, many researchers were already working on the topic of implementing nearly zero energy and plus energy buildings (nZEB and PEB) due to the greenhouse gas emissions already mentioned, which reduce the quality of life. In the various fields of research, the content usually concentrates only on a concrete view of a group of stakeholders. In this way, strategies have only ever been developed from a specific discipline, a specific field of study, in order to be able to successfully implement nZEB and PEB. The focus was often on architectural and technical details [2]. No matter which perspective was used for the research, the different perspectives usually have one aim in common. The necessary solutions for building optimization should be as cost-efficient as possible and have a positive influence on the life cycle of a building.

In addition, energy consumption should be reduced as far as possible in order not to pollute the environment further [3]. For this reason, research in the past concentrated to a large extent on the development of new technical concepts in implementation in order to be able to address these goals as quickly as possible. However, this is made more difficult because the lack of knowledge about new technologies and thus the lack of specialist know-how, the working methods of the commissioned project partners and the decision-makers are limited. Problems arise when life cycle costs are not considered in their entirety, but only the respective costs for individual sub-areas, in the planning and implementation. The main reason for this is that it is unclear to many project participants that up to 40% of operating costs can be saved by using slightly higher construction costs (approx. 2%) [4]. Due to such misjudgements, existing potentials for cost reduction are often used only partially or not at all.

The term Integral Planning, through such misjudgements and problems in the transparency and cooperation of different stakeholders, achieves an important meaning in the planning and implementation of nZEB and PEB. This means the early integration of technical/functional aspects in order to additionally support the planning process. Methodological and technical aspects are an important focus for successful planning and implementation [5]. The core objective here is to highlight the different interests and perspectives of the stakeholders involved in order to optimize building quality as best as possible over the entire life cycle.

Of course, this aim should be pursued for all buildings, regardless of the requirements. However, it is particularly important for nZEBs and PEBs, as this approach is essential for the success of the project.

In order to ensure the quality of buildings, a passive house construction method has been aimed since the beginning of the 21st century and the associated integral planning in the building industry [6].This is due in particular to the far greater scope for influencing the quality of a building at the beginning of a construction project, compared with the constantly changing views of various actors, which must be integrated into the planning. For this reason, it makes sense to involve all participants from the outset in order to be able to represent all opinions in the best possible way and to prevent emerging conflicts in the future. In addition, the more the project progresses, the greater the change effort and costs required.

2. Problem identification and challenges in the implementation of nZEB and PEB

The implementation of projects with a high energy standard is currently often carried out using the same procedures as projects with lower requirements. This is a result of the fact that these processes have been tried and tested. This procedure, however, involves risks, as it is often not considered that the standardized processes cannot offer the best solution for the implementation of nZEB and PEB. Such procedures often generate additional costs in planning and implementation, although the high costs only become apparent very late and countermeasures can therefore only be taken late. For this reason, previous processes should be analysed and their sequence reconsidered in order to achieve the desired standards as quickly and as effectively as possible [7].

Previous projects and works dedicated to these themes usually only refer to parts or individual actors of a design project. This complicates the cooperation of all participants, since the different approaches and focal aspects are often not recognized and for this reason the required cooperation does not work out. It is therefore important to create a decisive overview for all actors involved in the project planning and implementation of nZEB and PEB.

Based on this necessity to implement integral planning, barriers were filtered out using the online survey tool Mentimeter [8] as well as the results of the CRAVEzero project of the research institute AEE INTEC, which complicate the planning and implementation of nearly zero and plus energy buildings. In the survey conducted during the ISAC Conference 2018 in Graz, Austria, 102 stakeholders participated, who, although coming from different professional groups, largely agreed on the influence of individual parameters on the planning and implementation of nZEBs. This is also shown by the research project CRAVEzero. The results of the survey can be seen in the graph below. According to the survey and the CRAVEzero project, the biggest deficits are too high costs [9], a lack of support from politicians, poor communication among themselves and a lack of knowledge about new technologies [10]. In addition, misjudgements are often made in demand planning [9] and no clearly defined minimum target values are given.

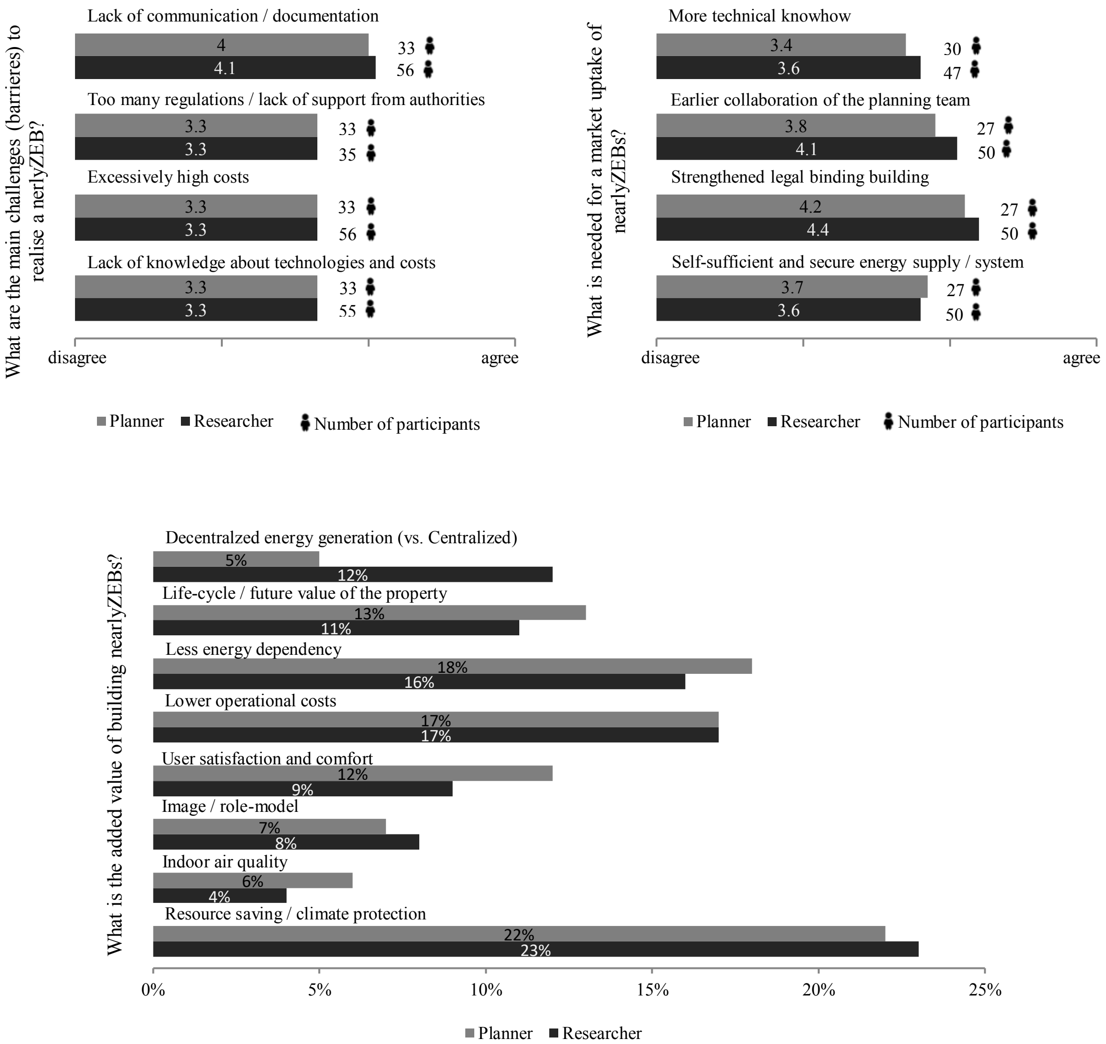

Figure 1. Results of the Mentimeter survey on the challenges, marketability and added value of nZEB and PEB (own illustration)

All these challenges are difficulties for the design and establishment of nZEB and PEB. In order to be able to handle them in the best possible way and thus guarantee error-free and time-efficient work, it is essential to clearly define which stakeholders are primarily responsible for which actions.

3. Methodology

In order to be able to carry out a successful optimisation of individual project processes, in addition to defining the circumstances causing the problems, it must be filtered out which stakeholder is responsible for which action and with which participants should be collaborated and communicated in order to promote constructive work. For this purpose, the filtered actions are divided into different project phases, prioritised and assigned to the stakeholders. In addition, the various dependencies of the actions dealt with are analysed.

By early recognition of interrelations between the individual actions, the actors can react quickly to changes and in the best case achieve a reduction in costs. However, the time savings that can be achieved in this way can also significantly influence the success of a project.

These positive effects are achieved, for example, when the thermal quality is coordinated with the heat output, since the heating system is often over dimensioned and therefore not economically viable. If, however, an early coordination between the responsible actors is aimed at, optimisations can be made in this area. Thus it becomes clear that these two parameters are interrelated and consequently influence each other.

These procedures are usually known in theory, but many of these steps are often circumvented in practice. This causes delays and errors in communication and processes. For this reason, it is necessary to sensitize and subsequently optimize in this respect.

In order to propose a process optimization, various existing optimization methods must be analysed and applied to construction projects. For this purpose, particular attention is paid to Business Process Reengineering, Total Quality Management, Lean Management and Artificial Intelligence since these methods of process optimization promise fast and targeted action with future-oriented solutions.

- Business Process Reengineering (BPR): This method pursues the approach of radically redesigning current business models or completely replacing them [11]. Thus every core process is questioned without considering the existing structures. The goal of this method is to achieve 30% of the four targets: Optimize quality, time, costs and service [12].
  This approach uses four process steps [13]:
  1. Uncover core processes
  2. Locate and identify vulnerabilities
  3. Radical restructuring of existing processes
  4. Adapt corporate structures

  The most important factors for the implementation of such projects are motivated and competent project partners, a systematic approach and clear guidelines to achieve the project goal.

- Total Quality Management (TQM): The aim here is to achieve an increase in processes. The satisfaction and motivation of the players are particularly important. The essential component, which is aimed at with the help of this method, is the increase of the execution quality. In particular, the active and independent action of all actors involved is assumed [14]. This is also made clear by Deming's 14 points on the characterisation of TQM [15]:

  - The will to continuous improvement
  - Creating awareness for quality
  - Preventive quality assurance
  - Check offers and pay attention to total costs
  - Continuous process improvement
  - Modern training methods
  - Cooperative management style
  - Open organization
  - Elimination of organizational barriers
  - Understandable goals and procedures
  - Qualitative target agreements
  - Identification with own activity
  - Continuing education
  - Create action plan

- Lean management: This involves organisational processes that aim to conserve resources and keep costs as low as possible. The focus is particularly on the "value-adding" processes. These are meant to identify waste and value-adding activities in order to save unnecessary processes and promote efficient procedures. The Lean Management method thus offers analysis possibilities for identifying non-value-adding activities and eliminating them [16]. When implementing lean management processes, it is important that all employees are involved in the new concept. The result is a new corporate philosophy that promotes cooperation and communication between all those involved [17]. The following objectives are decisive for the successful application of this method [11]:

- Process-oriented corporate management
- Highest possible efficiency
- Clearly defined processes and procedures
- Clearly distributed responsibilities and logical communication among each other

- Artificial intelligence: The fields of machine learning and artificial intelligence are expanding very rapidly and affect almost all technological aspects of society. One exception is the building sector [18]. Problems occurring in this area frequently require the use of optimization methods that enable the minimization or maximization of certain target functions. However, these problems cannot be solved precisely in most cases. For this reason, an approach is often more effective than a concrete solution to the problem at hand [19].
  This approach is particularly helpful in optimising the building sector. Intelligent systems can reduce the energy consumption of a building. This method is needed in order not to neglect not only energy savings but also the comfort of users [20].

The individual methods have their own character and rarely build on each other. This is because, depending on the method of optimization, there is a different focus on it. In TQM, for example, the focus is on independent action, while Lean Management is designed to promote communication among the participants. A more modern method is artificial intelligence, because it combines many factors, which are mostly considered individually in the planning, and shows how they can influence each other.

4. Results and Discussion

In the course of this research work, individual actions, which have a high priority especially for nearly zero and plus energy buildings, were analysed, assigned to responsible stakeholders and integrated into the already tested and known process flows. In this way, a clarity is created which should help all participants to integrate themselves into the processes. In this way, each participant sees by when which action must be completed and with whom he must contact in order to achieve this goal. This is important, because only together these often occurring problems can be tackled. In this way, the stakeholders involved are able to avoid problems at an early stage or solve them on their own.

These actions lay the foundation for the planning and implementation of nZEBs and PEBs. However, this does not eliminate the problems that have arisen so far. Here the methods for process optimization, which have already been explained in Methodology, are used. By the different approaches of the optimization methods best possible solutions can be found for the respective challenges. This corresponds to a learning process, which certainly takes a lot of time, but the knowledge gained in this way can significantly shape the future for the implementation of nearly zero and plus energy buildings.

5. Conclusion

Although the procedures for planning and implementing nearly zero and plus energy buildings are mostly known, individual steps are often skipped or only taken at a later stage. This has temporal, qualitative as well as financial consequences, since set goals are often delayed or not reached at all. In order to ensure the smooth planning and construction of almost energy free and energy efficient buildings, integral planning is indispensable for these reasons and should therefore be aimed at the very beginning of a project. In this way, initial communication difficulties can be avoided from the outset, as close cooperation already takes place between all parties involved.

t.weiss@aee.at

Abstract. Cost optimal and nearly zero-energy performance levels are principles initiated by the European Union's Energy Performance of Buildings Directive, which was recast in 2010. These will be significant drivers in the construction sector in the next few years because all new buildings in the EU from 2021 onwards have to be nearly zero energy buildings (nZEBs); public buildings need to achieve the standard already by 2019 [1].While nZEBs realised so far have clearly shown that the nearly zero-energy target can be achieved using existing technologies and practices, most experts agree that a broad-scale shift towards nearly zero-energy buildings requires significant adjustments to current building market structures. Cost-effective integration of efficient solution sets and renewable energy systems are the major challenges [2]. The EU Horizon project CRAVEzero focuses on proven and new approaches to reduce the costs of nZEBs at all stages of the life cycle. The primary goal is to identify and eliminate the extra costs for nZEBs related to processes, technologies, building operation and to promote innovative business models considering the cost-effectiveness for all stakeholders in the building's lifecycle. As a result, an international database for benchmarking actual nZEB life cycle costs (LCC) including urban and building planning, construction, commissioning, operation, maintenance, management, end-of-life, has been developed. Furthermore, an operative methodology to achieve the best conditions towards optimal cost nZEBs has been set-up.

1. Stakeholder centred life cycle processes

In addition to legal and urban boundaries, buildings are essentially defined by the client. Owners or investors want to construct or renovate buildings for a specific purpose. Also, the buildings technical quality and the comfort standard have to be achieved within project specific budget limitations. Architects and specialist planners translate the client's ideas and wish into real plans and are responsible for the appropriate execution of the building project. Construction companies and craftsmen from numerous different disciplines are involved in constructing the building. There is a constant coordination process between the client, the planners and the contractors in order to prepare the construction of a building and if necessary, to react to changing conditions like costs, schedules, changed requests from the client, weather, etc [3].

Especially in the planning phase, the choice and combination of building materials and technologies and the execution on the construction site as well as the overall integral planning, construction and operation are of great importance. The range of services provided to buildings in the urban context today has also changed over time and gained new aspects. Nearly zero energy buildings increasingly become active participants of our energy supply infrastructure and raise new challenges concerning the quality of planning, construction and operational phase of a building. This results in new approaches to innovative energy concepts for both the building and districts. Innovations related to the realisation of nZEBs arise in different life cycle phases of buildings and at different points of the value chain in the building industry.

To reduce costs and accelerate processes, and assure the quality of nZEBs the right decisions have to be taken at the ideal time within the overall process.

In order to be able to optimise existing processes, technical qualifications, actions to be taken and roles must be known and tasks and functions of the stakeholders assigned.

The assessment of the process for nZEBs depends strongly on the perspective. Building owners, investors, tenants, the construction industry, providers of energy efficiency solutions and planners have different interests and are involved in different phases in the life cycle of buildings. There is a general lack of understanding, transparency and uniform methods when it comes to the overall process of nZEBs. Which costs and time horizons are significant for different actors and to what extent?

In the life cycle of a building, there are different interests of the actors and derived from this also different perspectives, observation periods and target values. There is the tenant/user, the real estate agent, the building contractor, planner, property manager, investor, owner and also the company which is directly or indirectly involved with the building. As shown in Table 1, these actors are involved in the overall process over a certain period of time. While the tenant is primarily interested in the operational phase, the planner is usually more likely to deal with the building only until its completion. If a property is financed and used by the tenant himself, the entire life cycle up to a change of use is usually of interest. Depending on the approach, this can be between about 25 years after repayment of the bank loan and up to 50 years after increased consideration of the use. For society as a whole, the entire service life of a building, including its demolition and disposal, usually counts.

The period under consideration must, therefore, be determined in advance with the parties involved. For most of the considerations of the entire building, between 25 and 50 years have proven to be reasonable.

Table 1. Stakeholders time expectancy of a project and optimization goals

STAKEHOLDERS	OPTIMIZATION CRITERIA		TIME EXPECTANCY
	Costs	Energy	
Tenant / user	Rental costs, operating costs	Final energy demand	3 – 30 years
Real estate agents	Market price	Energy performance certificate	1 – 2 years
Construction company	Building costs		1 – 5 years (Guarantee)
Planner	Planning costs, building costs	Energy performance certificate	1 years
Property management	Maintenance costs, renovation costs	Final energy demand	1 – 50 years (Contract)
Investor	Investment cost		1 – 5 years
Building owner / landlord	Financing costs	final energy demand	20 - 50 years
Building owner (public)	Net present value	Primary energy, final energy, CO_2	50 – 100 years
Society	Life cycle costs, climate protection	Primary energy, CO_2	> 100 years

In addition to low rental costs, the tenant is also interested in low operating costs and thus in a good energy standard, e.g. so that he has low heating costs. The building contractor is usually anxious to keep his building costs low. In the case of owner-occupied real estate, both cost components are important, the initial investment as well as the running costs. For the company, the total costs and also the effects such as CO_2 emissions are important.

In addition to the optimisation criteria and thus the benefits that can be directly assessed in monetary terms, there are also different benefits and additional benefits for the individual actors, which often cannot be assessed directly in monetary terms and therefore do not appear in the life cycle cost analysis. These benefits and additional benefits are shown in Figure 1. This concerns marketability, rentability, value development, comfort, but also image, climate protection or regional goals such as energy autonomy. Where possible, these benefits and additional benefits should be taken into account in the decision-making process. However, examples exist where increased productivity, higher revenue, reduced employee turnover, reduced absenteeism, etc. have been quantified [4]. Additionally, studies do exist which may be used as a basis for analysing added values.

Studies show that staffs in high quality nZEBs perceive a positive effect of their work environment and productivity [5] [4] [6]. In one case, a 10 000 m2 office building, increased productivity of 0.3 % were reported, equal to 8 €/m2a. Two studies have found reduced absenteeism in green buildings [5]. An American study showed that roughly 20-25 % of 534 tenants/companies reported higher employee morale, easier to recruit employees and more effective client meetings [7]. Additionally, 19 % reported lower employee turnover. In addition to well-being and productivity, higher revenues from rent or sales may be expected. Bleyl et al. reviewed previous studies and concluded that higher rent income might range roughly between 5 % and 20 %. Furthermore, higher market valuations may range from below 10 % to up to 30 %. It should be noted, in relation to nZEBs and productivity and wellbeing, that a recent study pointed out that social factors may have a greater impact, in monetary terms, compared to environmental factors [8].

The value of a positive news article about a specific building or a specific project could also be comparable to advertising costs in the specific source, in which the article is published [9]. One way to discuss the importance to investigate different co-benefits may be to rank them as presented in Figure 1. The classification is a subjective judgement, highlighting the relevance and the difficulty in valuing the co-benefits discussed above.

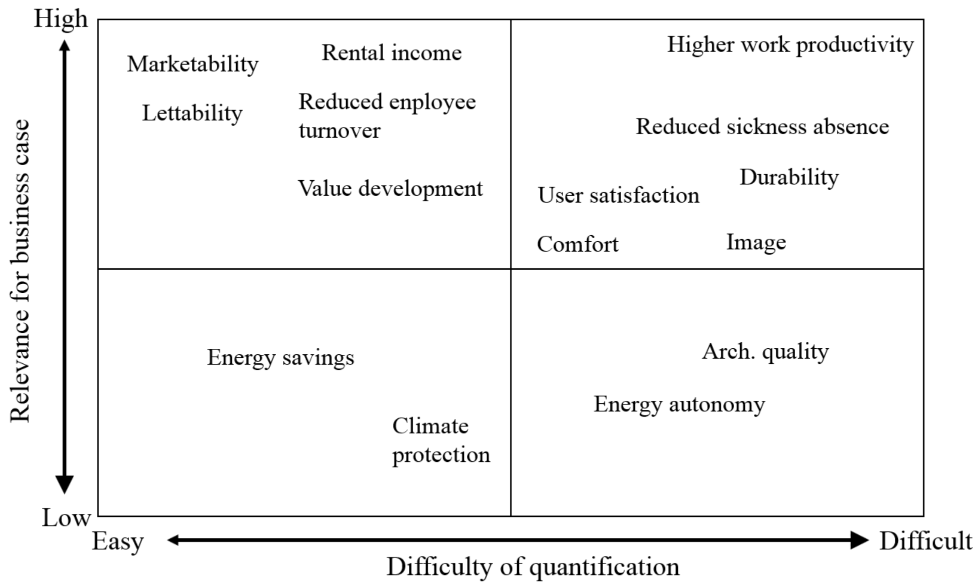

Figure 1. Co-benefits classifications, based on Bleyl et al. [1].

2. nZEB Technologies

For realising nZEBs, which are cost-efficient for all stakeholders throughout their lifecycles, the knowledge about possible cost developments of the most relevant technologies is essential. Furthermore, the identification of currently realised and promising technology sets for the future can help to reduce the cost of nZEBs and accelerate the respective market.

For the deduction of cost reduction potentials, there are in principle two approaches; the Top-down learning curve analysis and the Bottom-up analysis. Compared to the Top-down approach more detailed data and information is needed for the Bottom-up analysis. Therefore, the learning/ experience curve approach was chosen for the deduction of cost reduction potentials for all identified technologies, whereas the Bottom-up analysis was only conducted for three central technologies (PV, solar thermal, electricity storage). The calculation of cost reduction potentials with the experience curve approach is based on market and cost data as well as the determination of learning rates.

Even though the applied methodologies are widespread and established, it has to be mentioned that there are several uncertainties, which can influence the development of costs, especially over a relatively long period until 2050. The calculated market development can vary due to changing requirements or political changes, the actual learning rate can vary, and global commodity prices can fluctuate, which can also lead to price increases instead of decreases.

2.1. Top-down:

The various technologies analysed have different cost reduction potentials. The basis for the deduction of cost reduction potentials are current market and cost levels as well as market forecasts for each technology – if available for whole Europe and in case of limited data available only for Germany.

Established, fossil fuel-based technologies (oil and gas boilers) have the lowest cost reduction potential until 2050 (only about 1% and 9% respectively). A major reason is the comparably high CO_2-emissions, which contradict the climate protection targets of the European Union and will therefore lose market shares leading to only a small increase in the cumulative production volume. A slightly higher market share is predicted for biomass boilers which are more environmentally friendly as they use a renewable fuel. Biomass boilers have a cost reduction potential of approx. 14% until 2050.

Heat pumps are seen as a central heating (and probably cooling) technology in an energy system based on fluctuating renewable energies as they are one important technology for the coupling of the electricity and heating sector. Therefore, a strong market increase is expected to result in cost reductions of more than 20% by 2050.

Ventilation systems (central and decentralised) are of major importance for energy efficient buildings. They supply fresh air, reduce ventilation heat losses when equipped with heat recovery systems and assure good air quality by removing moisture, moulds, pollutants and vapours. Especially in airtight buildings assuring good air quality is almost impossible without mechanical ventilation. The market for ventilation systems will most probably grow in the coming decades leading to cost reductions of around 46% - 52% by 2050.

Thermal and electrical storages become more important in an energy system based on fluctuating renewable energies. Both storage types have substantial cost reduction potentials of about 29% (thermal) and 65% (electrical) by 2050.

With increasing indoor comfort requirements and further global warming, the need for air conditioning/ cooling is increasing leading to a strong market increase and associated cost reduction potentials of about 29% by 2050.

PV is an established renewable energy source with a global market, but still has the potential for optimisation. In all future scenarios with low green-house gas emissions, PV plays a key role in meeting emission targets and generating the required amount of renewable electricity. High cost reduction potentials are expected as fast market development is indispensable until 2050 for the achievement of the climate and emission targets of the Paris Agreement. The estimated cost reduction potential is around 49% by 2050. In addition to the established use on the roof, building-integrated PV (BiPV) is a promising and growing new field.

Solar thermal systems – even though already widespread – still have cost reduction potentials of 38% by 2050. Like for PV systems, there is the possibility to integrate solar thermal systems in the building envelope (e.g. the façade) and replace elements leading to overall lower costs for realising nZEBs.

For the building sector, insulation plays an important role in reducing overall energy demands especially concerning the heating demand in moderate and cold climate regions. However, for established and widespread insulation materials no further cost reduction is expected; cost reductions are only expected for new/ innovative materials and by improved mounting processes.

Besides insulating a building, there are additional passive strategies such as night cooling or natural ventilation, which reduce the end energy demand of a building and become increasingly important for the realisation of nZEBs. However, deriving cost reduction potentials is not possible based on the available data.

The derived cost reduction potentials of the Top-down approach are summarised in Figure 2.

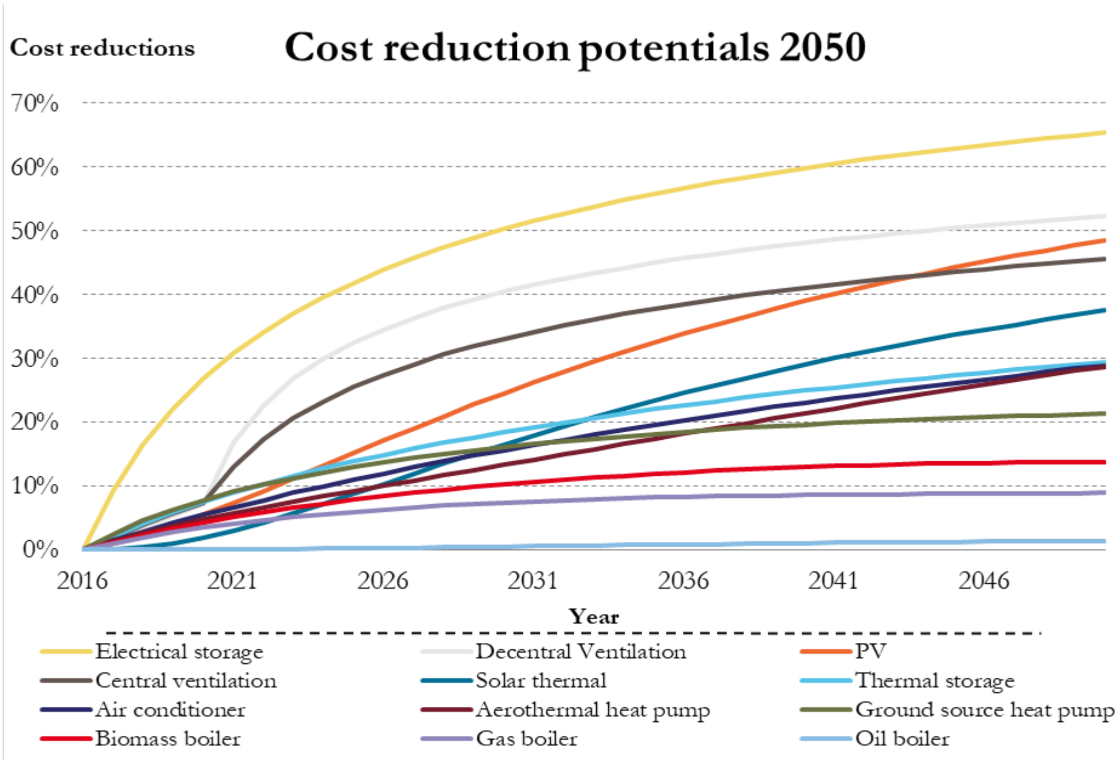

Figure 2. Cost reduction potentials till 2050 of major nZEB technologies calculated with the Top-down learning curve approach.

2.2. *Bottom-up:*

With the Bottom-up approach, specific cost drivers were determined for PV, solar thermal and electrical storages. For PV, cost reductions of up to 57% are estimated in different studies. Increased efficiency and material savings are the main possibilities for future cost reductions.

For solar thermal, the factors identified for possible cost reductions are the amount of material used, material changes, simplification of the system, faster assembly and changes in production methods; efficiency shows no high potential for further optimisation. Until 2030, cost reductions of up to 43% are described. For stationary batteries, the bottom-up analysis show cost reduction potentials of up to 65%. The main drivers are economy of scale and technological improvements such as an increased energy density, material savings and use of cheaper material.

Environmental pressure and policies on energy-efficient buildings with lower greenhouse gas emissions are probably the main reasons for the focus and increase in local renewable energy and energy-saving technologies powered by electricity instead of fossil fuels. The building sector plays an important role in reducing total greenhouse gas emissions and is currently still responsible for 32% of the world's final energy demand. Today, the energy supply is mainly based on fossil fuels causing CO2-emissions. Market demand for efficient and renewable technologies is a key factor for realising cost reduction potentials. The EPBD is thus an important factor in boosting the market for technologies like solar thermal, heat pumps, thermal insulation, PV and storages.

3. Life Cycle Cost Analysis

In the CRAVEzero project twelve case studies all over Europe, as can be seen in Figure 3 have been evaluated. The ISO 15686-5 [10] provides the main principles and features of an LCC calculation, while the European Code of Measurement one describes an EU-harmonised structure for the breakdown of the building elements, services, and processes, in order to enable a comprehensive evaluation of the building life costs.

The tool PHPP [11] has been used for the energy performance analysis. This tool summarises all the information dealing with the energy-related features of the building components and services and provides a comprehensive overview of the technologies installed.

Figure 3. CRAVEzero case studies

3.1. Life Cycle cost calculation

According to the ISO 15686-5:2008, the LCC of a building is the Net Present Value (NPV), that is the sum of the discounted costs, revenue streams, and value during the phases of the selected period of the life cycle.
Accordingly, the NPV is calculated as follows:

$X_{NPV} = \sum_{n=1}^{p} \frac{C_n}{(1+d)^n}$	C: cost occurred in year n; d: expected real discount rate per annum (assumed as 1.51%); n: number of years between the base date and the occurrence of the cost; p: period of analysis (40 years).

The analysis within CRAVEzero is based on standard values from EN 15459:2018 that provides yearly maintenance costs for each element, including operation, repair, and service, as a percentage of the initial construction cost. For the passive building elements, an average yearly value accounting for 1.5% of the construction cost has been assumed for the evaluation. The value has been cross-checked with average values coming from the experience of the industry partners.
The analysed case studies are located in different European countries, i.e. Austria, Germany, France, Italy, and Sweden, with specific characteristics in terms of climate conditions, construction, and energy market. Therefore, in order to compare the results of the case studies and to draw a general overview of the costs of the current nZEB practices, a normalization of the collected data is needed. In particular, the construction costs have been normalised considering the data from the ECC (European Construction Costs) that calculated a European construction cost index that quantifies the ratio among the construction costs of EU countries. For the climate conditions, the normalisation has been carried out considering the Heating Degree Days of the building locations. Concerning the energy
process, a common value has been adopted, accounting for 0,160 €/kWh of final energy consumed.

3.2. Presentation of the results – case studies comparative analysis

The second part reports an overview of the results, with the comparison of relevant indicators, costs, and performances among the case studies considering the effect of local specificities, different context and use of the buildings (i.e. normalised results).
Figure 4 shows an overview of the average impact of all the phases on the LCC, the investment costs for design, material labor and other initial expenditures is around 60% of the LCC, while the energy and maintenance account for around 40%.
As it was expected, the energy costs during the life cycle of a nZEB represent a minor contribution to the LCC, with an average of around 15%. Figure 5 shows the absolute values in €/m^2 of the LCC. It is important to point out that the contribution from the renewable energy systems like PV is accounted as a reduction of the energy cost of the overall life cycle (calculated as a balance between energy consumed

and produced). In case of "Greenhome", the energy costs reported in the chart assumes a negative value, since the energy produced is higher than the energy consumed, considering the large PV field installed.

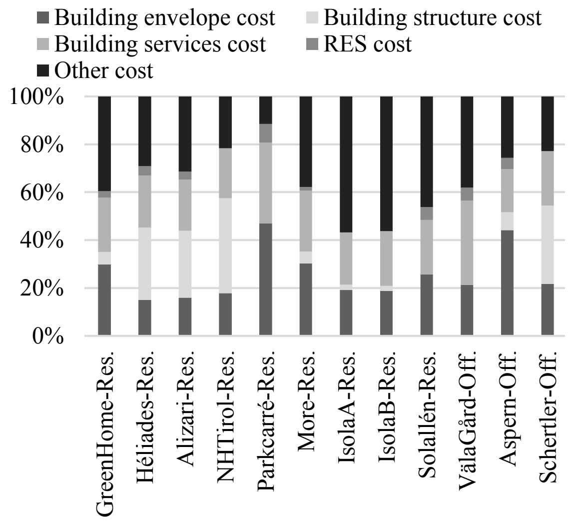

Figure 4. Construction cost breakdown

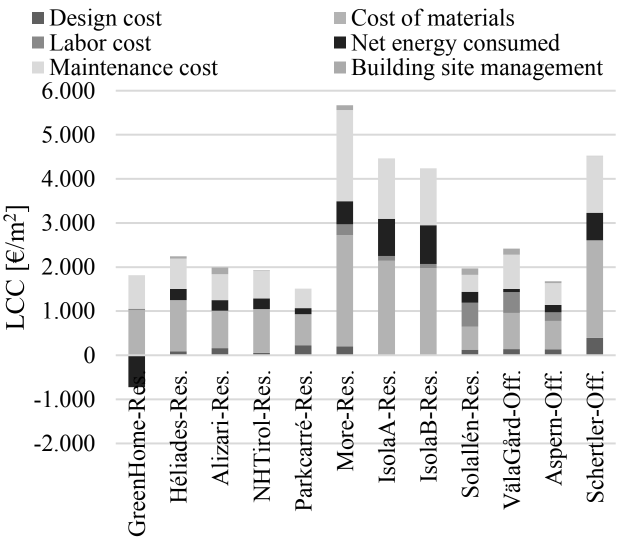

Figure 5. Life-cycle cost breakdown – normalized values.

Figure 4 reports the breakdown of the cost for the building elements, highlighting the impact on the construction costs. It shows that in some cases the structural elements represent a significant contribution to the construction, according to the complexity and the dimension of the building. On the other hand, nZEB related technologies have a small impact on the construction costs, although in comparison to a traditional building the cost for the HVAC system and the integration of renewables is more significant.

4. Multi- objective energy and life cycle costs analysis

The identification of suitable methods for the energetic-economic optimisation of highly efficient buildings in all life-cycle phases is a prerequisite for the broad market implementation.

As we have seen in the energetic-economic optimisation of buildings, there are different interests of the actors and, derived from this, different perspectives, time expectancies and goals. The term "multi-objective parametric analysis" in this report defines a method in which series of calculations are run by a computer program, systematically changing the value of parameters associated to one or more design variables. The key feature of this approach is that it allows evaluating the effect of individual design variables on energy, costs and environmental parameters in one step.

The multi-objective approach is based on the concept of Pareto frontier: a solution is optimal when no other feasible solution improves one of the objectives without affecting at least one of the other. In that case the multi-objective algorithms generate a set of solutions, known as the Pareto front. If the problem includes only two objectives, the Pareto front is a two-dimensional curve. This concept can also be applied to three or more objectives, although the results are more difficult to analyse. It is also important to note that this approach, rather than finding a single optimal solution, seeks to explore a set of optimal solutions and evaluate various trade-offs among them [12].

This approach was prototypically implemented in the case study Solallén based on the already gathered lcc data shown in the previous chapter. According to the defined general parameters in the previous chapter a set of ten different parameters with three to four levels are defined. The parameters consist of passive actions (Insulation standard, air-tightness, window U-values), active actions (ventilation-, PV-, heating-, cooling- and solar thermal system), user behaviour and economic sensitivities.

The analysis is performed for each parameter individually and in combination.
In total more than 31,000 different variants of different nZEB technology solution sets were calculated.
Figure 6 shows the overall results of the case study Solallén. In Figure 6 the financing costs of all investigated parameters are shown in relation to the balanced CO_2 emissions.
Figure 6 allows following short analysis:

- The financing costs range between 2100 Euro/m² and 2500 Euro/m². This is a range of ~ 20%.

- The balanced CO_2 emissions range between 14 kg/m²a and 52 kg/m²a. This is a range of ~70%.

Furthermore the analysis shows that similar financing costs can be achieved by the variants leftmost in the diagram and the variants rightmost. With these similar financing costs the balanced CO_2 emission can be reduced by nearly 70%.

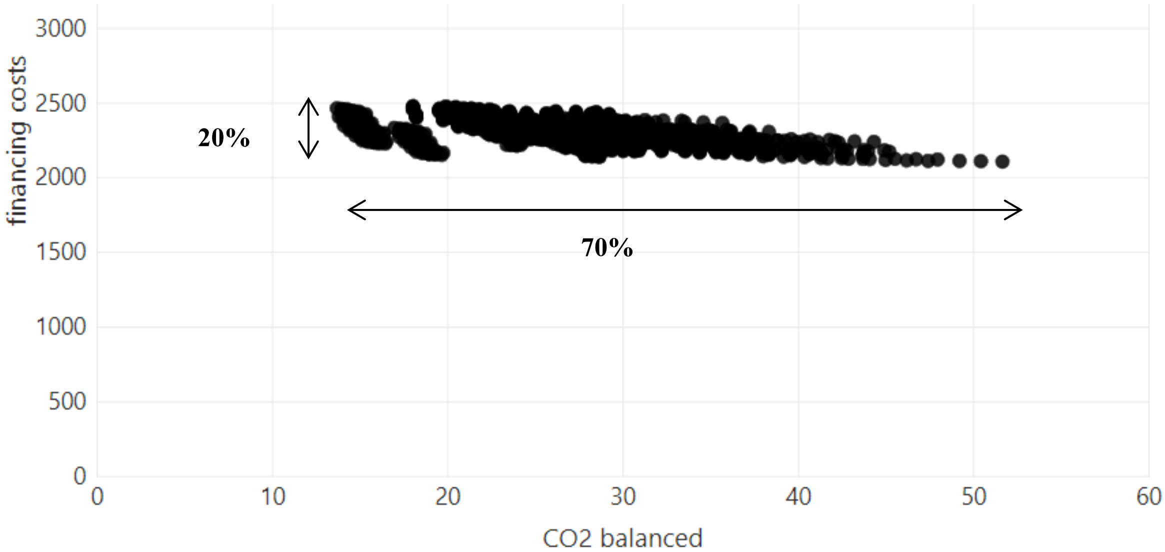

Figure 6. financing costs in relation to the balanced CO_2 emissions of all variants of the case study Solallén (related to treated floor area of the PHPP / CO_2 factors PHI/ without consideration of subsidies / no CO_2 credit for electricity fed into the grid)

5. Summary

On the basis of the results, the statement is confirmed: nZEBs are economical. It can now be shown that the additional costs of efficiency measures are so low that highly efficient buildings have the lowest life-cycle costs.

- In nZEBs, low energy demand is achieved through insulation and passive strategies is essential in order to be able to provide the remaining energy demand for the building operation (heating, cooling, ventilation, domestic hot water, and lighting) with onsite renewable energy.
- nZEB measures only have a small percentage influence on construction costs, but can reduce CO_2 emissions many times over.
- The energy standard has a small influence on the building and construction costs. Energy efficiency is therefore not a major cost driver in construction.
- The additional construction costs of nZEBs are compensated in the life-cycle of most technologies even without subsidies.
- The cost optimum of primary energy demand and CO_2 emissions is in the range of nearly zero and passive houses. Highly insulated envelopes and highly efficient windows are usually economical even without subsidies. This is also due to the long service life of these components in comparison to HVAC systems.
- The cost optimum curve in relation to CO_2 emissions is very flat. Low emissions and energy requirements can therefore be achieved with different energy concepts as long as the envelope is very efficient. This means architectural and conceptual freedom.
- The cost reduction potentials for nZEB technologies until 2050 vary from approx. 1% to 65%. Stationary batteries have the highest potential with 65%, followed by decentralised ventilation, PV, centralised ventilation with 52%, 49%, 46% and 38% respectively. Oil and gas boilers have the lowest potential of less than 10%.
- In many cases the return of investment in energy efficiency measures to reach the nZEB target is around 25-40 years, if calculated only in terms of energy cost saving. Nevertheless, as assessed by Berggren, Wallb, and Togeröc [13] the cost-effectiveness of nZEB construction becomes more apparent if the co-benefits and revenues are included in the analysis.

Abstract. The decision on constructing or renovating buildings is often based on construction costs; consequently, follow-up costs are not considered. *Life-cycle cost analysis* is a common method for assessing the economic viability of buildings over their entire life-cycle. In this project, life-cycle costs of a minimally invasive refurbishment with component activation are compared with those of a standard refurbishment approach with an external thermal insulation composite system (ETICS) and radiators. Although the follow-up costs approximate the life-cycle costs after a period of 50 years in this analysis, the additional erection costs of the minimally invasive refurbishment approach cannot be compensated. In order for the system to become economically competitive, the erection costs regarding the façade system and the associated building technology must be reduced by 36 %, assuming that the nominal follow-up costs remain the same. Since the current implementation is still a prototypical one, cost-saving potential is expected on basis of the experience of the executing companies. However, in addition to the economic efficiency, the non-monetary added value of the system in the form of a more homogeneous heat output, more ecological building materials, less stress for the inhabitants due to the minimally invasive approach, reduced use of floor space and increased sound insulation due to the sound insulation façade, should also be taken into account in the decision-making process.

1. Introduction

Due to the climate policy in the European Union and consequently in Austria, the energetic renovation of buildings is becoming more and more important. According to Statistics Austria, an average of 21252 new buildings were built each year between 2011 and 2017 [1]. In addition, 49.5 % of the existing buildings in Austria and 43.4 % in Salzburg were constructed between 1945 and 1980 (as of 2011) [2]. The age structure of these buildings will cause various problems and challenges in the near future. The object of investigation, an apartment building with twelve apartments, can be assigned to the early post-war architecture of the 1950s. The challenges and problems which need to be overcome concern the energy standard of the building envelope, building technology, sound insulation and the comfort of the occupants of the buildings. A thorough examination of the existing building stock will therefore be indispensable. The analyzed object is characterized by a lack of thermal insulation and the windows were last replaced in 1993 and require renovation. This is accompanied by high transmission heat losses and thus a high heating energy demand of 241.6 kWh/m²a (according to the energy performance certificate) in the existing building. Moreover, the heat supply system of the considered object is heterogeneous. Seven apartments are equipped with individual stove heating and five apartments are connected to the district heating grid. The refurbishment is currently in progress, but has not yet been completed.

The erection costs as well as the follow-up costs associated with such renovations vary over the entire life-cycle of a building depending on the chosen construction method, components and technologies. In most cases, the choice as to which components and construction method to use takes place without considering the follow-up costs and the decision is made solely on the basis of the investment or erection costs [3]. The refurbishment measures for this object are carried out in the course of a research project focusing primarily on a novel façade technology. A minimally invasive multifunctional façade is being tested, which combines thermal insulation, sound insulation, heat dissipation and façade cladding in prefabricated wooden elements. This contribution wants to compare the life-cycle costs of a minimally invasive refurbishment with those of a standard refurbishment (see description of the approaches in chapters 4.1 and 4.2), in which the refurbishment costs are kept as low as possible.

2. Objectives

Life-cycle costing is a widely used method for assessing the economics of a whole building or individual components over its entire life-cycle. Accordingly, the literature on life-cycle cost analysis (LCCA) in general is extensive, but there are only a few detailed studies on the analysis of facade systems. Floegl and Ipser [4], for example, examine the life-cycle costs of six different residential complexes of different construction years and sizes. Höfler and Kunesch [3], on the other hand, compare the life-cycle costs of different refurbishment concepts in the course of the e80^3 project. Furthermore, a facade module and a building services module have been developed and implemented in a demonstration building. One of the objectives was the prefabrication of energy-efficient elements. The present research project differs from the described system as it integrates the heating system within the façade in the form of a component activation, as well as the installation of wood cement panels as sound absorbing elements. Schmidt et al. [5] have developed and tested an external component activation in the course of the research project "LEXU" and "LEXU II". In this case, the system was combined with an external thermal insulation composite system. Höfler et al. [6] have investigated prefabricated systems for the refurbishment of residential buildings in the course of the IEA ECBCS Annex 50 and developed prefabricated modules with a focus on thermal refurbishment for a demonstration object in Graz-Dieselweg. A life-cycle cost analysis has not been carried out for the latter two projects. At the moment, the available data for a detailed LCCA is insufficient; therefore, the basis for this contribution is a rough estimate of the costs of the refurbishment method currently being carried out with a prefabricated multifunctional façade and component activation on the basis of an apartment building in Hallein, Salzburg. The chosen renovation method represents a prototype and is planned to be applied to other buildings with similar characteristics. The life-cycle costs are calculated on the basis of the tool Lekoecos, which in turn is based on the corresponding standards ÖNORM B 1801-1 [7] for the calculation of the erection costs and ÖNORM B 1801-2 [8] for the calculation of the follow-up costs. The applied calculation method uses the present values of the follow-up costs for the selected period of 50 years. The costs for the minimal invasive refurbishment are to be compared with those of a conventional renovation with a similar energetic standard.

3. Research process

In this chapter, basic data for the calculation of the life-cycle costs as well as the boundaries of the treated costs are expounded.

3.1. *Basic data*

The considered life-cycle costs are based on data about the minimally invasive refurbishment still under construction as well as the estimation of the renovation costs of a standard approach. Based on the current data situation, the estimated costs are thus made up in part of actual costs, obtained offers and estimated costs. The following documents are available for the calculation and input:

- as-built and execution plans (architecture and building technology)
- energy performance certificates (stock and renovation)
- simulation of heating demand
- invoices of measures already carried out including redensification by adding a story in solid wood construction, multifunctional façade, building technology of the minimally invasive refurbishment, renovation of the existing bathrooms and planning services
- offers and estimates of the work still to be carried out and the standard refurbishment including façade cladding of the added story, roofer and plumber, electrician, dry construction, outside facilities, measurement and control technology, external thermal insulation composite system (ETICS), building technology of the standard refurbishment

The calculation parameters are based on the tool LEKOECOS of the Danube University Krems in beta version 1.3. The input of the object parameters refers to the execution and as-built plans as well as the energy certificate. In addition, the respective invoices, if available, are used to determine the construction costs. With regard to the minimally invasive refurbishment, the existing offers serve as a basis for the input of construction measures that have not yet been carried out. If there is neither an invoice nor an offer, a cost estimate based on the ÖNORM B 1801-1 [7] is made. The calculation of the erection costs for the standard refurbishment is also done on the basis of existing offers as well as cost estimates based on the ÖNORM B 1801-1 [7]. The heating energy demand results predominantly from the simulation of the two divergent heating- as well as construction variants. Furthermore, the heat losses of the heating system are obtained from the respective energy performance certificate, since only the simulation of a part of the building and the building technology system is carried out. The energy required for hot water preparation is similarly obtained from the energy certificate. Any energy gains from the photovoltaic system are not taken into account. The assessed costs per kWh for heat supply correspond to the costs actually charged. The operational life spans for calculating the usage costs of technical building systems were obtained from the VDI 2067-1 [9], and the operational life spans of the building components originate from the Federal Ministry of the Interior, Building and Community Germany [10].

3.2. Boundaries

The ÖNORM B 1801-4 [11] divides life-cycle costs into erection costs and follow-up costs, the latter in turn includes usage costs as well as object removal and demolition costs. The following economic efficiency comparison is drawn for selected cost groups on the basis of LCC (Figure 1). In this project, the erection costs thereby include those cost groups according to ÖNORM B 1801-1 [7] that are actually generated during the renovation process, namely costs for the building shell (E2), building technology (E3), building extension (E4), outside facilities (E6), planning services (E7) and reserves (E9). In addition, standard refurbishment costs for incidental expenses (E8) are taken into account, since it is assumed that the occupants must be resettled during the renovation. Therefore, this cost group includes the loss of rent during the renovation as well as one-off relocation expenses. Because of the observation of two façade systems and the associated heat release systems, the follow-up costs are limited to the relevant usage costs of the cost groups technical building operation (F2), supply and disposal (F3), cleaning and maintenance (F4) as well as overhaul and modification (F7). Owing to the current data situation, costs for object removal and demolition (F9) are not considered. In addition, according to Höfler and Kunesch [3], when a dynamic calculation method is applied, object removal and demolition costs lose much of their significance when observed for longer periods of time.

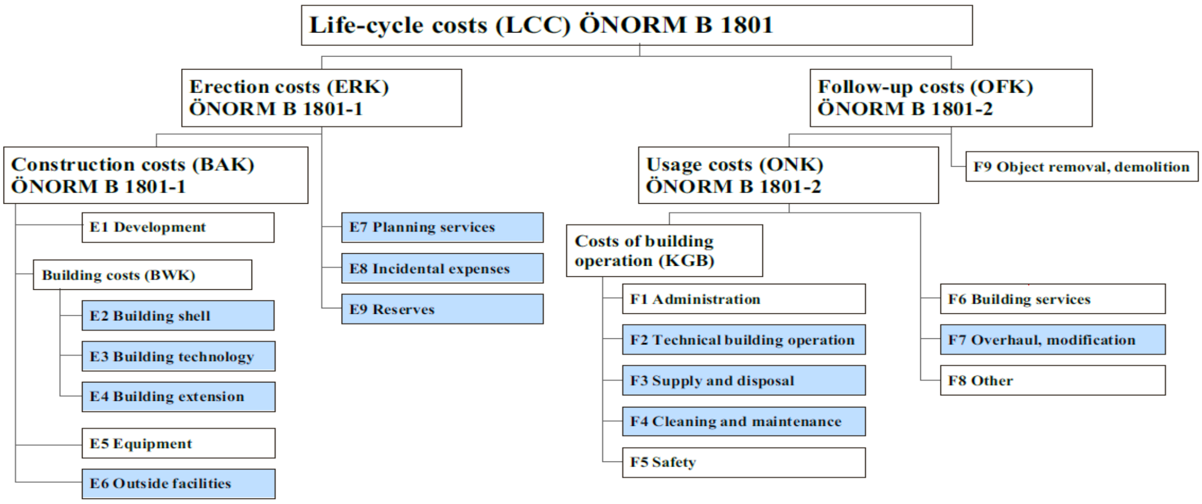

Figure 1. Selected cost groups of the considered life-cycle costs according to the ÖNORM B 1801.

4. Life-cycle analysis

In this chapter, a description of the considered renovation variants is given. In principle, the costs of the entire renovation are included in the consideration of the life-cycle costs, whereas differences between the two variants only affect parts of individual cost groups. The basis for the two renovation variants is an apartment building in solid brick construction, which contained twelve apartments before the renovation. In the course of the refurbishment, the building gets extended and seven apartments are added, resulting in a total of 19 apartments after the refurbishment. The differences between the two variants are limited to the chosen façade and heating system. The two variants share the following measurements regarding to the construction costs:

- redensification by adding a story in solid wood construction
- roofer and plumber
- electrician
- renovation of the existing bathrooms and planning services
- installation of a photovoltaic system
- installation of home transfer stations in each apartment
- outside facilities
- district heating connection
- dry construction

Below, the differences between the two variants are explained and the considered construction systems (Table 1) and technologies are described.

Table 1. Comparison of the selected variants.

	Minimal invasive refurbishment	Standard refurbishment
Component structure		U-Value	0,182 W/m²K	0,182 W/m²K
Thickness	81,5-84,5 cm	64,5 cm
Heat dissipation	Component activation	Radiator

4.1. *Minimally invasive refurbishment*

The exterior walls of the existing building are constructed as externally and internally plastered standard format brick walls. The so-called *multifunctional façade* comprises a thermally activated mortar layer (8 cm), in which the heating coils for the external component activation are positioned, a composite wood panel (6 cm), cavity insulation using cellulose (18 cm), and all-over MDF-cladding (1.5 cm). Externally, there are both a ventilation level (3 cm) and sound-absorbing wood cement panels (5-8 cm). A schematic structure of the actual wall structure can be seen in Table 1. This wall structure reaches a U-value of 0.182 W/m²K.

The façade elements, i.e. the composite wood panels, the cellulose insulation and the planking, are prefabricated and displaced as floor-to-ceiling elements. The resulting space between the existing masonry and the prefabricated façade element is filled with injection mortar after the installation. This layer contains the heating coils for the component activation. The distance between the coils is usually 20-25 cm. These are multi-layer composite coils with an outer diameter of 20 mm and a material thickness of 2.25 mm, and are attached to the existing wall before the façade modules get displaced.

4.2. Standard refurbishment

In order for the standard refurbishment to be compared to the minimally invasive refurbishment, a wall structure is chosen that has a similar U-value to that of the minimally invasive refurbishment. Thus, the external thermal insulation composite system, which is often used in renovation procedures, represents the standard refurbishment. This variant comprises a façade insulation consisting of expanded polystyrene (20 cm) and reinforced synthetic resin plaster (1 cm) attached to the existing wall. The wall structure described above obtains a U-value of 0.182 W/m²K. A schematic structure of the standard refurbishment can be seen in Table 1.

In minimally invasive refurbishment, the building is heated via the façade, whereas in standard refurbishment heating is provided by radiators. The additional costs for the standard system cover the installation of the surface-mounted heating pipes and the radiators as well as the corresponding material costs. Since risers and transfer stations in the individual residential units are installed as part of the bathroom refurbishment, additional costs in standard refurbishment have to be taken into account only for the distribution pipes within the apartments, as opposed to the minimally invasive refurbishment, where additional distribution pipes need to be installed starting from the distribution stations in the basement.

4.3. Comparison of life-cycle costs

The results of the minimally invasive refurbishment are now compared with those of the standard refurbishment. Therefore, the life-cycle costs of selected cost groups are displayed in the following figures.

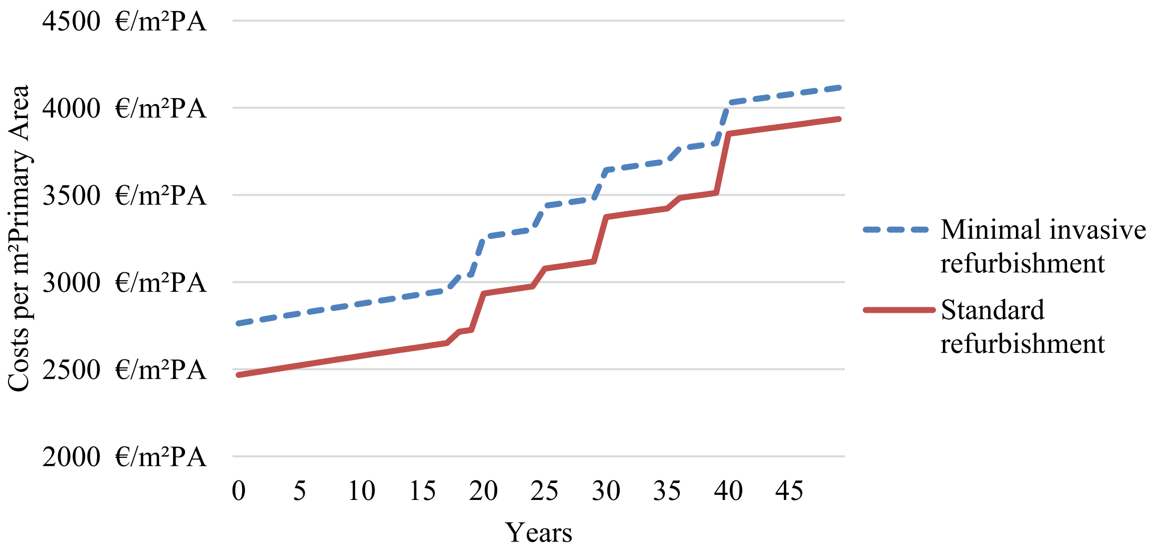

Figure 2. Trend of the life-cycle costs of selected cost groups over a period of 50 years.

Figure 2 shows that the minimally invasive refurbishment is more expensive as far as construction costs are concerned, but not regarding usage costs. Yet the benefits as a result of the lower usage costs over the considered 50-year period are not sufficient to offset the higher construction costs. In principle, three major rises can be observed in the course of life-cycle costs. First, the rise in usage costs after 20 years due to required renewals of some building technology components. Second, after 30 years it is assumed that it will be necessary to replace windows. The standard refurbishment involves higher costs, since a renewal of the heat release system is included. Third, after 40 years, the investment once again mainly relates to the renewal of some components of the building technology. The refurbishment of the thermal insulation composite system is taken in standard refurbishment, too. This results in a discrepancy in the rise of the two systems regarding usage costs.

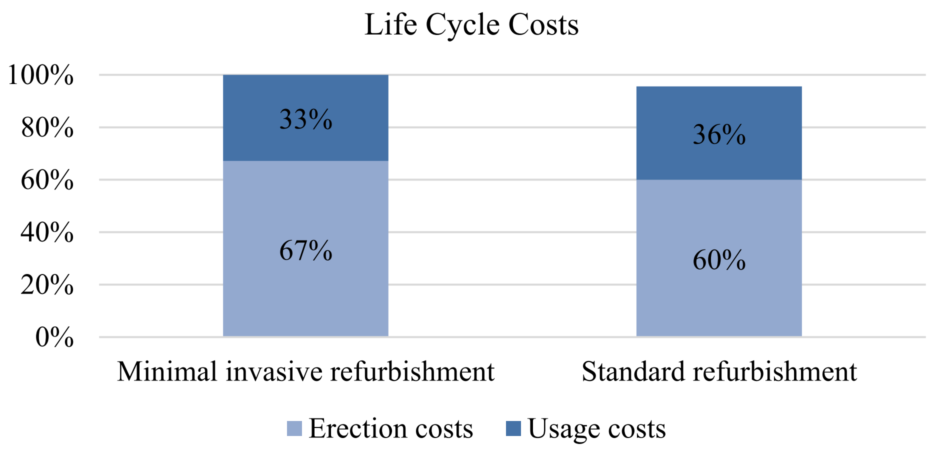

Figure 3. Life-cycle-costs in percent based on the minimally invasive refurbishment.

As can be seen by the ratio of construction costs and usage costs in Figure 3, usage costs of the minimally invasive refurbishment are 3 % lower and construction costs 7 % higher than in standard refurbishment. These differences relate to the cost groups technical building operation (F2), supply and disposal (F3) and overhaul, modification (F7). Standard refurbishment only bears lower costs in the cost group supply and disposal (F3), since the minimally invasive refurbishment entails higher heat losses due to the positioning of the building component activation on the outside of the existing wall. With regard to the erection costs, the costs of the minimally invasive refurbishment in the cost groups building technology (E3) and building extension (E4) are 2 % and 7 % respectively above those of the standard refurbishment. Standard refurbishment in turn includes additional costs of 2 % regarding incidental expenses (cost group E8). This results in the aforementioned difference of 7 %. Overall, the lower costs of standard refurbishment thus amount to 4 % in comparison to the minimally invasive refurbishment.

5. Conclusion

The results of the life-cycle cost analysis, excluding the cost group of object removal and demolition (F9), show that the additional costs of the minimally invasive refurbishment concerning construction costs cannot be compensated by the incurred additional costs of standard refurbishment due to the relocation of the tenants and the associated rent loss. Although usage costs of standard refurbishment with regard to the thermal insulation composite system and the heat dissipation system are now somewhat higher, mainly due to the shorter operational life spans, at the end of the considered 50-year period a difference in life-cycle costs of 4 % remains. In order for the multifunctional façade and the building service system to be economically competitive with a standard refurbishment as described, cost savings regarding construction costs are required. If the construction costs of the façade and the associated building services system could be reduced by 36 %, the difference of 4% in life-cycle costs of the two variants could be compensated, assuming that the nominal follow-up costs remain the same. The calculation of follow-up costs in Lekoecos is in some cost groups based on a percentage of the construction costs. This results in the problem that the advantage of high-quality, innovative components and systems leading to lower follow-up costs cannot be expressed [12].

In addition, it is important to consider the added value of the system, which cannot be monetized. It includes the reduced burden on the tenants due to the minimally invasive refurbishment. The minimally invasive refurbishment approach allows residents to remain in the building during conversion work. This is based on the demands of the building operator (the city of Hallein) and the tenants, surveyed during the stocktaking analysis of the project area [13]. The heat dissipation through component activation instead of isolated radiators and the reduced use of floor space due to the piping on the outside add another aspect. The installation of sound absorbing wood-cement panels has the potential to reduce noise levels in open spaces throughout the district, getting more effective by the number of surrounding buildings reconstructed with absorbing elements. The sound behavior was examined in detail and a potential sound level reduction of 1 to 3 dB was determined [14]. The use of wood-based materials and good decomposability make the variant more sustainable and ecological compared to a thermal insulation composite system. All these added values cannot be taken into account in a purely monetary valuation and analysis.

The life-cycle cost analysis did not take into account any advantages in terms of subsidies.

6. Outlook

Due to the fact that this system still is in a prototypical state, a future optimization and cost reduction is quite foreseeable. It is difficult to estimate the extent of possible cost reductions, but savings can basically be achieved by optimizing both the building service system and the construction of the façade. In the course of the research project, further optimizations of the multifunctional façade will be tested in a similar building, starting in autumn 2019.

7. Acknowledgments

The results presented here originate from the ongoing research project "Wohnen findet Stadt - Hallein DEMO" funded by the Climate and Energy Fund under the direction of the Federal Ministry for Transport, Innovation and Technology (BMVIT). We would like to thank the entire project team and all the contractors for their outstanding cooperation.

Abstract. The 2010 Energy Performance of Buildings Directive (EPBD recast) [1] established that all new buildings have to reach, by the end of 2020, the nearly-Zero Energy (nZEB) target as set by the Member States. In order to achieve the nZEB standards, while keeping investments sustainable, it is strategic to focus more on the operational phase and to guide the decision-support with a lifetime perspective. In this regard, a crucial step is to adopt a shared methodology for evaluating the Life-Cycle Cost (LCC), in order to minimize the effect of uncertainties, the impact of calculation approach and the variability of the boundaries at EU level. The H2020 CRAVEzero project developed a LCC spreadsheet, aimed at calculating a set of relevant indicators for assessing the cost during the investment phase (design, labour and material costs) as well as during the operational phase of a building (energy and maintenance costs). The LCC spreadsheet implements an approach for normalising the results according to the main relevant boundaries that can affect the comparability at EU level (e.g. energy prices, the national construction costs, the climatic conditions, etc.). Moreover, it introduces a sensitivity analysis that aims to provide the impact that the boundary conditions can have on the results, reducing the uncertainties in the LCC calculations due to a long-term perspective (*http://www.cravezero.eu/lcc spreadsheet/)*. This paper presents the structure of the LCC calculation approach defined within the project, the structure of the spreadsheet and the main indicators as evaluated for a set of relevant nZEB case studies across Europe.

1. Introduction

Despite the EPBD 2020/31/EU [1] that established the nearly Zero Energy Buildings (nZEB) target for all the new buildings by 2020, there are still many barriers affecting the update process of the construction markets towards nZEB. In fact, even though the MS established minimum nZEB requirements according to the cost-optimal principles indicated by the EPBD, the extra-cost of investment for nZEB technologies is rarely accepted by stakeholders. This is mainly because the investor usually adopts a reduced time-horizon for evaluating the cost-optimality of an investment, and this strongly affects the building design and the reachable targets, as stated in [2].

H2020 CRAVEzero project aims at changing the approach, identifying the costs of nZEBs in a life cycle perspective in order to propose solutions for cost optimisation or cost shifting.

In this regard, a structured methodology for assessing building Life Cycle Cost (LCC), with benchmarks, exemplary cases and standard values is needed. This paper presents the results of the work carried out within the CRAVEzero "Cost Reduction and market Acceleration for Viable nZEBs" as a starting point for developing a structured and EU-wide approach for LCC evaluations, including data collection templates, references and standard costs to be adopted for preliminary evaluations.

The approach has been traduced in the so-called "CRAVEzero nZEB spreadsheet" implementing a comprehensive and structured methodology to evaluate the LCC, which was used for analysing a set of 12 exemplary nZEBs representing current best practices across Europe.

The paper also presents an overview of the results, including the comparison of relevant costs and performance indicators among the case studies and a differential Sensitivity Analysis (SA), aimed at identifying the main boundaries and inputs affecting the LCC of a building.

2. Case studies and data collection

The first step of the analysis is to set-up the framework for the data collection. Following a series of workshops and feedback loops with project partners and potential stakeholders, we developed a reference template structured in three main parts:

1. General project information: it includes the main information of a case study (i.e. building features, context, principles for the business model),
2. Non-construction costs: it deals with the enabling and preliminary costs for the building construction,
3. Life-Cycle Costs: it reports all the costs for building elements and services from the design phase until the construction and operation, including maintenance and energy costs.

The data collection template is structured according to the approach provided by two primary sources: the Standard ISO 15686-5 (Buildings and constructed assets - Service life planning - Part 5: Life-cycle costing) [2]; providing the main principles and features of an LCC calculation and the European Code of Measurements [3], defining an EU-harmonised structure for the breakdown of the building elements, services, and processes, in order to enable a comprehensive evaluation of the LCC.

The defined approach has been implemented for the analysis of the 12 exemplary case studies, representative of the best nZEB practices across Europe (Table 1).

Table 1. Case studies main features.

Case study	Location	Year	Typology	NFA [m^2]
Green Home	Nanterre (France)	2016	Residential	9267
Les Héliades	Angers (France)	2015	Residential	4590
Résidence Alizari	Malaunay (France)	2015	Residential	2776
NH - Tirol	Innsbruck (Austria)	2008/2009	Residential	44959
Parkcarré	Eggenstein (Germany)	2014	Residential	1109
More	Lodi (Italy)	2014	Residential	128
Isola Nel Verde A	Milan (Italy)	2012	Residential	1409
Isola Nel Verde B	Milan (Italy)	2012	Residential	1745
Solallén	Växjö (Sweden)	2015	Residential	1778
Väla Gård	Helsingborg (Sweden)	2012	Office	1670
Aspern	Vienna (Austria)	2012	Office	8817
I.+R. Schertler	Lauterach (Austria)	2011/2013	Office	2759

The following sections present an overview of the methodology for the case study analysis and the main results from the application.

3. Methodology for calculating Life Cycle Cost

The ISO 15686-5:2008 standard provides a structured methodology for calculating LCC of buildings, setting the general principles, phases, and assumptions of the evaluation. It defines two main indices:

1. The Life Cycle Cost (LCC), focused on design, construction, and operation phase
2. The Whole-Life Cost (WLC) including the initial non-construction costs for enabling the building.

Table 2 shows the phases and contributions to be included in the analysis of LCC and WLC

Table 2. Phases and costs in WLC and LCC

			Life cycle processes	**Included costs**
WLC			1. Political decision and urban design phase	Non-construction cost (cost of land, fees and enabling costs, externalities)
	LCC	**Initial Investment**	2. Building design phase	Building design costs
			3. Construction phase	Construction and building site management costs
			4. Operation phase	Energy and ordinary maintenance costs
			5. Renovation phase	Repair and renovation costs
			6. Recycling, dismantling and reuse phase	The residual value of the elements

Although both LCC and WLC evaluation includes all the cost until the end of life, the presented analyses neglected both dismantling and residual values, since no structured and relevant data from the case studies was available.

Following the framework of ISO 15686-5:2008 standard, the first step for the calculation of the LCC is to set the time period, according to the purpose of the analysis. The standard indicates that the largest period to be selected is 100 years. On the one hand, shorter periods allow more reliable assessments, since the time-uncertainties are less affecting. On the other hand, longer periods, while having more uncertainties in the results, allow for more comprehensive evaluations, including maintenance costs. As stated in [4] "the International standard ISO 15686-5:2008 recommends that the estimated service life of a building should not be less than its design life". Furthermore, [5] suggested an analysis period between 25 and 40 years, since the present value of future costs, which arise after 40 years might not be consistent because of a large number of uncertainties. Therefore, for the purposes of this analysis, a period of 40 years has been selected. Regarding the actualisation of future costs over the 40 years lifespan, a common value of interest rate for all the case studies has been adopted. The selected value is taken from FRED Economic Database [6], which provides an average interest rate of 1.51% for the time period going from 2008 (year of construction of the oldest case study) to 2017.

According to the ISO 15686-5:2008, the LCC of a building is the Net Present Value (NPV), that is the sum of the discounted costs, revenue streams, and value during the phases of the selected period of the life cycle.

Accordingly, the NPV is calculated as follows:

$$X_{NPV} = \sum_{n=1}^{p} \frac{C_n}{(1+d)^n} \quad (1)$$

- C: cost occurred in year n;
- d: expected real discount rate per annum (assumed as 1.51%);
- n: number of years between the base date and the occurrence of the cost;
- p: period of analysis (40 years).

Finally, costs are grouped according to the life cycle phases: design, construction, building site management, operation, and maintenance. The effective estimation of energy and maintenance costs required a set of assumptions, described in the following sections.

3.1. Determination of the energy costs

In order to provide a homogeneous and comparable estimation of the energy costs of the case studies, since the official bills were not available in most of the cases, the evaluation was based on the calculated energy demand. As stated before, energy performance analysis was carried out by using the PHPP tool [7], which allows the implementation of the data dealing with the energy performance of a building, including the features of the envelope, HVAC system and renewables installed.

In particular, energy costs (C_{energy}) were estimated through a the difference of the cost due to the energy consumed ($C_{consumed}$), including heating, domestic hot water production, cooling and household/auxiliaries electricity and the revenues from the energy produced ($C_{produced}$) thanks to the renewables installed, (i.e. the contributions of final energy generated by a photovoltaic system and solar thermal system), both calculated on monthly base during month i (Equation 2):

$$C_{energy} = \sum_{i=1}^{12} C_{consumed,i} - C_{produced,i} \quad (2)$$

For each country the unitary energy prices (€/kWh) applied to calculate the costs for the energy consumed and produced, have been taken from Eurostat [8], considering the average values in the period 2010 – 2017. Most of the case studies are supplied by electricity, since the most common technology adopted is the heat pump. Nevertheless, for other energy fuels, the same approach the costs definition has been adopted.

As a general assumption, for the evaluations described in this report, a common value for considering the increase of the energy price has been adopted. According to the data reported in [8], the inflation of electricity prices in CRAVEzero countries from 2010 to 2017 amounts to 1.0%, and this value is used in the LCC evaluation.

3.2. Maintenance costs

Maintenance costs for the case studies were not fully available with a relevant level of accuracy and detail. In fact, the analysed buildings were built between 2009 and 2016, and only minor maintenance had already taken place. Therefore, the analysis within CRAVEzero is based on standard values from the literature. In particular, the standard EN 15459:2017 “Energy performance of buildings - Economic evaluation procedure for energy systems in buildings” [9] provides the life span and the yearly maintenance costs for each element, including operation, repair, and service, as a percentage of the initial construction cost. For the passive building elements, an average yearly value accounting for 1.5% of the construction cost was assumed for the evaluation, while the standard reports more detailed figures for the HVAC components (for both life span and annual maintenance). The value was crosschecked with average values coming from the experience of the industry partners.

4. Approach for the normalisation of Life Cycle Cost in the EU

The analysed case studies are located in different European countries (Table 1), i.e. Austria, Germany, France, Italy, and Sweden. Each country presents specific characteristics in terms of climate conditions, construction, and energy market. Therefore, in order to compare the results of the case studies and to draw a general overview of the costs of the current nZEB practices across Europe, a normalisation of the collected data is needed. In this regard, the following sections present an overview of the normalisation factors adopted for comparing the data of the case studies for construction, climate conditions and energy prices.

4.1. Construction cost

The impact of the construction costs on the life cycle is affected by several country-related factors. In fact, the price of the materials can be influenced by several national and international economic factors, as well as the costs of transports, strongly affected by the fuel costs, and the labour cost. In order to reduce the perturbations of the results caused by these national specificities, it is essential to find a common factor to normalise the construction costs.

Table 3. Construction cost index for CRAVEzero countries according to ECC [10].

Construction cost index				
France	**Austria**	**Germany**	**Italy**	**Sweden**
103.87%	100.67%	96.62%	93.63%	134.19%

The ECC [10] has calculated a comprehensive European construction cost index that quantifies the ratio among the construction costs of EU countries, considering the above-mentioned factors. Table 3 reports the normalisation factors of the construction costs adopted within CRAVEzero.

4.2. Year of construction

Another factor influencing the costs of investment and operation is the adopted reference year for the actualisation, usually the year of the construction. For this analysis, considering that 10 out of 12 case studies were built between 2012 and 2015, in order to simplify the evaluation process, the normalisation of the year of construction was neglected.

4.3. Climate

It is important to normalise the energy costs according to the climate conditions of the building location, to neglect their effect on energy consumption. In this regard, the heating degree days (HDD) was assumed as a normalisation factor. The values were derived from the report “U-value and better energy performance” [11], which provides the HDD for a set of reference cities of the EU-countries.

4.4. Energy price

Finally, in order to compare the energy costs, a normalisation, which considers differences in energy prices among countries, was implemented. 0.16 €/kWh has been assumed as the average energy price for the normalisation. This value was calculated considering the average price for each energy vector and its weight among the other energy vectors according to the technology installed.

5. Key performance indicators and sensitivity analysis

To display the results of the data analysis of each case study, a set of key performance indicators is proposed. A list of performance indicators was submitted to the project partners, with the request to rate the KPIs on a scale of 1-3 (“3 - very interesting”, “2 - interesting” and “1 - not interesting”). According to the ranking, it has been decided to include in the final list the KPIs with an average score ranging from 2 to 3. Table 4 presents the selected indicators.

Table 4. Rated key performance indicators.

KPI	Rating	KPI	Rating
LCC / usable floor surface	3	Cooling energy demand for cooling	2.4
Investment cost / usable floor	2.8	Energy demand for hot water production	2.4
Operation cost / usable floor	2.6	Annual renewable energy generation	2.4
Renewable energy share	2.6	Maintenance cost / usable floor surface	2.2
PV annual electricity yield	2.6	Maintenance cost / investment cost	2.2
Annual CO2 emissions	2.6	Final energy consumption	2.2
Life-cycle CO_2 emissions	2.5	Specific heating demand	2.2
LCC	2.4	Specific cooling energy consumption	2.2
WLC	2.4	Specific hot water energy consumption	2.2
Investment cost	2.4	Specific Electricity energy demand	2.2
Operation cost	2.4	LCC / renewable energy installed capacity	2
Maintenance cost	2.4	Operation cost / PV energy production	2
Primary energy consumption	2.4	Electricity energy demand (lighting,	2
Heating demand for heating	2.4	Energy demand for ventilation	2

5.1. Sensitivity analysis

One of the main drawbacks of the LCC analysis is the high level of uncertainty affecting the evaluation of the costs during the building life cycle. In fact, on the one hand, the calculation requires a series of simplifications and assumptions for defining the input parameters, and, on the other hand, the complex cost structure and the uncertainties in predicting future events that may affect the results [12, 13]. A proper cost analysis requires the quality of input data and accurate long-term forecasts of these values over the analysed lifespan [12]. The difficult access to this type of data leads to uncertainty in LCC methods, limiting their application. Hence, to tackle the uncertainty issue, the CRAVEzero LCC evaluation includes a sensitivity analysis to define the impact of the uncertain boundaries and input values on the LCC. SA measures the effect on the outputs, caused by input variation, due to uncertainty or risk. In this way is it possible to define uncertainty-adjusted LCC ranges, allowing decision makers to concentrate on the analysis of the most critical parameters [13].

The present paper reports the outcome of differential SA. This method belongs to the class of the "One factor At a Time" (OAT) screening techniques, since it evaluates the effect of the variation of a single input parameter on the output, while the other set of inputs are set equal to their baseline value:

$$s\% = \frac{\frac{\Delta O}{O_{un}}}{\frac{\Delta I}{I_{un}}} \quad (3),$$

Where:

- S%: Sensitivity index
- O_{un}: Baseline value
- ΔI: Input variation
- ΔO: Output variation
- I_{un}: Baseline value

Figure 1 and Figure 2 report the results of the SA for one of the case studies, i.e. Résidence Alizari, in terms of Sensitivity Index and LCC variation around the baseline. In particular, the analysis focused on boundary conditions and general assumptions that are mainly affected by uncertainty issues: interest rate, energy cost and its inflation rate, maintenance cost (evaluated as a % of the construction cost) and operational cost. As shown in Figure 1, the maintenance and the lifespan of the buildings have the highest impact on the LCC, that can range from 2610 and 2675 €/m² according to the variation of the inputs.

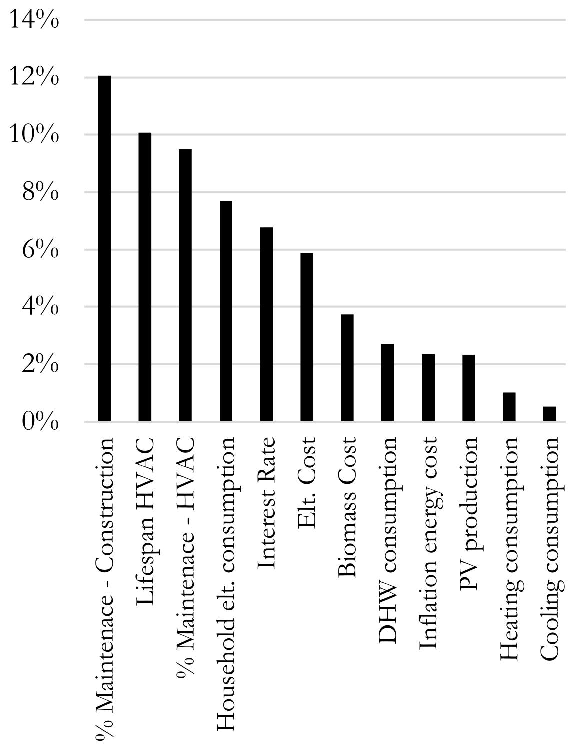

Figure 1. Sensitivity index (s%) of boundary and assumptions – Résidence Alizari.

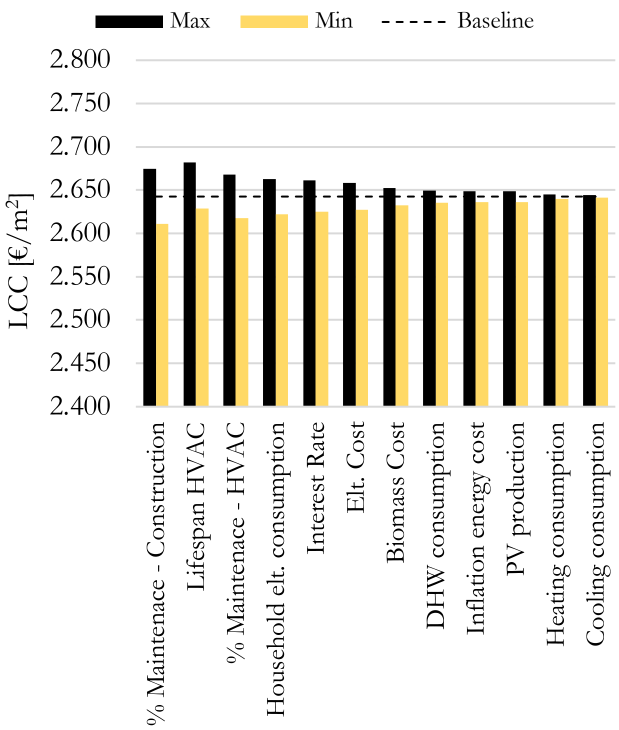

Figure 2. LCC variability according to the variations of boundaries and assumptions

6. Spreadsheet

The set of selected KPIs, shown in Section 5, have been combined in the CRAVEzero nZEB spreadsheet describing, in both numerical and graphical form, the normalised life cycle cost of nZEBs for an EU-wide comparison of the results.

Figure 3 shows the first page of the CRAVEzero spreadsheet, including an overview section of the main features of the case study and the KPIs related to investment costs and energy consumption. In particular, it reports the investment cost with the breakdown and a special focus on design and construction, and a detailed analysis of labour and material cost for each building and HVAC element with the impact on the investment. Finally, there is a section dedicated to the energy performance of the nZEB, including specific energy demand, consumption CO_2 emission and production from renewable energy sources. The second page (Figure 4) focus on life-cycle cost KPIs, with a general overview of the cost during the life span (40 years), a distribution according to the phase with a special focus on the maintenance and a detailed breakdown of the specific costs for each unit surface during all the phases of the life cycle.

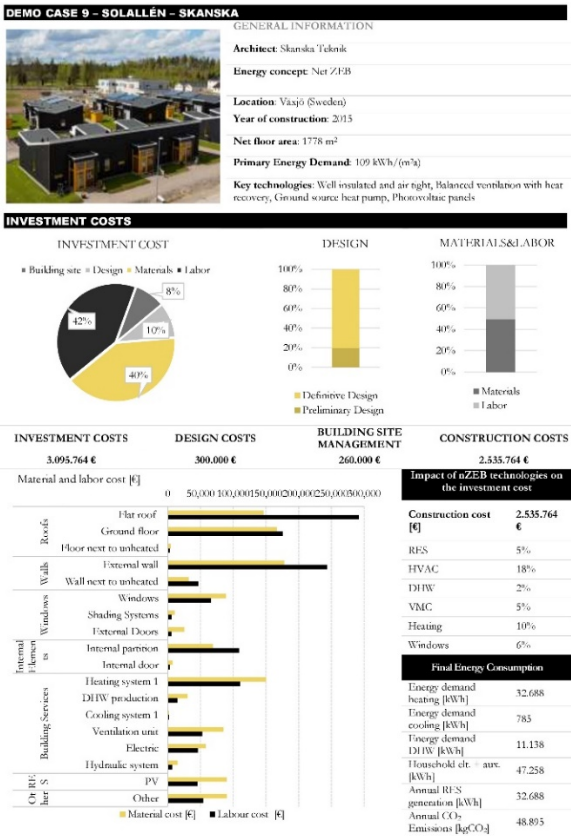

Figure 3. Investment KPIs.

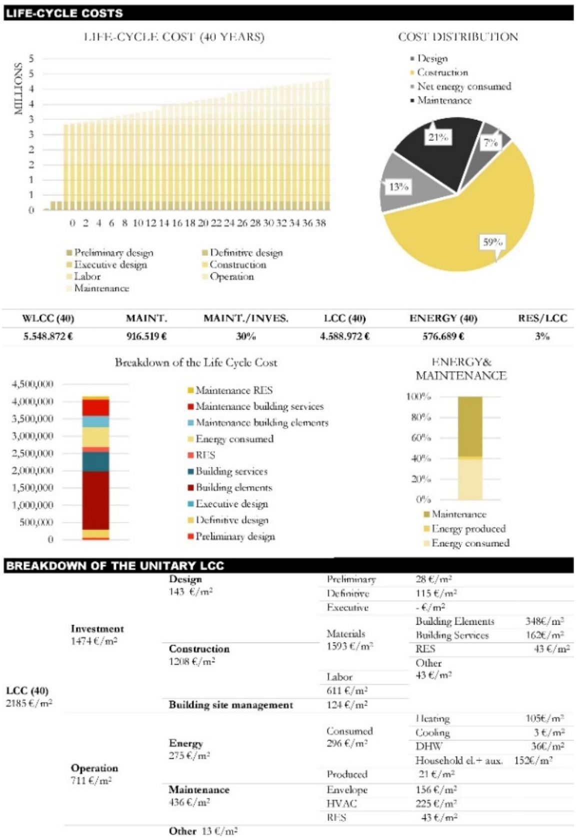

Figure 4. Life-cycle cost KPIs.

7. Comparative analysis

This section reports a general overview of the application of the methodology described in Section 3 and 4 to the CRAVEzero case studies, providing a comparative analysis highlighting the impact of the different phases on the overall LCC is provided. It is important to point out that the results are normalised according to the criteria illustrated in Section 4, in order to ensure the comparability of the indicators. Figure 5 shows the overview of LCC calculated considering a period of 40 years for the twelve case studies, with a breakdown of the cost for each phase. It is possible to point out that design cost has a reduced impact on the LCC, ranging from 3% (Case NH-Tirol) to 15% (Parkcarré), but with an average value of 5%. Cost of materials ranges from around 27% (for the case study Solallén) up to 53% (i.e. Les

Héliades). Since labour costs were in most cases, either not available or included in the cost of materials, a reliable breakdown of the construction costs into materials costs and labour costs was not possible.

As it was expected, for the analysed case studies the energy costs during the life cycle of an nZEB represent a minor component of the LCC, with an average of around 12% (Figure 7). It is important to point out that the contribution from the renewable energy sources (RES) is accounted for as a reduction of the energy cost (calculated as a balance between energy consumed and produced).

Figure 6 shows an overview of the average impact of all the phases on the LCC, the investment costs for design, construction and other initial expenditures is around 54% of the LCC, while the energy and maintenance account for around 44%.

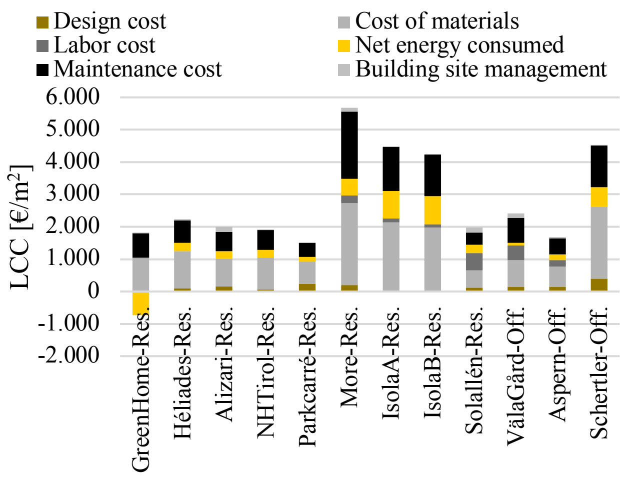

Figure 5. LCC breakdown.

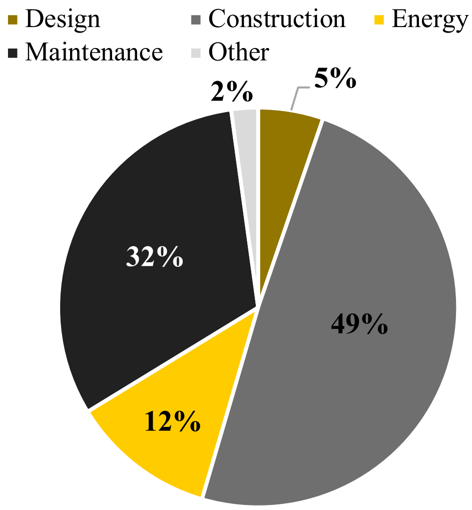

Figure 6. LCC breakdown – average.

Figure 7 displays the energy cost in relation to the average U-value of the opaque components. Figure reports the breakdown of the cost for the building elements, highlighting the impact on the construction costs. It shows that in some cases the structural elements represent a significant contribution to the construction, according to the complexity and the dimension of the building. On the other hand, nZEB related technologies have a small impact on the construction costs, although in comparison to a traditional building the cost for the HVAC system and the integration of renewables is more significant.

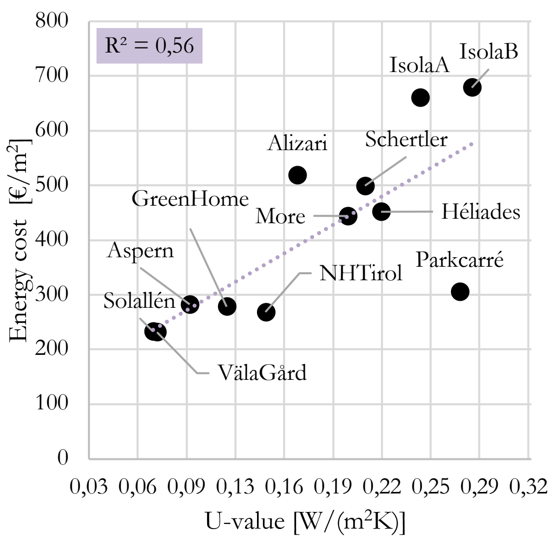

Figure 7. Correlation between energy cost and U-value.

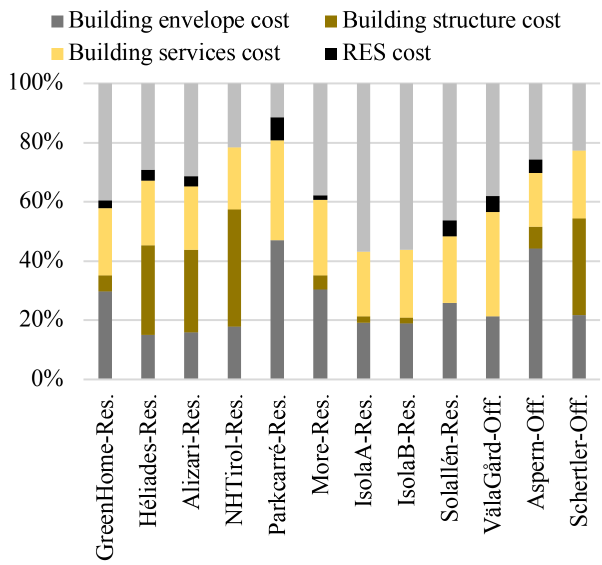

Figure 8. Construction cost breakdown

8. Conclusion and further development

This paper presents an operative methodology for an EU-wide evaluation of Life Cycle Cost, including boundary conditions, reference values, normalisation factors and sensitivity analysis. In addition, it reports an overview of the main results for 12 exemplary case studies analysed within the H2020 CRAVEzero project. The H2020 CRAVEzero project, is going to release an effective tool for producing the nZEB spreadsheet, including all the main indicators for analysing in detail the performances in terms of cost and energy of a building, identifying the main phases and elements affecting both the investment and the Life Cycle Costs. At EU level, a shared and operative LCC methodology and a comprehensive database with detailed building Life Cycle Cost evaluation represent the strategic references for a broader implementation of LCC analyses, providing useful benchmarks for comparison and increasing the reliability of LCC. The broad application of the LCC analysis will foster the market uptake of nZEBs, highlighting the cost-effectiveness and benefits during the life cycle. More information are available on the project website: http://www.cravezero.eu

Abstract. Possible cost saving potentials in the planning and construction of future building standards are often not sufficiently assessed, as only a few possible variants are considered in the traditional planning process. Often planning and analysis are not carried out in parallel, and the various possibilities are discarded at an early stage. If, on the other hand, several variants are realistically compared in the planning phase, including life-cycle costs, a profound decision can be made. Therefore parameter studies were carried out as part of the national research project "KoPro LZK+" (cost and process optimization in the life cycle of nearly zero energy buildings) for seven buildings, five multi-family buildings, a school and an office building. For this purpose, a VBA macro was programmed in MS-Excel©, which automatically carries out energy demand calculations in the "Passive House Planning Package" (PHPP) and life-cycle cost calculations in the tool "econ calc". A total of more than 216,000 variants were investigated in this way, whereby on the one hand a variety of technologies, such as insulation of the building envelope, ventilation or electricity and heat supply, and on the other hand a variation of the boundary conditions (such as observation period, user behaviour, energy price increases or CO_2 costs) were carried out. The results were analysed energetically and economically over the life cycle (separately from each other and combined) with the objectives of identifying coherences, deriving trends and optimizations over the life cycle.

1. Methodology

In the traditional planning process client, architect and technical planners develop a building with the relevant technical equipment and building services. In many cases, everyone optimizes in "his/her" area, and thus the building project as a whole is being lost out of sight. Thus, it can happen that at the end a building is built and in operation, it turns out that, e.g. the running costs are extremely high. If, on the other hand, several variants are being compared in the planning phase, including life-cycle costs (LCC), a sound decision can be made already in advance. Research and demonstration projects show that it is already possible today to construct new or to renovate buildings to near zero and plus energy standards that achieve extremely low energy consumption and CO_2 emissions and can be operated economically. [1]

The term "parametric analysis" in this paper defines a method in which series of calculations are run by a computer program, systematically changing the value of parameters associated with one or more design variables. The key feature of this approach is that it allows evaluating the effect of individual design variables on energy, costs and environmental parameters in one step. This so-called multi-objective optimization analysis has become more popular in recent years. [2]

The multi-objective approach is based on the concept of Pareto frontier: a solution is optimal when no other feasible solution improves one of the objectives without affecting at least one of the other. In that case, the multi-objective algorithms generate a set of solutions, known as the Pareto front. If the problem includes only two objectives, the Pareto front is a two-dimensional curve. This concept can also be applied to three or more objectives, although the results are more difficult to analyse. This approach seeks to explore a set of optimal solutions rather than to find a single optimal solution. [3]

The difference between a conventional optimization method and the parametric optimization is clearly shown in following figure 1. With the conventional method, only selected technology combinations are checked and compared with each other. The optimization, therefore, takes place within this selection but does not include all possible combinations. This is the big difference between the conventional method and the parametric analysis and optimization. Here, all possible combinations are calculated, analyzed and the optimal variant is determined.

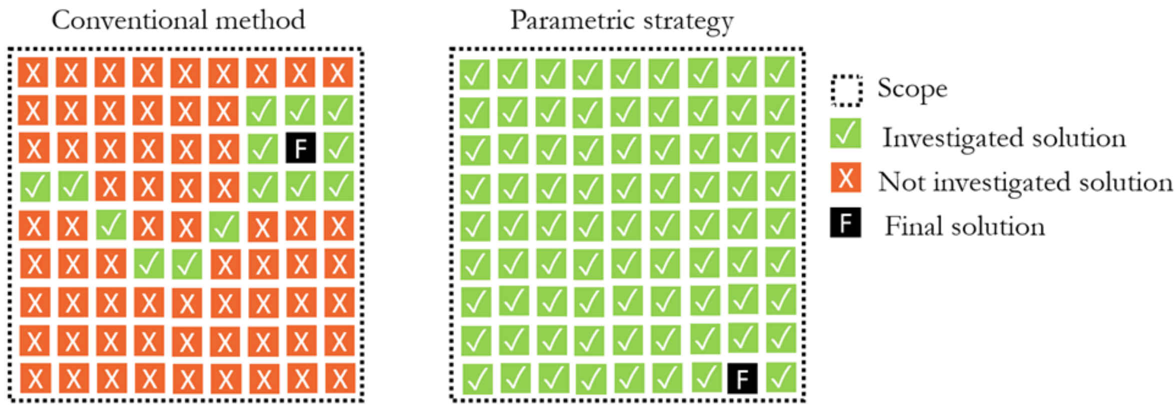

Figure 1. Comparison of conventional optimisation method vs. parametric optimisation [4]

The method of parametric analysis and energy-economic optimization in the research project "KoPro LZK+ - cost and process optimization in the life cycle of nearly zero energy buildings" (https://nachhaltigwirtschaften.at/en/sdz/projects/kopro-lzk-plus.php) follows the order below:

- Design
- Determination of target values and goals
- Determination of the parameters to be varied and their levels e.g. envelope quality, heating system, window size, window quality.
- Energy demand calculations with the "Passive House Planning Package (PHPP)"
- Calculation of the life cycle costs of each variant, taking into account operating costs, maintenance, replacement investments and residual values, using the LCC tool "econ calc"
- Evaluation and presentation of the results.

With this method, more than 216,000 different variants could be calculated in a manageable amount of time for seven prototypical case studies.

2. Investigated Case Studies

In the KoPro LZK+ project, seven buildings were investigated in detail. These case studies were selected so that they reflect a limited cross-section over different uses (multi-family residential, office and school) and include new as well as renovated buildings.

All buildings have already been completed and are in operation, except for one multi-family building, which was still in the construction phase at the beginning of 2019. The investigation of the buildings was therefore carried out after completion of the building. This procedure was chosen because in the short time of the project duration it was not possible to find several real buildings, which were in the planning phase at this time and that can be managed within the research project. However, the examples can be used to show the potentials and commonalities of the projects and to identify the levers and influencing variables. In future construction projects, however, the method shown should be used in the planning process of the building.

To give a short overview of the investigated case studies, table 1 summarizes some facts and figures of the buildings. Table 1 also gives some information about the investigated parameters.

Table 1. Overview of the case studies and the investigated parameters.

parameter	case study 1	case study 2	case study 3	case study 4	case study 5	case study 6	case study 7
use	residential	residential	residential	residential	residential	office	school
gross floor area [m²]	1,495	589	1,822	2,845	1,450	1,283	3,243
treated floor area [m²]	1,212	432	1,421	2,091	1,025	822	2,580
year of completion	2019	2013	2017	2014	2015	2012	2013

number of investigated variants							
variants	53,000	49,000	75,000	7,300	5,800	23,000	3,500

The construction costs for the seven example buildings were provided by the project partners. The costs for the investigated technology options were provided directly by the property developers or building services planners or derived from other reference projects. The costs for the PV systems were derived exclusively from current market prices, as there has been a significant cost reduction in recent years. All costs are stated as net costs, excluding VAT. Furthermore, land costs were not taken into account in all projects, as they can strongly distort the life cycle cost analysis.

As the buildings were built between 2013 and 2017, the costs cannot be directly compared. To ensure some comparability, the costs for all case studies have been index-adjusted to the year 2017. Since the costs in the KoPro LZK+ project are viewed more from the buyer's or user's point of view, the construction price index was used. The indices are given with different reference years (2015, 2010, 2005, 2000, 1996...).

The interest rate for the bank rate has been set at 3.0% nominal for the 25 year credit period. The current rate for the 10-year fixed rate is around 1.8%. The inflation rate is set at 1.7%. The principal or discount rate is set at 3.0% nominal, similar to the bank rate.

3. Example multi-family building “+ERS” (case study 5)

3.1. Description of the case study. The project “Plus Energy Network Reininghaus Süd (+ERS)" is an integral part of the "Energy City Graz-Reininghaus (ECR)" project and follows the specifications of the overall urban planning framework. The project is divided into two sections: part 1 is an office and business complex with residential use on the upper floors, part 2 consists of 12 multi-family houses with 162 residential units in total. In the national research project KoPro LZK+, one of the 12 multi-family buildings was investigated in detail. All results in chapter 3.3. refer to this building, which is shown in figure 2.

Figure 2: +ERS - Plus Energy Network Reininghaus Süd (source: Martin Grabner)

3.2. Variants and sensitivity analysis. Table 2 shows an overview of the investigated technologies. For each technology, different parameters were varied, which can be classified into a maximum of three levels.

Table 2. Overview of the investigated technologies and parameters.

Parameter	level 1	level 2	level 3
building envelope	passive house standard	national regulation	-
ventilation	mechanical ventilation with heat recovery	window ventilation	-
heating system	ground source heat pump + earth piles	ground source heat pump +ground collector	air source heat pump
photovoltaics (PV)	no PV	medium-sized PV	large-sized PV
solar thermal system	no solar thermal system	solar thermal system for DHW	solar thermal for DHW + heating

In addition to the technologies also some boundary conditions were varied like user behaviour, the energy tariff, energy tariff increase, the calculation period and CO_2 follow-up costs. Table 2 shows, for example, the assumptions for the investigated user behaviour.

Table 3. Investigated user behaviour and assumptions.

user behaviour	room temperature in winter	DHW demand (60°C)	additional shading in winter due to misuse of external blinds	additional window ventilation in winter due to misuse
ideal	21°C	25 L/pers/d	+ 0%	+0,00 1/h
standard	22°C	30 L/pers/d	+10%	+0,05 1/h
inefficient	23°C	35 L/pers/d	+20%	+0,10 1/h

3.3. Results. This chapter contains some selected results of the many calculations available. All results with detailed descriptions can be found in the final report of the national research project under the link: https://nachhaltigwirtschaften.at/en/sdz/projects/kopro-lzk-plus.php and on the website of AEE INTEC (https://www.aee-intec.at/index.php?params=&lang=en).

To analyse the energy performance in combination with cost efficiency scatter plots were used. Each technology was analysed separately and in combination with other technologies.

For every single technology, the net present value was compared to the balanced CO_2 emissions and the balanced primary energy demand. The results of this analysis are shown in following figure 3. "Balanced" in this case means that the self-consumption of the PV system was considered, transferred into CO_2 emissions (and in into primary energy) by the conversion factors for electricity and then subtracted from the calculated CO_2 emissions (respectively primary energy demand).

Written as a formula, the balanced CO_2 emissions were calculated as follows:

$$CO_{2\_balanced} = CO_2 \left[\frac{kg}{m^2a}\right] - PV\ selfconsumption \left[\frac{kWh}{m^2a}\right] \times electricity\ conversion\ factor\ [\frac{kg}{kWh}]$$

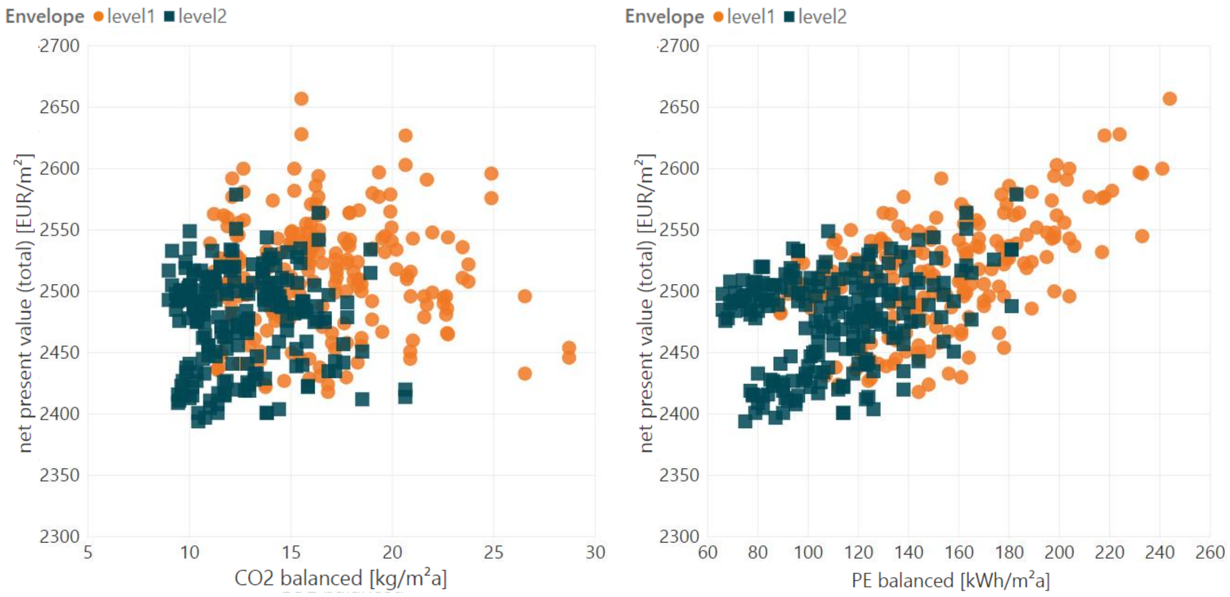

Figure 3. Analysis of the influence of the building envelope on the net present value, the balanced CO_2 emissions (left) and the balanced primary energy demand (right) (related to treated floor area of the PHPP / energy tariff standard / user behaviour standard / CO_2 and PE factors OIB RL-6 2015 / without consideration of subsidies / no CO_2 or PE credit for electricity fed into the grid).

Figure 3 shows the influence of the building envelope on the net present value, the balanced CO_2 emission and the balanced primary energy demand. The analysis shows that the improvement of the insulation from level 1 to level 2 leads to a reduction of the CO_2 emission and the primary energy demand, and also to a reduced net present value. Looking at the whole life cycle of the building it is, therefore, advisable to improve the quality of the building envelope, in this case to passive house standard.

In further consequence, the sensitivity of the individual technologies to the indicated performance indicators "balanced CO_2 emission", "balanced primary energy demand", "financing costs" and "net present value" was investigated. For this purpose boxplots were produced to show the sensitivity of all investigated technologies on the named indicators. These results indicate the sensitivity of the investigated performance indicators for the multi-objective building life-cycle cost and performance optimisation.

The analysis was done in two parts:

- Part 1: Technologies that could be counted as "energy efficiency measures" or "passive measures", like insulation of the building envelope or mechanical ventilation.
- Part 2: Technologies counted as part of the "energy supply system" or "active measures", like heating system, solar thermal installation and PV system.

When the difference in median value and the standard deviation is small, it is assumed that the indicator is not sensitive.

Figure 4 shows as an example the sensitivity of the energy supply measures on the defined indicators.

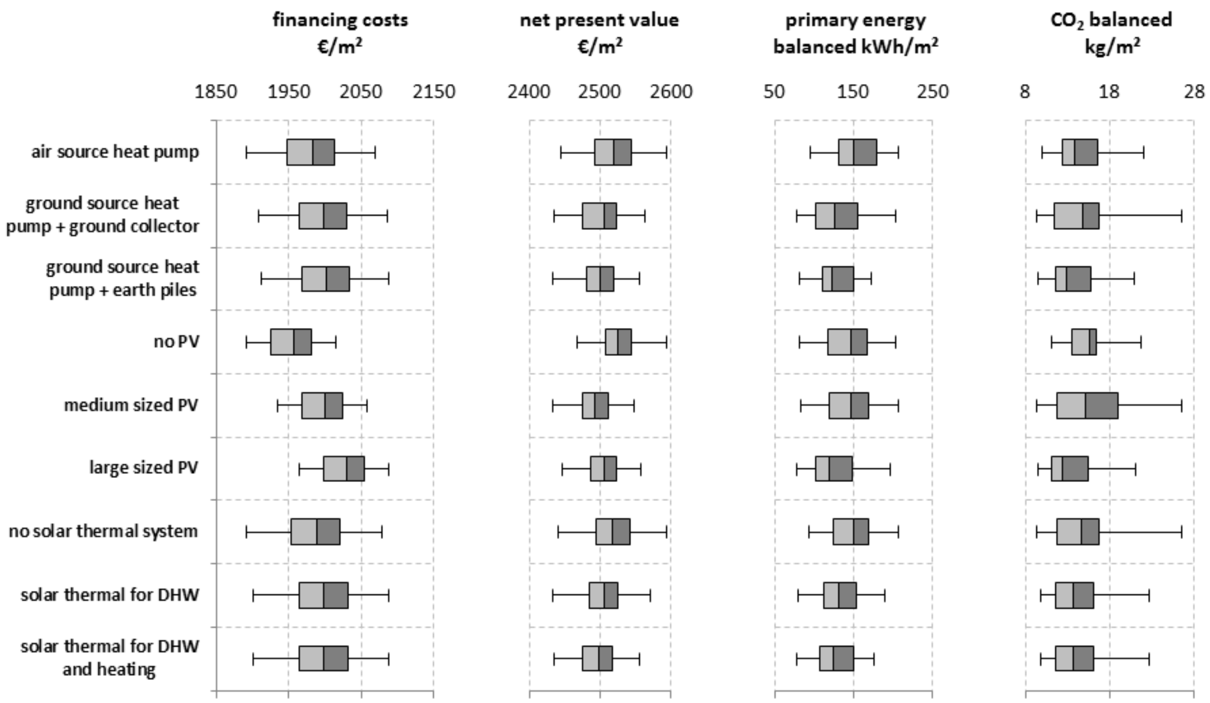

Figure 4. The sensitivity of the financing costs, the net present value, the balanced primary energy demand and the balanced CO_2 emissions to the energy supply measures (heating system, PV and solar thermal system)

All results from the project were integrated into an interactive web-based guideline for zero and plus energy buildings, which makes it possible to evaluate all variants individually. This means that estimations of cost and energy reduction potentials can be analysed at an early stage of the project using the example buildings (see https://www.aee-intec.at/kostenreduktion-plusenergiegebaeude-n-koprolzk-p218).

4. Lessons learned

Determining the best global solutions for nearly zero energy buildings design variables, in terms of energy, environmental and cost performance, is not an easy task, mainly because the variables affect each other through processes that are often not linear, and the optimisation goal of each variable can change significantly based on the optimisation goal and the importance of the key performance indicators (e.g. financing costs, net present value, primary energy demand, CO_2 emissions).

The assumption that the additional costs of energy efficiency measures are so low that energy efficient buildings have the lowest life-cycle costs can now be confirmed by the investigation of seven example buildings (with different use / new constructions and renovations). Energy efficiency measures have only a small percentage influence on construction costs but can save many times more CO_2 emissions. Regarded over the whole life cycle of the building, these efficiency measures are then usually cost-neutral or even economical.

In detail the results of the evaluations within the national research project KoPro LZK+ can be summarized as followed:

- The energy efficiency level has only a small influence on building and construction costs. Energy efficiency is therefore not a significant cost driver.
- For most technologies, the additional construction costs of energy-efficient variants are compensated over the life cycle of the building even without subsidies.
- Considering the life cycle costs, the primary energy demand and the CO_2 emissions the optimum is in the range of passive houses. Passive house envelopes and highly efficient

windows are in most cases economical even without subsidies. This is due to the long service life of these components in comparison to the building services.

- The optimum for life-cycle costs and CO_2 emissions are very flat. Low emissions and energy consumptions can, therefore, be achieved with different energy concepts as long as the building envelope is very efficient. This allows creative and conceptual freedom.

It is shown that energy efficiency and economic efficiency are not contradictory strategies, but can complement each other very well. The selection of variants according to life-cycle costs, therefore, makes sense and should be increasingly used as a decision criterion.

Contradictions of low-emission nZEB buildings

Severnyák K

University of Debrecen, Hungary

severnyakk@yahoo.co.uk

Abstract. Based on the EPBD 2010 directive and the mandated method of cost-optimum calculation the forthcoming national regulations require “nearly zero energy buildings” which have high energy performance, significant share of renewables in covering the low energy need and harmonizing the requirement system and the cost-optimum all over in Europe. Known intention of the EU Member States as well as some research reports create the impression that predominant use of biomass in the forthcoming years will be the right way to fulfil the above requirements of nearly zero energy buildings. Taking advantage of regulations in many Member States, the amount of yearly primary energy demand is favourably influenced by the low primary energy conversion factor determined by the very states; besides the delivered energy does not decrease. The CO_2 neutrality of biomass is not real. It is true that the emission of gas firing far exceeds that of wood firing, but emissions from the production of natural gas might be lower than that of the production of certain wood products. Overall, the lifecycle-based emission of biomass firing for the most converted fuels is already significant. In the case of wood combustion, the local pollutant emissions, which occur in cities, are significant, while the CO_2 constraint take place in the forests.

1. Introduction

Based on the European Parliament’s directive published in 2010[1], all new buildings built after 31 December 2020 within the EU should meet the requirements of nearly zero-energy buildings.
According to the definition, these buildings must be characterized by low energy consumption and extensive use of renewable energy. The European Union has entrusted the Member States to set a maximum primary energy consumption requirement for nearly zero-energy buildings, which varies from one Member State to another.

The maximum value of the energy consumption of nearly zero-energy buildings is determined per year and floor area in primary energy. The method of calculating the yearly energy consumption is determined by the Member States individually (figure 1).

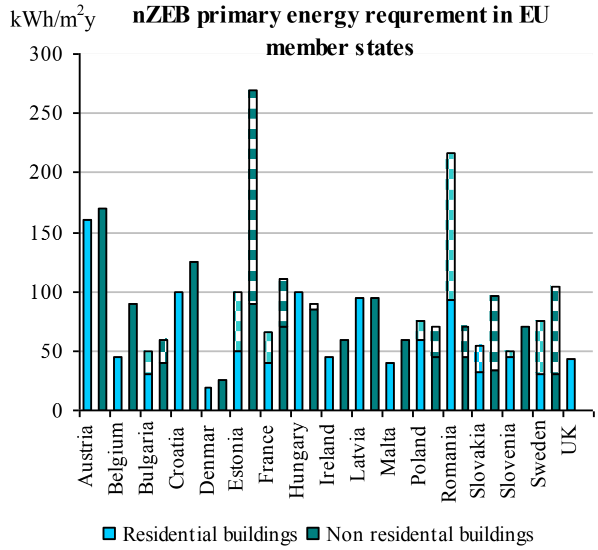

Figure 1. The primary energy demand for NZEB buildings in some EU Member States BPIE [2] (including renewable energy use).

The regulation gives Member States a broad opportunity to define the criterion, and this criterion can be met in a number of favorable computational ways.

2. Primary energy calculation mode interpretation in the EU

Buildings use heat, electricity, or mechanical energy. Different forms of useful energy must be converted into primary energy for comparability. Renewable and non-renewable energy sources such as coal, crude oil, natural gas, water energy, wind, and solar radiation found in nature are so-called primary energy carriers. Most of them are not used directly, but after conversion. The conversion into a directly usable energy carrier, such as gasoline, diesel, electricity, involves energy use and losses. The magnitude of the loss depends on the degree of conversion and the technology used. In Hungary, for example, the primary energy conversion factor for electricity (e) equals with 2.5 determined by the current regulation, which means that by investing 2.5 kWh of primary energy we get 1 kWh of useful electricity.

Member States of the European Union use primary energy conversion factors (e) with different values for the same energy carrier, that is, they determine their primary energy consumption individually depending on the energy, loss and other factors of the conversion of energy carriers[3]At the same time, these conversion factors may conceal central subsidies or other incentives that may cause energy consumption results to be subjectively distorted in individual Member States. The e-factor is set by the Member States on a subjective basis, mostly according to their own energy policy[4]. However, this should be an energy statistics parameter that could be determined by statistical measurements by tracking energy paths to territorial and / or consumer groups.

Most decision-makers in the EU are convinced that the nZEB requirement could be met with a widespread use of biomass [5]. As an example, the conversion factor for biomass energy is 0.6 in Hungary, 1.08 in Austria and 0.2 in Slovakia. Considering an example building, the same amount of fuel on the opposite sides of the border shows a completely different level of total primary energy consumption in Hungary, Austria and Slovakia. In many Member States, the primary conversion factor for biomass is surprisingly low (figure 2), which results in low total primary energy consumption simply by conversion factors. This way only the total primary energy use is reduced, not the heat demand.

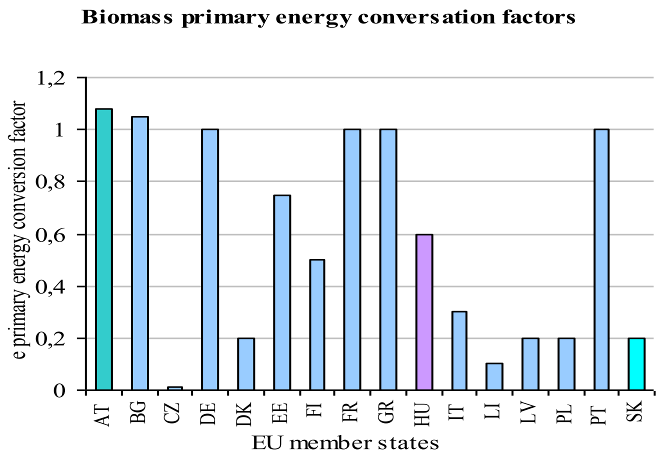

Figure 2. Primary energy conversion factors for biomass in some Member States

Let us calculate [6] [7] and compare the primary energy need of identical buildings on the opposite sides of the Hungarian-Austrian and Hungarian-Slovak borders. The sample building is a one-storey single-family house with a floor area of 100 m^2 made from manually built building blocks, widely used in Hungary between 1960 and 1980. Assuming the same environmental conditions the primary energy demand for heating the building is not the same in the three countries if biomass is used. The buildings were just a few meters away from each other on the opposite side of the border, and locally processed forest tree was used as fuel, which requires minimal processing (figures 3,4).

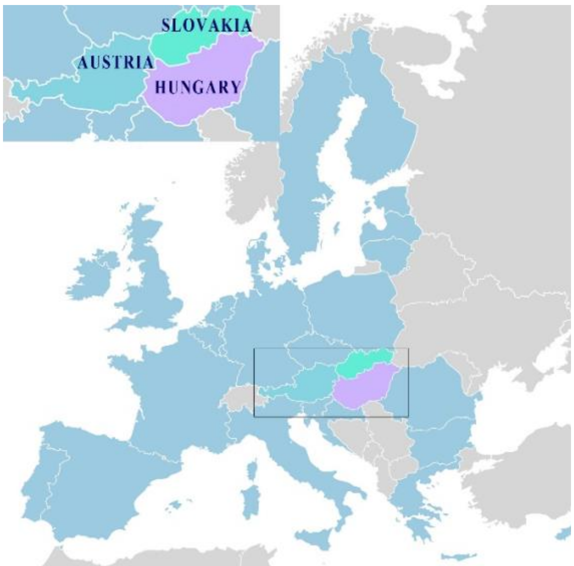

Figure 3. Austria-Hungary-Slovakia neighbouring countries

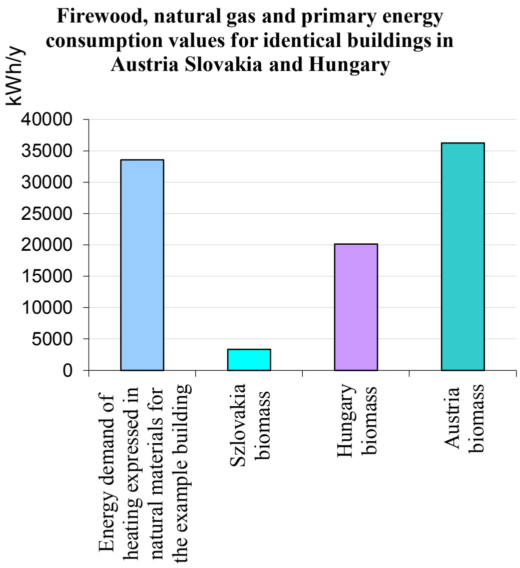

Figure 4. Energy need in identical buildings in identical climatic zone- from left to right: in delivered energy, in primary energy in Slovakia-Hungary-Austria

The truth is when different fuels are used, consumption of the sample Hungarian building shown in figure 5, taking into account the efficiency of the system, and the primary energy conversation factors more primary energy carrier is needed when using biomass.

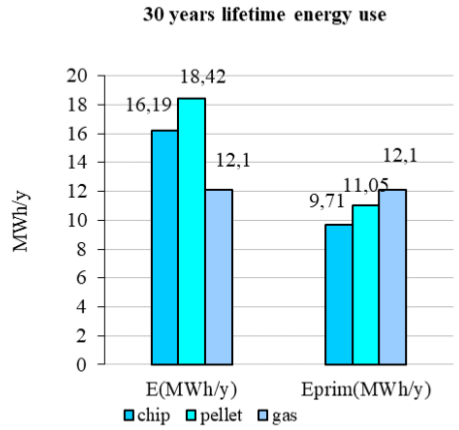

Figure 5. Primary energy and energy carrier consumption of the sample building

3. Fulfilment of nZEB building criteria in EU member states

Biomass use is expected to be the key to solving the problem of high renewable share of nZEB buildings. Biomass as an energy source can be renewed, but it has limitations. If we only look at the heat demand of buildings, it is likely that the growing demand for biomass poses a risk to resources and will result in rising prices (not to mention the biomass needs of thermal power plants, which is an important source of green electricity in Europe) [8].

Scientists, looked at the dynamic simulations of a single-family house and an office building in four representative European climates [2]. The results of each study put biomass use in the centre. This approach is reflected in the plans of some Member States which includes the share of the various renewable energy sources planned to be used in the future.

With some simplification, Member States distinguish renewable sources for heat production for example: solar, geothermal, biomass, heat pump, (the amount of heat or electricity generated above the needed auxiliary power).

Although this classification is not considered consistent, these data are available (figure 6).

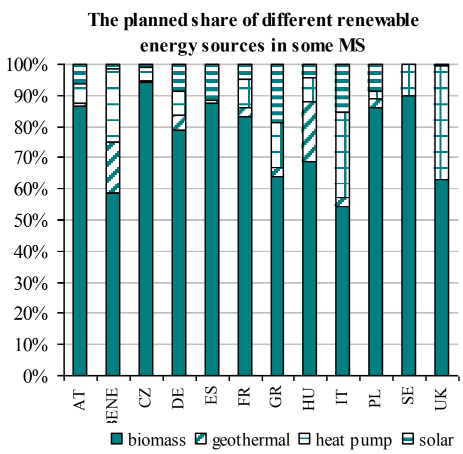

Figure 6. The planned share of different renewable energy sources in some member state [9]

However the acquisition of biomass fuel in the European Union is difficult for many Member States, e.g. GB imports from the USA, whilst Denmark from the Baltic States. [8].

4. Cost optimum requirements within the EPBD

"EPBD Recast" sets additional criteria for increased energy efficiency. EU Member States were asked to draw up action plans by 2020 and radically reduce energy consumption according to specific milestones. Member States shall regulate their own national energy criteria, which should be reviewed every five years. The Commission has published its regulation in support of the review and the Member States were asked to take into account the methodology and the criteria [10].

The methodology requires the identification of cost-optimal energy criteria for buildings and building elements. The primary energy consumption of buildings found in the energy certificate and the global cost of buildings, which consists of the sum of the present value of the initial investment costs, sum of running costs, and replacement costs (referred to the starting year), as well as disposal costs if applicable., are considered as the basis for the determination of the optimum.

Based on this method, the Member States calculated the costs of building renovating and maintaining optimum-including operation costs. The calculations had to take into account the national legislation in force in the Member States. Under the EPBD Regulation, the national minimum energy performance requirements should not deviate from the cost-optimal calculations by 15%. The cost-optimal level shall lie within the range of performance levels where the cost benefit analysis calculated over the lifecycle is positive [11] figure7.

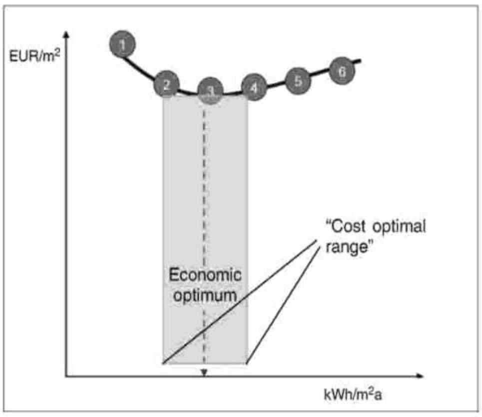

Figure 7. Cost optimum range by the EC

Based on the results, biomass use was highlighted by several advisory organizations supporting the Commission. Hungarian calculations also showed that progressive passive renovation and the complex renewal of engineering system to biomass use should be optimal. [6]

5. Cost aspects

In Hungary, the calculation underlying the report was prepared by Energiaklub Climate Policy Institute and Applied Communications; we studied a total of 15 reference buildings. [6]

The biomass fuel based optimum of nearly zero-energy buildings is shown through the cost optimum analysis of one of the reference buildings.

This type of building is typically a cube-shaped building constructed of B30 blocks, so-called "Kádár kocka" or "Kádár cube" (Hungary's leader between 1956(1961)-1988) based on the survey of the Energiaklub Negajoule2020 [11]. Built between 1960-1980, two-bedroom house with gas convector heating, gas-boiler hot water producing equipment. The typical annual energy consumption of the building is 38,520kWh / year, the CO2 emissions are 7.82t / year, calculations based on the 7/2006 Decree by the Minister without Portfolio of Hungary. [12]

The B30 block was a modern building unit in the Hungarian building materials market from 1960 to 1980. According to the data of the Hungarian Central Statistical Office based on the 2011 census data, of the stone, masonry unit buildings (2.48 M), more than 800,000 buildings could be built masonry units, therefore it can be considered a typical type of building in Hungary's single-family housing stock (figure

8). According to the result of the analyses, the optimum renovation of this building will result in an nZEB building.

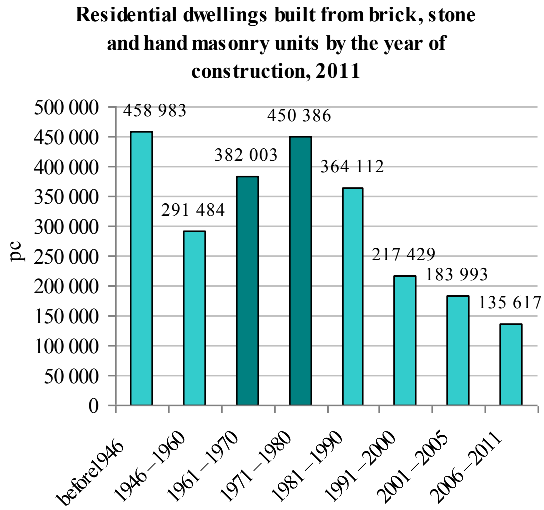

Figure 8. According to the data of the Hungarian Central Statistical Office, the census data prepared in 2011: by the building material of residential homes

According to the published methodology, Member States had to determine energy performance requirements for buildings in order to optimize costs. Examination was mandatory both at the level of the annual energy consumption of buildings and that of building elements.

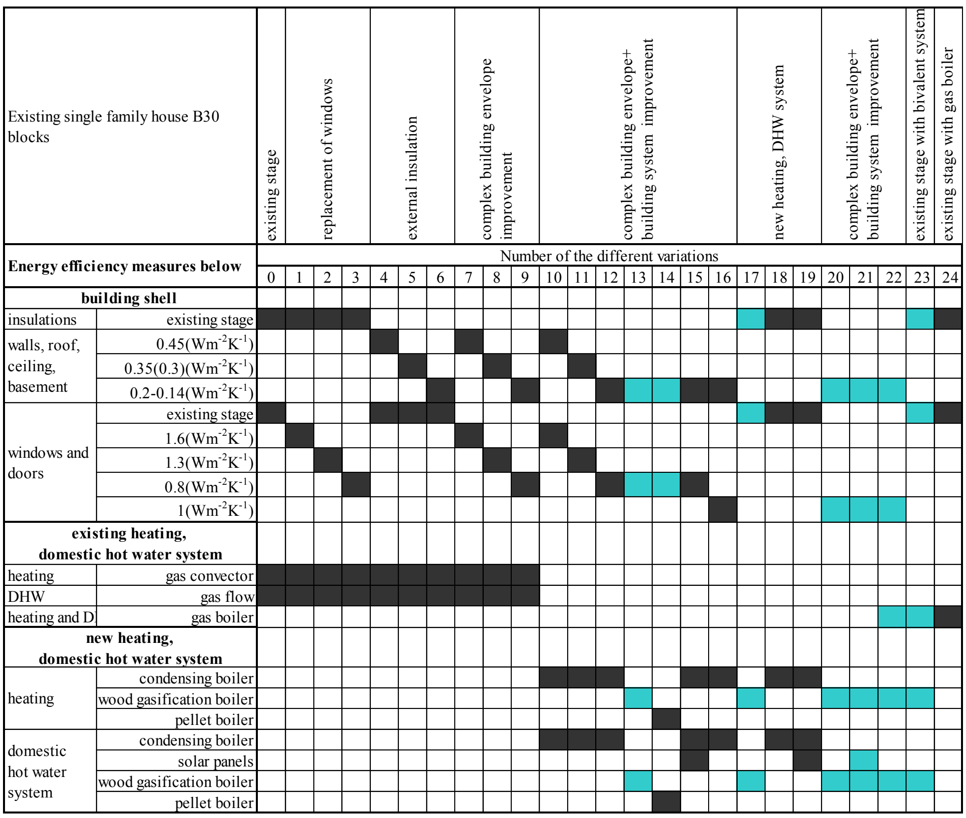

Table 1. Building shell and energy system versions for a reference single family house

The examination followed the next steps:

In the first step, the heating demand was reduced from the moderate to the progressive level by modernizing the energy performance of the building shell (wall, attic, cellar thermal insulation and replacement of windows), by building elements and their combination, and then such combinations were examined. Following the reduction of heat demand, combined alternatives were analyzed with various engineering solutions and the use of mandatory renewable energy sources. calculations based on the 7/2006 Decree by the Minister without Portfolio of Hungary. [12]

In the reference single family house, we looked at 24 really feasible alternatives for modernization. For combinations, see table 1. The results of the analysis are given in figure 9. The optimum solution No.20 is a complex refurbishment, based on wood heating.

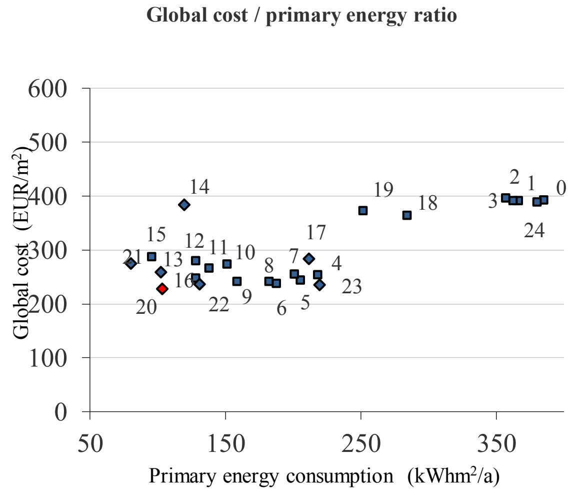

Figure 9. Global cost (EUR) in function of building shell and energy system combinations. Numbers identifies the combinations in Table 1.

However, the life-cycle CO2 emission examination of biomass firing, it can be established that it is by no means CO2 neutral. Depending on the fuel, fuel production and transport may show significant CO2 emission values which might be even higher than those of the production of natural gas.

During our research, we have examined whether life-cycle CO2 emissions show higher values for biomass or natural gas use, considering different transport distances.

Harmful emissions of buildings calculated by life cycle have been determined in two parts.

5.1. Emissions from fuel production and transport

a, CO_2 emissions during biomass production and transport (pellet, chip) was calculated on the basis of the Solid and Gaseous Biomass Carbon Calculator 2.0. [13] The calculator uses the Life Cycle Analysis defined in Renewables Obligation Order [14] and in the Renewables Obligation, in the Ofgem Sustainability Criteria Guide [15].

Our calculations were carried out with the delivery of the fuel to the house included.

During the calculation, the following phases can be considered in the user chain:

Chip production:
1, Corp production (fully for firing)
2, Harvesting
3, Drying (artificial, natural)
4, Raw material transport (by land to place of processing)
5, Biomass processing / conversion to chip
6, Fuel transport (by land to storage)

7, Storage
8, Fuel transport (by land to place of use)

Pellet production
1, Corp production (fully for firing)
2, Harvesting
3, Raw material transport (by land to place of processing)
5, Biomass processing / conversion to pellet
4, Drying (artificial,)
5, Biomass processing / conversion to pellet
6, Fuel transport (by land to storage)
7, Storage
8, Fuel transport (by land to place of use)

In the production of chips and pellets, the following CO_2 emission values were received taking into account the production-specific production chain. (figure10).

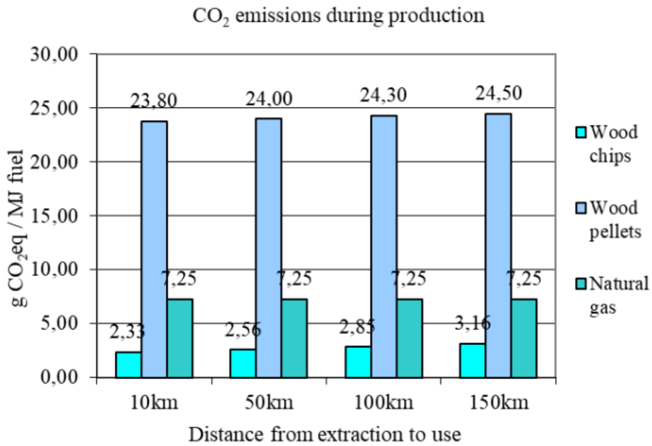

Figure 10. CO_2(g) emission of biomass production

b, Emissions from the production and transport of natural gas come from the SHALE GAS UPDATE FOR GHGENIUS study by (S&T)2 Consultants Inc. [16]. The emission value given in the report is as in Table 2.

Table 2. Emission value for producing natural gas

Natural Resources Canada	g CO_2eq / MJ fuel
Natural gas upstream emissions	7, 25

The method of calculating the emission values of natural gas production and the size of the final result vary by country, but for comparability, the above two results are accepted because of the available and traceable calculation method.

5.2. Annual CO_2 emissions of the reference building according to EPBD calculations

a, When using chip
b, When using pellet
c, For natural gas

The calculation methodology is based on the EPBD directive. The amount of carbon dioxide produced during the combustion of wood was constraint during the growth of tree. This constraint in the forest has improved the air quality of the environment. During combustion, emission happens in a residential environment (if not power plant use), so that the emitted pollutants return to the living environment and pollute it. The final results are aggregated to give CO_2 emissions values for producing natural gas and biomass during 30 years lifetime of the sample building (figure 11) as it is calculated in Table 3.

Table 3. Emission value for producing natural gas

Domestic hot water + Heating production	Energy demand E(MWh/y)	Energy demand E(MJ/30yrs)	Fuel carbon intensity (g CO2eq / MJ fuel)	CO2 emission of fuel production of sample building during 30 years (g CO2eq)
chip	16,19	1748520	2,33	4 074 020
pellet	18,42	1989360	23,80	47 346 768
gas	12,1	1306800	7,25	9 474 300

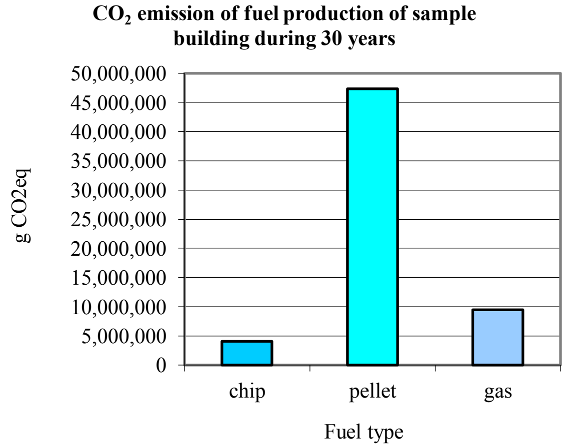

Figure 11. CO_2 emission of fuel production of sample building during 30 years

6. Summary

Cost-optimal calculations, as defined by the European Commission, have in many cases resulted in a biomass renewal version as cost-optimal, on the basis of which EC advisors recommend the use of significant biomass at nZEB buildings.

These studies do not take into account that:

Biomass production has territorial limits in many EU countries.

Taking advantage of regulations in many Member States, the amount of yearly primary energy demand is favorably influenced by the low primary energy conversion factor determined by the very states; besides the annual heat demand does not decrease in naturals. Therefore, nZEB buildings may use more energy through biomass firing than in gas heating.

The Commission advisers suggest that biomass fuel should be used to reduce CO_2 emissions, even if the availability of this fuel is limited in Europe. The CO_2 neutrality of biomass is not real. It is true that the emission of gas firing far exceeds that of wood firing, but emissions from the production of natural gas might be lower than that of the production of certain wood products. Overall, the lifecycle-based emission of biomass firing for the most converted fuels is already significant. In the case of wood combustion, the local pollutant emissions are significant, while the CO_2 constraint occurs in the forests.

Design transformation from standard conformity to Net Surplus Energy

Trinius W

Ingenieurbüro Trinius GmbH, Barmbeker Str. 9a, 22303 Hamburg, Germany

trinius@trinius.de

Abstract. The energy performance of buildings directive requires all new buildings to be near zero by 2020. With that target year approaching, the lacking definition of what "near zero" actually means becomes increasingly prominent. While a weak definition threatens to undermine credibility of near zero claims, it is both environmentally profound, technically feasible and beneficial with regards to user qualities and indoor comfort aspects to plan and build net surplus energy and carbon neutral houses.
One goal of the project was to demonstrate that established building developers can shift their building practice to deliver surplus energy homes – without leaving their range of experience.
After analysing the base-line-design, incremental improvements focused on optimising the building envelope, including thermal bridges, air-tightness, fault-free insulation. The remaining energy demand is covered entirely from locally available renewable sources. Key elements are building integrated PV and power storage, geothermal heat pump for heating and warm water, ventilation system with heat recovery and LED lighting.
The PV installation is designed to generate more than twice the energy needed by the building and the users, providing that surplus to electric mobility applications. Displacing electricity purchased from the grid and displacing fuel combusted in vehicles is key to life cycle carbon and cost optimisation.
Energy efficiency is not in conflict with user comfort, especially not with daylight aspects or with architectural design. The successful merger of a wide range of sustainability aspects was highlighted by this building being category winner of the international activehouse awards 2018.

1. Introduction

Buildings account for 36% of global final energy consumption and nearly 40% of total carbon emissions [1] [2]. These generalised numbers include the energy demand in building operation as well as material-related contributions. Despite increasingly restrictive regulation on the energy demand of buildings in operation, the use stage typically remains being the main contributor to the life cycle environmental impacts of buildings.

Consequently still, the key strategy to reduce building related environmental impact remains to optimize the building layout to create a profound basis for energy efficiency; to energy demand in operation and to optimize the supply of the remaining energy demand, preferably under consideration of locally available renewable energy sources. While successfully optimizing the building however, material-related environmental impacts will increase in their relative importance, and from a certain energy performance level on, the strategy for further improvements will need to increasingly consider the materials.

The European energy performance of buildings directive [3] defines the target that all new buildings are to be “nearly zero energy buildings” by 2020. Currently, there appear to be two major problems associated with that target. Firstly, it is not defined what “nearly zero” actually is. This leaves room for interpretation when national or regional authorities are to apply the directive in their building regulation. Further, if buildings are to be nearly zero by 2020, this would need to be planning reality today. Planners ought to design buildings with highest levels of energy performance as standard practice. Meanwhile planning reality appears to be far behind.

2. Practice Case

This built case is based on the rather unique setting, that we as sustainable building consultant are the owner and user of the building. Often claimed lack of interest of the building client being a core obstacle to design and develop energy efficient buildings here obviously was not the case. Due to contractual agreements of the former owner of the plot, the building site was linked to a building developer, neither the selection of an architect or the building company was free.

The initial key task was to find a route that would enable the owner to get the desired surplus energy building without forcing the construction company into solutions, obligations or liabilities beyond their experience. Not including these performance goals into the contracts and at the same time acting as consultant to the designers and buildings solved these concerns. Consequently, the design optimization started with an analysis of the typical construction solutions applied by the company, and by acting as energy and sustainability consultant to the design team.

3. Conceptual Design

Besides the initial design and room concept, the ambition to create at least a net zero energy building, was set.

The ambition on energy performance was paired with the explicit vision on the future living environment, with key aspects of a melting interior-exterior boundary where rooms would expand from the inside to the outside, and where the availability of daylight with the experience of daytime and seasonal shiftings was a paramount interest.

The distribution and orientation of rooms followed a detailed discussion and analysis of how and when rooms would mainly be used. At those times, they ought to have daylight access and views to preferably at least two directions. The orientation to access to sunlight as well has a positive influence on the energy demand, where however care must be directed to both the winter-case as well as the summer-case.

The L-shaped footprint with rather narrow dimensions allows all rooms with a residence function (living room, kitchen/dining room, master bedroom) to be flooded with daylight from two opposing directions. The living room features a floating gallery, open to the second floor’s roof top, including north-faced skylights. The shape of the room acts as a light-chute.

Inspired by the active house concept [4], health, comfort and wellbeing, energy performance, environmental aspects and an overall feasible economy were the paramount objectives for the building design.

4. Active House Concept and Sustainable Building

The active house vision states that “Active Houses are buildings that create healthier and more comfortable lives for the occupants without negative impact on the climate – moving us towards a cleaner, healthier and safer world.” [4] Compared to sustainable building assessment schemes, like for instance DGNB [5], the scope of considered aspects is focussed on selected aspects, but still addressing a wide range of issues, a full comparison can be found in [6].

A stand-alone single family building is often challenged from a sustainability perspective, as an array of aspects are typically difficult to mitigate. Due to their extensive use and their typical location, single family buildings show disadvantages in terms of area demand, influence on urban sprawl, generation of traffic load, demand in infrastructure and - measured per useful floor area – relatively high material and energy demand.

On the other hand, smaller houses often show a realistic potential to supply their energy demand from building or site integrated renewable energy sources. The relatively large roof areas and the site here provide advantages.

The ambition in terms of sustainability was that the building would generate the building related energy demand locally from renewable sources, would supply the users energy demand as well, and would generate an additional surplus to provide electricity for a significant share of the commuter traffic to be carried out by electric mobility solutions.

5. Design Transition and Result

The beforementioned starting situation included a selected construction company having no practice in the design or construction of zero-energy buildings. The applied material and construction method rely on massive construction, including concrete slabs and sand-lime bricks. The energy performance of their standard building would outperform German energy performance regulation by roughly 15 to 20%.

Based on the conceptual design of the building, an early energy demand calculation based on the builder's standard solutions was carried out. Key features of the changes then were:

- Increased insulation thickness (+20%) in all construction elements in the thermal envelope
- Increased thermal resistance (+10%) of all insulation materials
- Controlled mechanical ventilation system with heat recovery
- Windows and external doors according to passive-house performance levels
- External solar shading to prevent summer-heat loads
- Careful design of thermal bridges
-

While all these measures are far from radical, they are highly effective. The selection of where to apply which changes has always been discussed with the construction company and the craftsmen involved. That way, both avoidance of exorbitant cost increases and practical applicability on site could early be integrated in decision making.

The optimisation resulted in a heating energy demand of 17 kWh/(m^{2}a), the share of the building related energy demand is provided in figure 1 below.

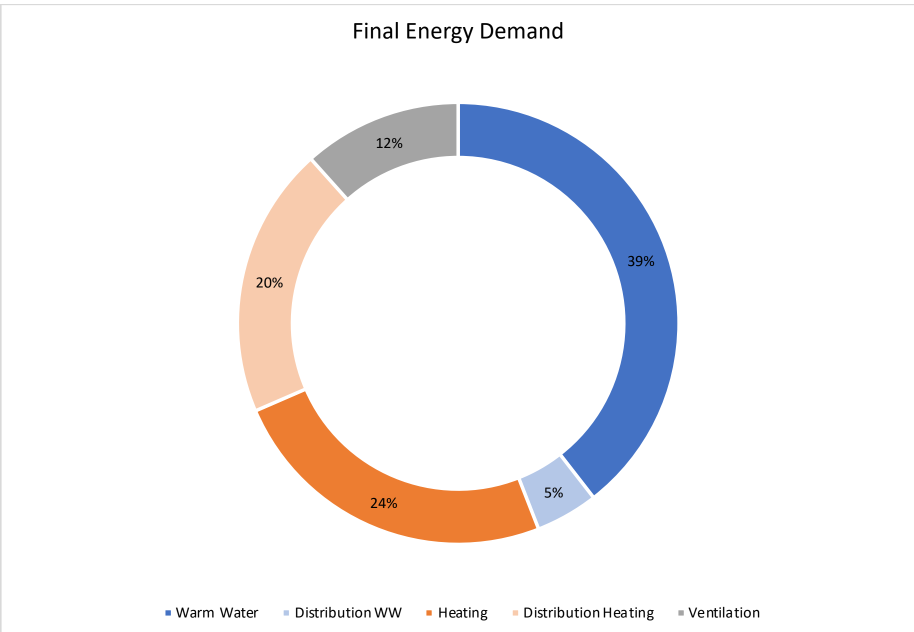

Figure 1 – final energy demand expressed as share of the total building demand in kWh per year

The following step of the design was to implement an energy supply based entirely on locally available renewable energy sources. In this case, the system features:

- Geothermal heat pump system with a COP-factor of 5.2
- Natural cooling function of the heat pump system to ensure summer comfort
- PV installation with 8.8 kWp
- electricity storage system
- domestic hot water storage system

The PV installation geometrically suits the roof shape. For prediction of the annual energy generation, several tools have been applied, amongst them the passive-house planning package [7].

According to the calculated energy demand and supply, the building will have a net-energy demand in November to February, all other months will provide a surplus energy. In reality, the PV generated the energy required for heating and hot water throughout November 2018, but could not supply the user-related electricity demand. After a few months of building operation, the real energy balance appears slightly better than predicted. Figure 2 below shows the calculated energy balance of the building, where the amount of energy available for e-mobility is assumed to apply all net-remaining energy. As the electricity storage is currently not at maximum capacity, but possible to be expanded to 40kWh capacity, some of that energy might actually by fed to the grid instead.

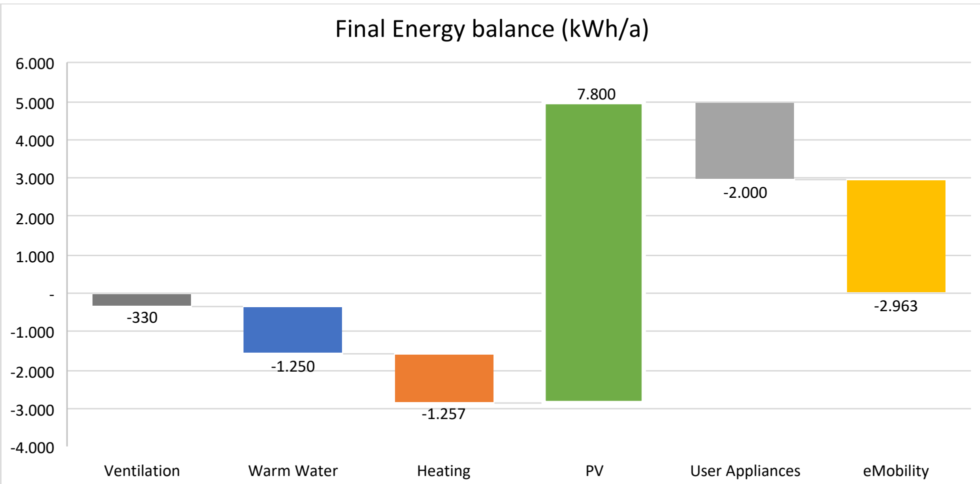

Figure 2 – final energy balance including building energy, PV generation, user and mobility

The energy surplus can basically be applied in two ways, it can either be fed to the grid, or be used for e-mobility applications. The latter is largely preferable, as the feed-in-tariffs for feeding electricity to the grid are not as attractive as a couple of years ago, with current feed-in tariffs lying at about 10ct (EUR cent) per kWh, while purchasing electricity from the grid lies at about 30ct. The more attractive option is to use the electricity for e-mobility, effectively replacing fuel combusted in cars.

The effect can be highlighted by figure 3, showing the CO2 emissions or savings associated with applying PV power instead of the German electricity grid mix.

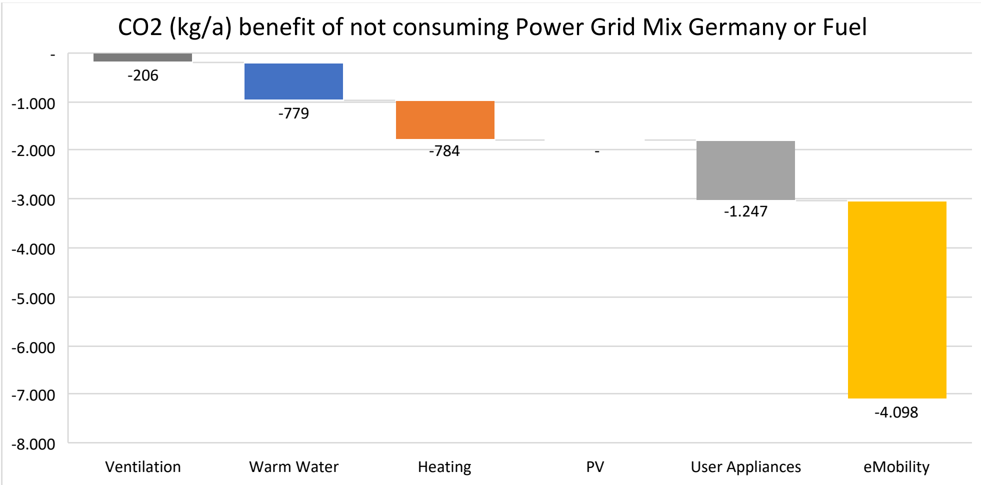

Figure 3 – CO2 benefit of replacing German Power Grid mix, respectively fuel (gas) for mobility, based on energy amounts from figure 2

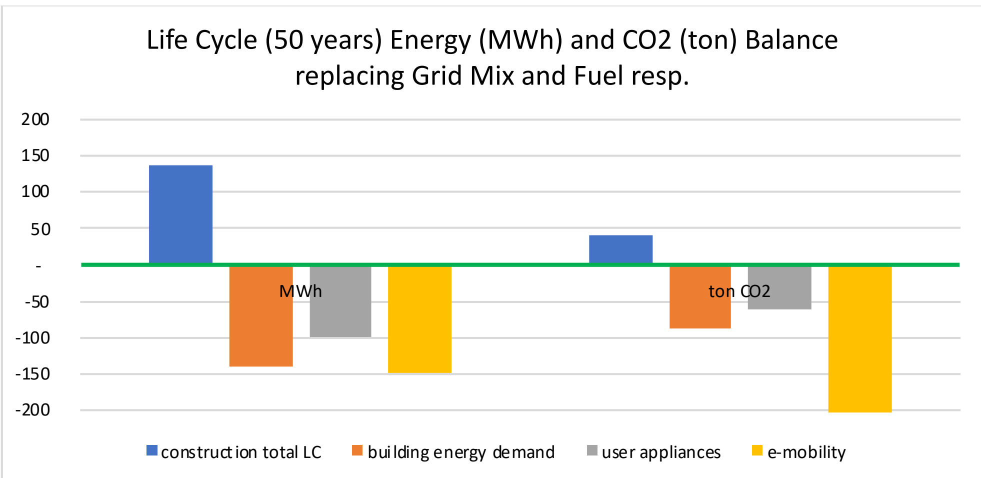
For a consideration of the life cycle impact of the design transition, a building LCA according to the DGNB calculation parameters has been carried out. The LCA includes the construction of the building, future impacts related to deconstruction and waste management (including potential benefits of material recycling or incineration) and includes the use stage calculated for an assumed operating period of 50 years.

Below, the carbon indicator (global warming potential GWP) is presented as an example for the LCA results. The building construction results in a significant carbon footprint, mainly related to concrete, massive mineral materials, glazing etc. Figure 4 presents three lines starting from that initial carbon footprint. The first (orange) line including construction and building related energy demand for heating and domestic hot water (this corresponds to the scope of energy performance of buildings regulation). The line continues horizontally, as the energy demand is covered by PV, not contributing to CO2 emissions.

The second (grey) line includes user appliances. The line tilts to negative, as the energy is provided by PV and replaces German electricity mix and its associated emissions. With that scope the building is carbon neutral after roughly 35 years or operation

The third (yellow) line additionally includes the remaining energy surplus being fed to mobility and replacing fuel and its standard emissions. The electricity as well as the fuel consumption are calculated from the real consumption data of the user (not based on test cycles) and the CO2 emissions are read from data published by [8].



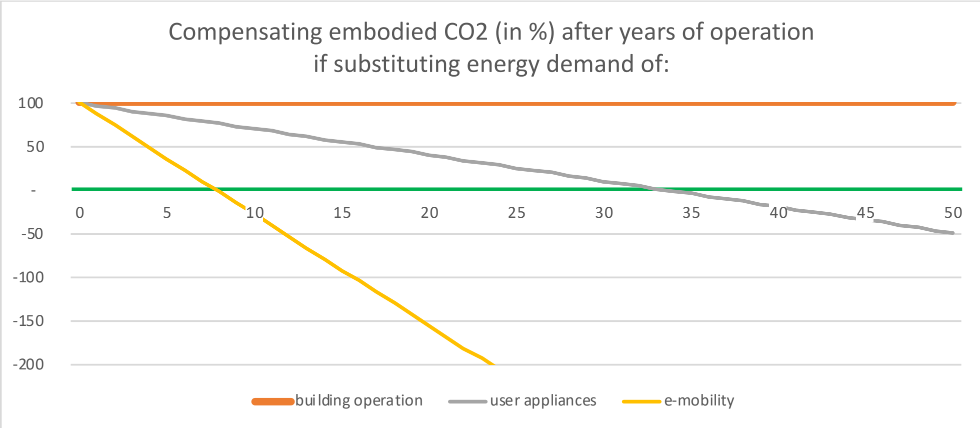


Figure 4 – Life Cycle Energy and Carbon balance, Time to Carbon Neutrality

6. Conclusion and Discussion

The presented building clearly demonstrates that it is without doubt possible and feasible to not only build nearly zero energy buildings, but surplus energy buildings. Not in the future, but today. The building demonstrates that it is possible to achieve that goal without needing to rely on a specific building and construction concept, but that it rather is possible to reach that performance level with a standard builder applying their normal but refined building concept. Also, the active house concept indicates a route that combines energy efficiency with quality and wellbeing aspects, demonstrating that there is no other side of the coin of energy performance.

Meanwhile required of course is that the building client has clear ambitions and that the planners are able to or supported in delivering to these goals.

Conducting cost assessments of design options and environmental assessments of the options as well as of the finalized building design allows to direct resources to where they are most efficiently and most effectively being used. In our case, the expansion of the system view – to include non-building related aspects of the users life, in this case the demand on mobility, clearly indicates that the surplus energy being applied in mobility currently spurs the carbon payback as well as the cost effectiveness.

The building has been awarded as category winner of the international active house alliance 2018.

Abstract. Nearly Zero-Energy Buildings (nZEBs) will be the standard for new constructions in Europe from 2019 (public buildings) and 2021 (private buildings). Even though several technologies for realizing nZEBs are already available, their market penetration in Europe is still low. This can be ascribed to both high initial investment for nZEBs and limited adequate business models for several stakeholders along the buildings' lifecycle. The aim of this paper is to present and analyse examples of existing business models for nZEBs in different European countries. A broad overview of these business models, accompanied by evidence of their key factors and strengths is essential for developing new business models that ensure a cost-optimal nZEB implementation and adequate profitability for all stakeholders involved. Therefore, at first business models of different European markets and nZEB lifecycle phases are searched for and described in a profile-like manner. Secondly, the key factors and strengths of each business model are pointed out. In the end, a cross-comparison of the business models is done according to some key parameters, such as involved stakeholders and covered life cycle phases. This knowledge serves as a basis for the development of innovative nZEB business models. The work presented in this paper is developed in the frame of EU funded project CRAVEzero – Cost Reduction and market Acceleration for Viable nearly zero-Energy buildings which is co-funded by the Intelligent Energy Europe Programme within the Horizon 2020 Framework Programme of the European Union.

1. Introduction and Objective

1.1. Introduction

High investment costs and the lack of business models that are both reliable and economically viable for companies have been identified to be among of the main obstacles to nearly Zero-Energy Building's market-uptake [1]. Thus, in order to allow for the nZEB market acceleration needed to ensure Europe decarbonization objectives, solutions and innovative business models need to be developed. They should be reliable and predictable in terms of costs and thereby reduce a company's uncertainties and economical risks. Simultaneously, these models should be efficient enough to provide offers at reasonable price or/and with convincing benefits for customers.

The aim of this report is to give an extensive overview on the different kinds of business models that exist in the major European markets today. Therefore, CRAVEzero project partners contributed with descriptions of both their own and additional business models found on the internet. Additional business models were retrieved through interviews with companies not directly involved with the project. A comparative analysis of the findings is conducted in order to evaluate whether there are patterns according to different stakeholder perspectives that indicate success potential. Different stakeholder perspectives analyzed include planner, real estate/urban developer, construction companies, general contractor, facility manager building operators. Thus, in this report the business models introduced are actually practiced ones instead of general categories and therefore give more insight. Based on results generated with the analysis, main features useful to attract customer and strategic partnerships to create efficient win-win-situations emerge clearly, as well as phases along nZEBs' life cycle that are still lacking appropriate business models. This knowledge then serves as a basis for profiling new business models focused on nZEBs.

1.2. Objective

A business model is a simplified depiction of the way a complex and profit-oriented system generates, delivers and captures value. It illustrates the systems essential elements. With the term being relatively new in academic discussions and not formally defined yet, business modeling has not reached sophisticated maturity in many companies, especially in the construction sector. As a matter of fact, a number of companies developed certain business ideas and sections that work successfully. However, they often have not defined a complete and exhaustive business model including all necessary parameters required to describe its functioning. Usually, looking at one's own business from that perspective can be eye-opening. Gathering business ideas of companies, as it is done for this report, has a similar effect. It broadens the horizon of what is possible and in which manner. Most importantly, though, it spots business areas that are not covered yet or parts of business models that either help companies to be successful or cause the opposite. Thereby, the objective of this paper is collecting and analyzing existing business models, an essential preparatory step for generating innovative business models.

2. Scope and Methodology

In order to describe existing nZEB business models, a standardized blank profile has been developed. It includes parameters described in Table 1. The parameters are mainly based on the deliberations of Osterwalder and Pigneur [2] and their so called business model Canvas.

Table 1: Parameters of the business model profiles and their description

PARAMETER	DESCRIPTION
Value Proposition	Products, services, features, benefits creating value for the customers
Customer Relationship	Intensity of customer-provider relationship, channels to reach the customers
Customer Segment	Typical Customer group that the product/services is directed at
Activities and Capabilities	The most important activities a company needs to conduct in order to provide the offer and necessary resources required
Revenues	Type of streams a company generates revenues with
Costs	Most important expenditures that incur for the provision of the offer
Maturity	Stage a company is situated in regard to how elaborated and integrated a business model is.
Key Factors and Strengths	The most important factors and strengths that make the business model work successfully.

This profile was used to describe all business models of companies in different European countries and other major European markets. Furthermore, the CRAVEzero-partners described their own business models. The descriptions of third party business models are based solely on information found on companies' websites rather than insider knowledge. The work therefore does not claim to provide all information about the business models, nor it can be guaranteed that the information given online have been interpreted correctly. However, descriptions aim to provide an overview of different existing business models in various major markets (Germany, France, Italy, Sweden, Austria, Great Britain, Belgium, and Netherlands) and the variety of offers provided.

After collecting information on business models related to various phases along the nZEB life cycle, a comparative analysis was conducted. Repetitive patterns are highlighted and common strengths and key factors are identified. In the end, the key findings of the analysis are described.

3. Analyzed nZEB-Business Models

In a first step, 17 business models, provided by the project partners, have been analyzed in depth (see [3,4]). The business models are mostly performed by the companies directly benefitting from the project and have therefore been described based on first-hand information and experience. In addition to the 17 business models, more nZEB business models of the European markets were collected and described. In total, 60 business models with more than fifteen different stakeholder perspectives and for all stages in a building life-cycle were analyzed. The Business models cover several different stages of a building's lifecycle as shown in Figure 1. Figure 1 also shows that there are stages in the life cycle with many business models available (e.g. Planning, Construction), and stages with only few models (e.g. Political Decision, Monitoring, Recycling/ Dismantling/ Reuse). Detailed descriptions of the analyzed business models can be found in [2].

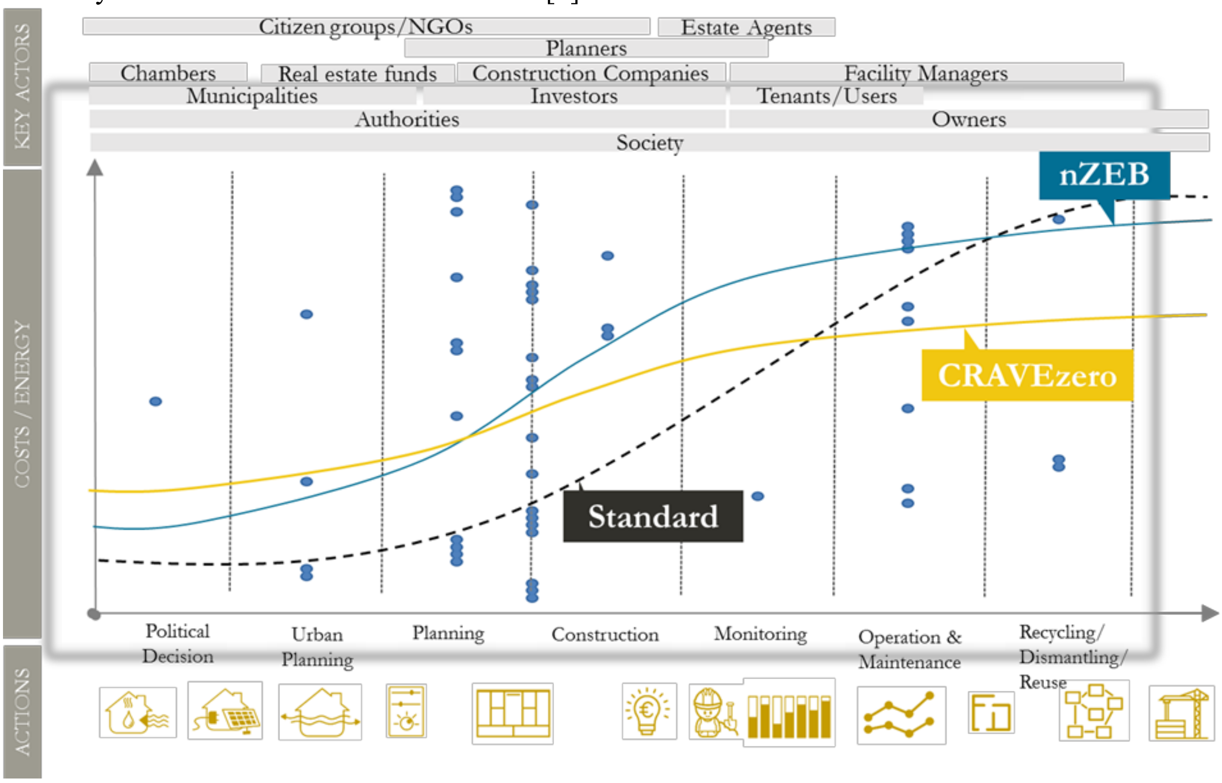

Figure 1: Life cycle phases of nZEBs and Business Model allocation

The business models are categorized according to their stakeholder perspective as follows (the number of analyzed business models is given in brackets):

- Cooperative in Real Estates (1)
- Energy Service Company (6)
- Engineering and Construction (9)
- Facility Management (4)
- Planner (6)
- Real Estate Developer (2)
- User/owner (1)
- Urban Planner (1)
- Certifier (1)
- Consultancy (2)
- Financier (2)
- General Contractor/ Developer (7)
- Political Entity (2)
- Promoter & Information Provider (2)
- Trading Platform (2)
- Vendor (7)
- Research Entity (3)
- Other/ not defined (2)

4. Results of the Business Model Analysis

Results described in the following are based on [2]. The paper presents only the most significant results in detail. However, in the discussion below, also additional results from the cross comparison of the analyzed business models within the CRAVEzero project are shortly summarized.

4.1. Value Proposition

The value proposition describes products and services offered to the market, how benefits for customers are created by relieving pain or creating gains, as well as supporting customers to manage and achieve a certain task. Figure 2 shows the value propositions offered within the collected business models in a comparative analysis. The most common features/ values of the business models are green labels and sustainability; comfort and innovation, (energy) cost reductions and efficient energy performance. Furthermore, the focus on good quality customer services is essential for many analyzed BMs. All these features can be found in BMs of different stakeholder perspectives. Features like customization, the increase of a building's residual value and products' durability, as well as a focus on social responsibility within a company's offer are less common and depend on the stakeholder offering the service/product, often very focused product manufacturers or service provider.

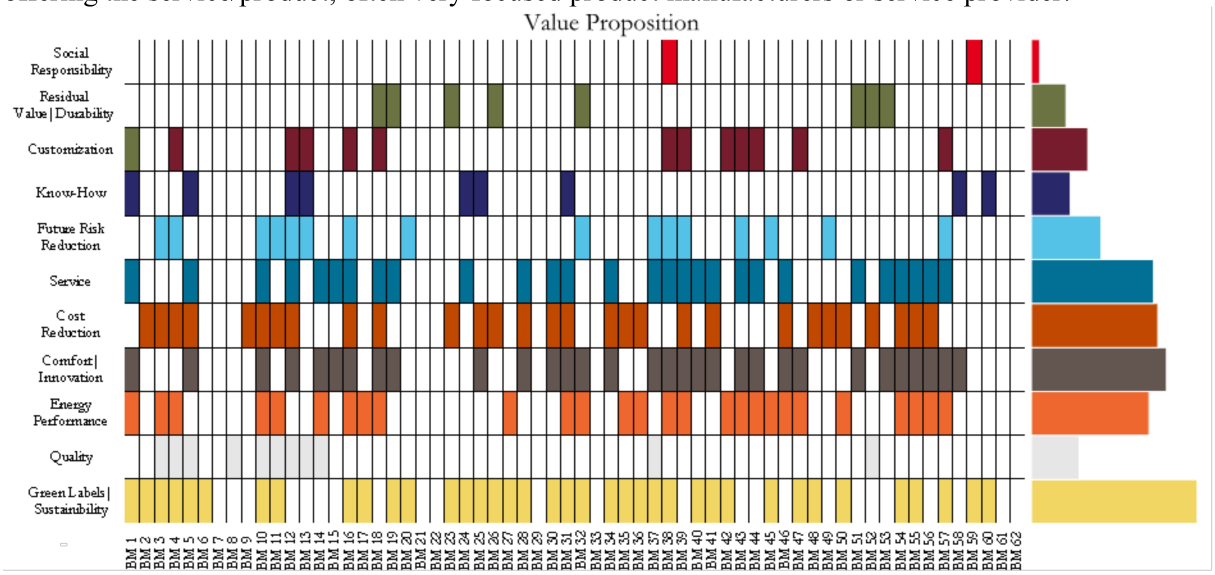

Figure 2: Comparative analysis - Value proposition

4.2. Strengths and Key Factors

The strengths and key factors identified in the analyzed BMs are summarized and compared in Figure 3. These factors contribute to the success of a business. The identification of these factors is important both for the enhancement of existing BMs and for the creation of new innovative ones.

Comparing the collected BM, patterns of common strengths and key factors become apparent. To simplify the analysis the business models are clustered according to different stakeholder perspectives. The most recurring strengths and success factors are: widespread competencies (all services in-house) as well as lock-in, which describes the ability of a company to create and maintain good customer relationships. Thereby the companies are able to convince customers to purchase, win their trust and create long term relationships. Know-how, innovation and sustainability as well as guaranteed prices/ performances are also common strengths and key factors. More specific and less frequently mentioned is the capability of prefabrication, which allows faster building process, and supports the company's image.

For General contractors, scalability (up/down scaling the resources depending on the project size) seems to be important, while real estate developers benefit from having influence on the (political) decision level. Vendors of technical equipment and materials take the whole life cycle of their products into account, take care of waste reduction and stress transparency as well as a strong customer relationship. While developers and general contractors cover the full range of services along the building's life cycle, planners often focus their expertise on a specific and confined planning phase. Innovative planning tools and the capability of using them efficiently are important success factors for planning and design businesses. This includes know-how in the field and experienced and well trained employees. Besides the internal competencies, many nZEB BMs strongly depend on the collaboration of different partners and stakeholders.

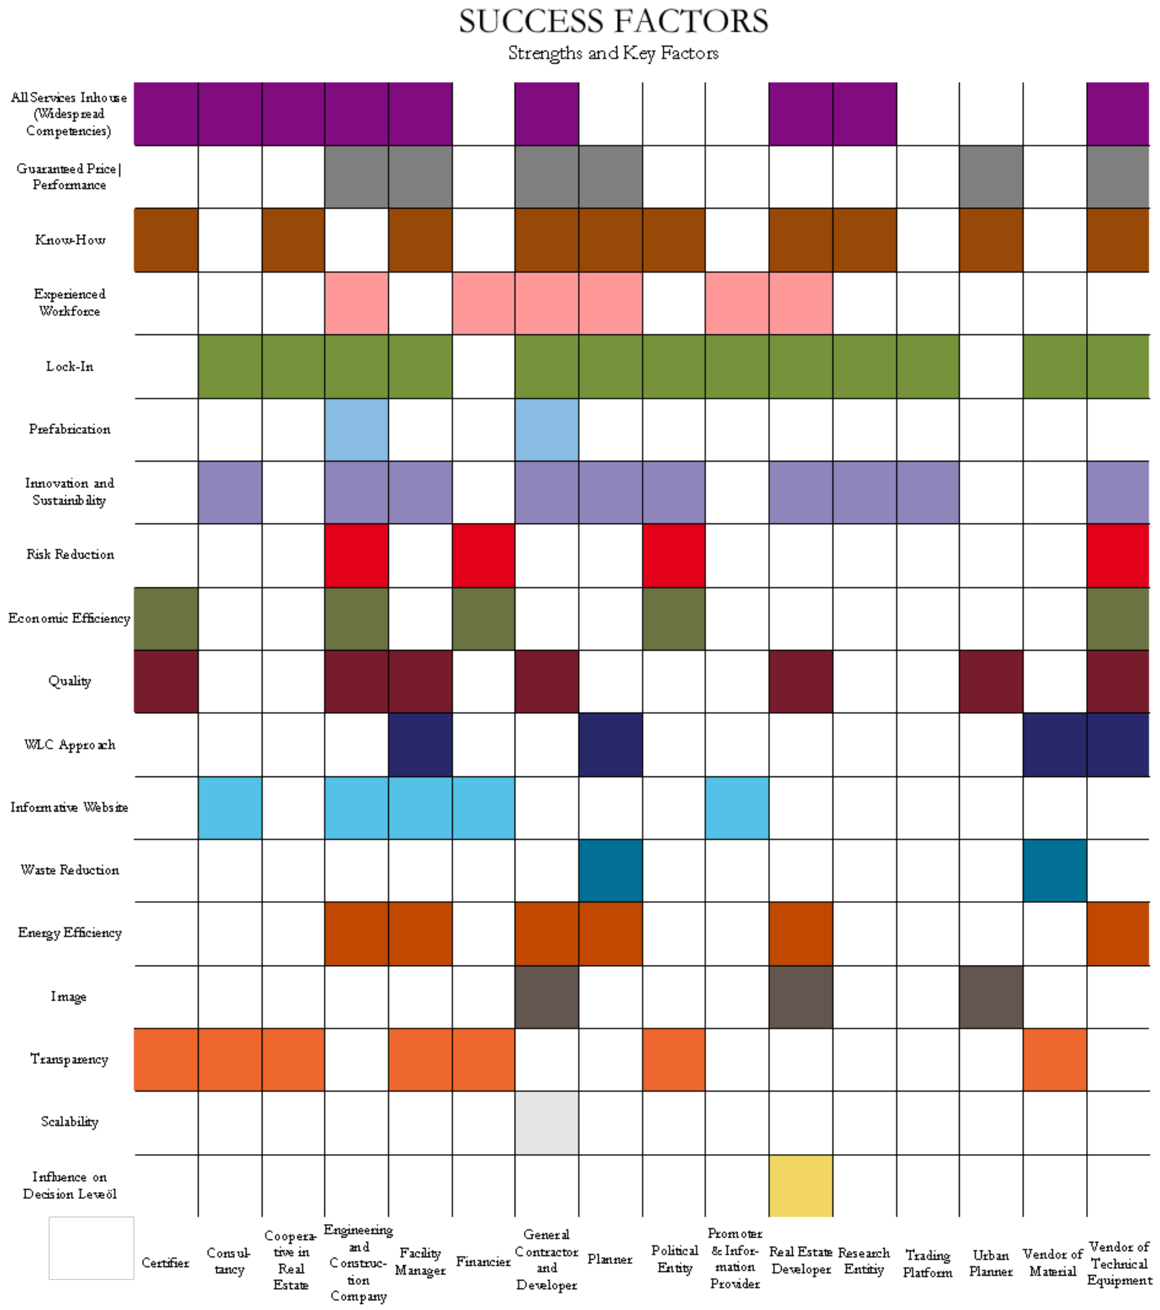

Figure 3: Strengths and Key Factors as factors of success for the Business Models

4.3. Life Cycle Phases

The different nZEB life cycle phases covered by the collected BMs are shown and described in Figure 1. It becomes apparent, which phase still runs behind in terms of business models availability (e.g. Political Decision, Monitoring and Recycling/ Dismantling/ Reuse).

To get an overview of the different business models that evolve around nZEBs, the entire life cycle of a building needs to be analyzed. This includes the phases of political decision-making, urban planning, technical design, construction, operation, maintenance and renovation, as well as dismantling and recycling at life-cycle end. In each of these phases various stakeholders are involved in the buildings life cycle while trying to capture value with their business model. Within CRAVEzero 17 business models of project partners and additional 43 BMs of European markets have been analyzed. Most BMs are in the planning and construction phases. Only one business model has been described for the political decision or monitoring phase. This latter can be a supplement to existing models or be done with partnerships (business model packages). The same could apply for BMs in the recycling/dismantling and reuse phase where only few have been found so far. Here, plenty of room for new business ideas is given.

Comparing the life cycle cost of a Standard building, a nZEB and a CRAVEzero building (see Figure 1), some substantial differences may be observed. At first sight, a standard building seems to be the cheapest solution; in fact, political decision and planning phase have lower costs, however this leads to higher follow up costs. On the other hand, nZEB buildings show greater efforts in the first planning phase, which allows to optimize the following phases. Due to careful study and detailed work during the planning and construction phase, it is possible to have some benefits: monitoring, operation, maintenance and renovation phases involve lower costs. In the CRAVEzero building the goal is to give even more importance to the planning phase leading to higher costs in early stages of the building's life cycle. This additional effort, however, lowers the cost in the following stages. It leads to an improvement of the management of the building and the follow up costs such as energy consumption, operation and maintenance costs in all phases will be lower.

5. Discussion and Conclusion

The results of the comparative analysis are discussed and summarized in the following. Especially noticeable insights, saliences and special learnings are pointed out.

A comparative analysis based on the information of the business model profiles is conducted in order to evaluate whether there are patterns according to different stakeholder perspectives that indicate success potential.

The analysis of the value propositions shows that the most common features have been identified to be green labels, sustainability, energy and cost reductions and efficient energy performance. The usage of renewable energies and sustainable materials is a value that the customer requires to the company in order to increase the efficiency and the value of the building. The customer relationship is a very important point as it is the beginning to build trust. The main way customers get in touch with the company is the website: here it is possible to see references and past projects, with the description of the problem, solution adopted and benefits obtained. Another point that characterizes a business model of a company is the customer segment, described by location, demographic, financial and functional characteristics. Building owners are the most frequently mentioned segment, followed by companies, investors and municipalities. Regarding activities and capabilities, the main tasks are design/engineering and development of projects/buildings; less common are services such as dismantling, reuse and renovation, facility management, certifications, prefabrication of building parts and grid services.

Since the aim of a company is to capture value with their offer, the main sources of revenues are related to asset sales and additional services for administration, management and maintenance. Accordingly, the main costs of a company are represented by personnel expenditures followed by costs for the building and production process and administration/office costs. It could be interesting for future examination how processes can be created or transformed for a better efficiency around personnel related work and to enhance potentials.

The most recurring strengths and key factors identified in the analyzed business models are widespread competencies, know-how, innovation and sustainability and guaranteed prices/ performances. It is important to identify these factors, because they can contribute to a business success or limit the success potential. Finally, the analysis of the maturity stages of business model innovation shows that a company with an established stage has Business Model Innovation as a central topic within the general innovation management of the company.

Energy Flexible Buildings - The impact of building design on energy flexibility

Weiß T[1]

[1]AEE INTEC, Austria

t.weiss@aee.at

Abstract. Thermal load management has substantial theoretical potential for energy flexibility. To use the inherent flexibility in buildings, for example, district heating companies could temporarily control the heating system of buildings to switch-off or preheat dwellings in the morning to avoid using peak load gas boilers. The »thermal flexibility« in this study indicates the tolerance of buildings towards the changes of its heating system operation according to an external signal. The focus of this investigation is to give an overview of »thermal flexibility« of residential buildings in Austria from 1920 – 2020 with different envelope qualities, construction types and heating systems. Existing residential buildings in Austria usually have a high thermal mass within their massive brick or concrete primary structure, and therefore their indoor thermal conditions react slowly to operative changes in the supply of thermal energy. Depending on the buildings ability to retain or store heat **inside** the building envelope, space heating can be used to offer energy flexibility. Among other factors, especially the quality of the thermal envelope, the thermal capacity of the building, the sluggishness of the heat delivery system and passive solar gains are crucial for keeping indoor thermal comfort. Dynamic building simulation in IDA ICE is used to evaluate the potential of selected building typologies to shift heating loads away from peak demand periods. Potentials of various building archetypes according to the EU-Tabula building database to time-shift the operation of the heating system are pointed out respecting occupants' comfort.

1. Background and objectives

Domestic space heating is responsible for about 45% of the total household energy demand in Austria [1]. Especially old buildings before the 1970ies with a high domestic space heating demand have the highest share in the overall heating energy consumption. Still due to their high heat storage capacity, if they have a certain thermal envelope quality, they can stay pleasantly warm for some time after the heating system has been switched off. Austrian buildings before 1970 were often heated by single furnaces as heating systems, and the air-temperature control was depending on how the air supply was adjusted and how the fuel was added to the furnace. Under these conditions, a large heat storage capacity of old buildings was highly desirable and helpful. It reduced the increase in air temperature when there was an excess of thermal heating energy and slowed down the drop in temperature when the furnace was turned off. The heat storage capacity has a »temperature-equalising« or »temperature-stabilising« effect especially useful for uneven or so-called transient-heat-delivery-systems like old furnaces. Under these heating conditions, the heat storage capacity was thus able to compensate for the poor controllability of the heating systems in a certain sense. The larger the storage mass, the better [2]. Most of the old inefficient furnaces and heat delivery systems have been replaced in old buildings in the meantime, often by district heating grid connected heating supply systems or electric heat pumps. With today's low-temperature (compared to furnaces) heating systems and control options, the heat storage capacity has become less important for space heating. Mainly also because the charging of the storage masses by convective heat transfer is incomparably lower than by radiation. With convective heat transfer, the storage mass can at best be charged with the air temperature of the room and not - as in the past - absorb the radiant heat of the furnace. However, with the arising challenge of integrating high shares of renewable energy in energy supply grids, particularly variable wind and solar puts the idea of the heat storage capacity of a building into a new perspective. The concept of flexibility of buildings is to manage their loads based on the requirements of the surrounding grids. In the context of heating flexibility, this means to heat-up the building when there is excess solar, and wind energy available in electricity grids, or renewable heating grids can be operated ideally and reducing heating power at other times. Especially during cold winter periods, control systems in residential buildings can be used to reduce peak demands and take stress from electricity and heating grids [3]. The energy flexibility of heating systems depends on the ability of a building to retain or store the heat inside the building envelope concerning comfort requirements. The amount of insulation, the thermal capacity and the passive solar gains of buildings are crucial for keeping indoor thermal comfort [4] and [5].

The focus is here a quantitative evaluation of the potentials of heating flexibility of residential buildings in Austria from 1920 – 2020 on the level of usable energy. The difference of envelope qualities, construction types and heating systems plays a crucial role in defining the possible heating flexibility of a certain building typology. Dynamic building simulation in IDA ICE is used to evaluate the potential of these building typologies to shift heating loads away from the peak demand periods. Potentials of various building archetypes to time-shift the operation of the heating system will be pointed out, with attention to occupant comfort. With the obtained data, it is possible to offer an estimation of the heating flexibility of prototypical residential buildings in Austria assuming that they are equipped with a grid-connected heating system like electric heat pumps, district heating or direct electric heating. Also, the effect of the insulation level applied to the building envelope as well as the effect of thermal mass on the heating flexibility is analysed.

2. Evaluation Methodology

Heating energy flexibility also referred to as »thermal load shifting« is here defined as the number of hours the energy system can be delayed or forced to operate considering the indoor comfort band as a constraint. For example, when space heating is switched off at the upper excepted limit of the indoor comfort temperature, the indoor temperature remains within the comfort zone for a certain period depending on the level building insulation, ventilation and thermal mass. As the thermal energy inside the building envelope is vanishing, the indoor temperature drops. ΔT denotes the time after which the temperature has fallen from the upper comfort limit to the lower comfort limit, yielding a temperature difference of ΔT [°C]. Other essential definitions are explained in Figure 1.

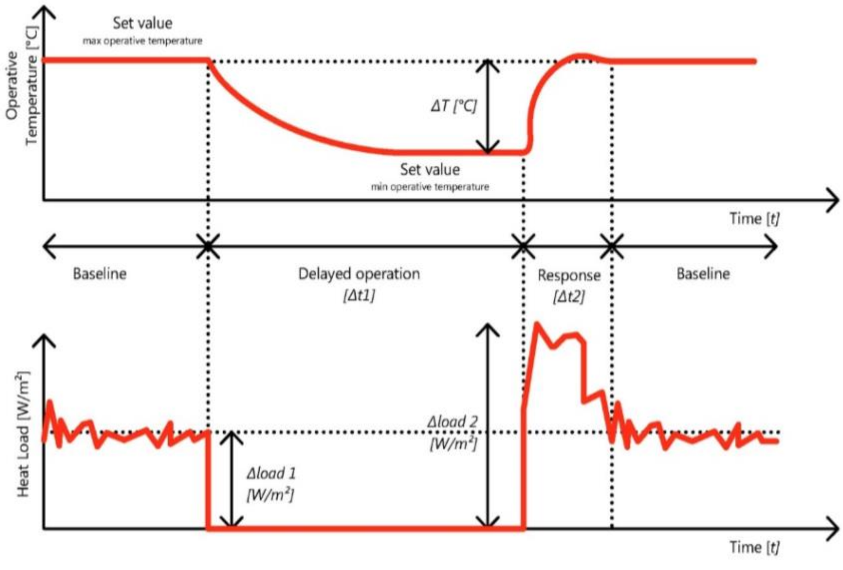

Figure 1 Demand-side control of set temperatures, representation of the cooling-down curve (delayed operation- Δt1) and heating-up time (response - Δt2) (graph based on [9]).

3. Austrian dwellings - Simulation models

The calculation of thermal load management potentials for representative building typologies has been derived from the TABULA/EPISCOPE web database [6]. For the simulation, the weather conditions of the test reference year of Graz, from the 2013 ASHRAE [7] – see figure 2, has been applied. Four different detailed building models with different years of construction and controllable heating systems and defined user behaviour were modelled in IDA ICE. The ventilation and infiltration corresponds to 0,4 air change per hour in order to guarantee sufficient air renewal. All buildings are modelled as a single zone, with the exact physical characteristics derived from the TABULA/EPISCOPE database. Internal heat gains for multifamily buildings according to SIA 2024 [8] have been applied to the building models. The set-point for the indoor operative temperature is 22°C. The allowed temperature band is 22 ± 2°C, and the minimum allowed operative temperature 19°C matches to the PMV-PPD category II of the comfort standard EN 15251 (PPD < 15%, -0.7<PMV<0.7). The influence of different occupancy behaviour on the heat flexibility is not considered here.

4. Results

The resulting load shifting potentials for analysed building typologies defined in Table 1 are presented in the following.

4.1. Delayed operation – cooling down

The simulations were firstly carried out for a characteristic winter week, 16th – 23rd of January, using a simulation time step of 10-minutes. During the working days, the building is non-occupied from 8.00 am. to 17.00 pm. Each occupant emits 80 W due to the metabolism, and the assumed net floor are per person is 30 m². There are also internal gains from appliances during occupied hours resulting in internal heat gains of 13 W/m² as shown in table 1.2. Figure 3 shows the cooling down of the operative temperature after the heating system is switched off. The period it takes for the operative temperature to reach the lower comfort level of 19°C is referred to as the potential »delayed operation« of the heating system. The changes in of operative temperature after switch-off of the heating system on the 16th of January starting at 0:00 is shown in figure 3. When the heating is switched off, the operative room temperature drops rapidly at first and then more slowly. When the room air temperature drops during the first hour after the heat cut-off, the heat stored in the wall returns to the room, and the temperature drops more slowly. Throughout the day, the passive solar gains via the window surfaces lead to an increase in the temperature, which then drops again constantly during the evening and night-time. The positive effect of the passive solar gains during the daytime influences here only the newer better insulated cases (C and D) since the old buildings (A and B) cool down too fast in order to benefit from passive solar gains. If however the switch-off occurred during sunshine, building A and B would also benefit somewhat from the solar radiation.

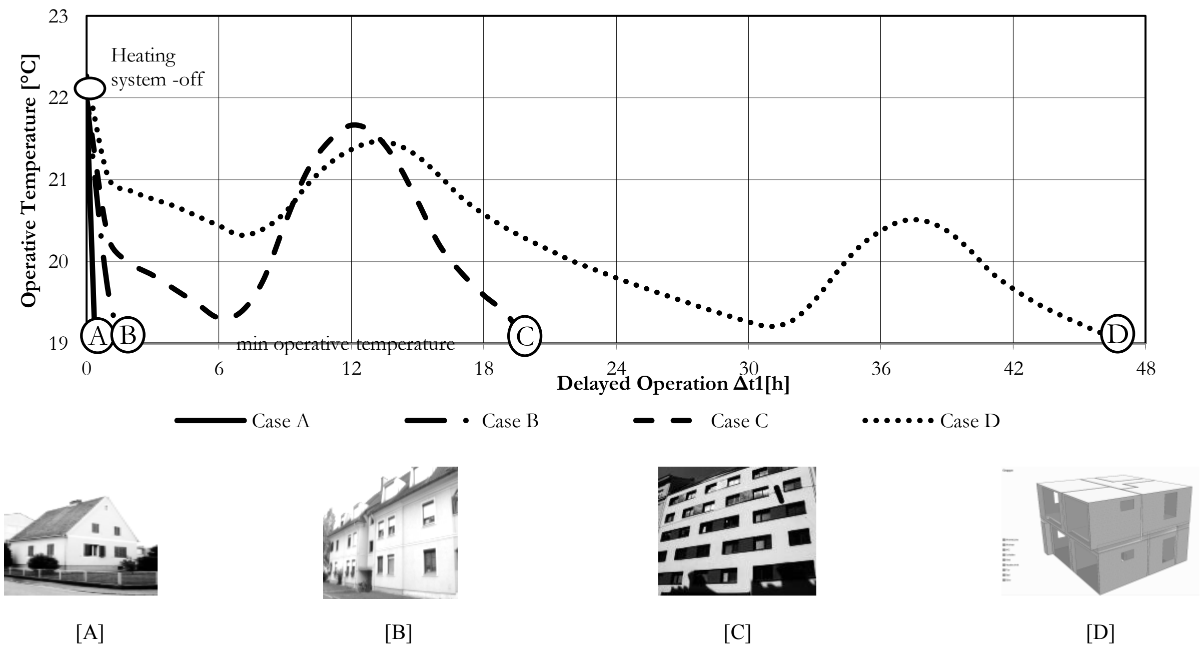

Figure 3 Cooling down time of 4 case studies - delayed operation (Δt1).

It should be noted that the shiftable heating loads are not constant over time as can be seen in figure 4. Further, the average heating power needed to keep the buildings operative temperature at 22°C in this January week ranges from 55 W/m² in case A, 37 W/m² in case B, 18 W/m² in case C to less than 10 W/m² in case D. Buildings with lower heating loads, have longer delayed operation times. Passive solar gains have shown to increase the delayed operation time which is also noticeable in the reduced heating energy power during the daytime These results lead us to the first conclusion: Old buildings, represented in simulation models [A and B], in contrast to new- and highly energy efficient buildings [C and D] have a higher specific performance due to the lower insulation standard. This leads on the one hand to a higher shiftable heating load, but shorter delayed operation periods as seen in figure 3 and figure 4. Figure 5 combines the simulation results of figure 3 and figure 4. The resulting curve displays the delayed operation time (the time that it takes for the room to cool down from 22°C to 19°C) on the x-axis and the shiftable heating power (the average heating power that can be switched off during this period) on the y-axis. The curve shows how long the average specific heating power [W/m²] of the four different building typologies (A to D) can be switched-off while the operative temperature inside the building stays in the specified comfort band of 19°C-22°C operating temperature after the heating system has been switched off.

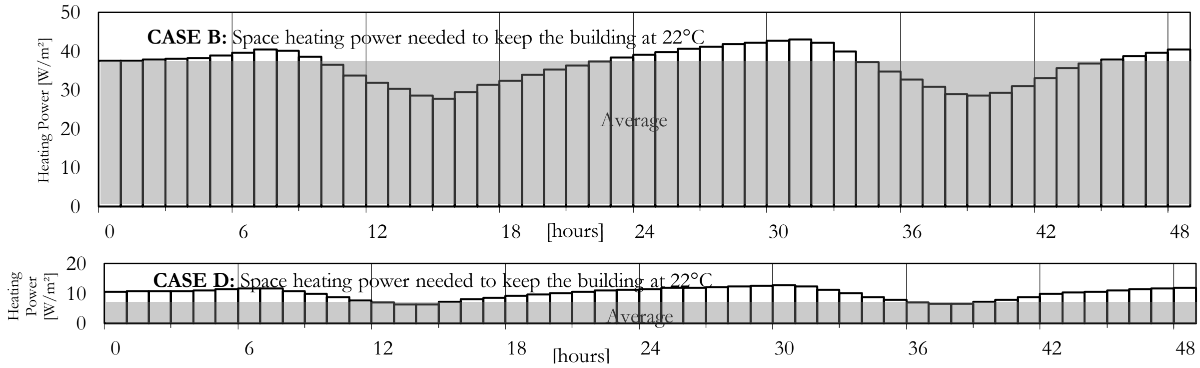

Figure 4 Heating power demand to keep the temperature of the building at a 22°C setpoint temperature (without load shifting) for case B and D.

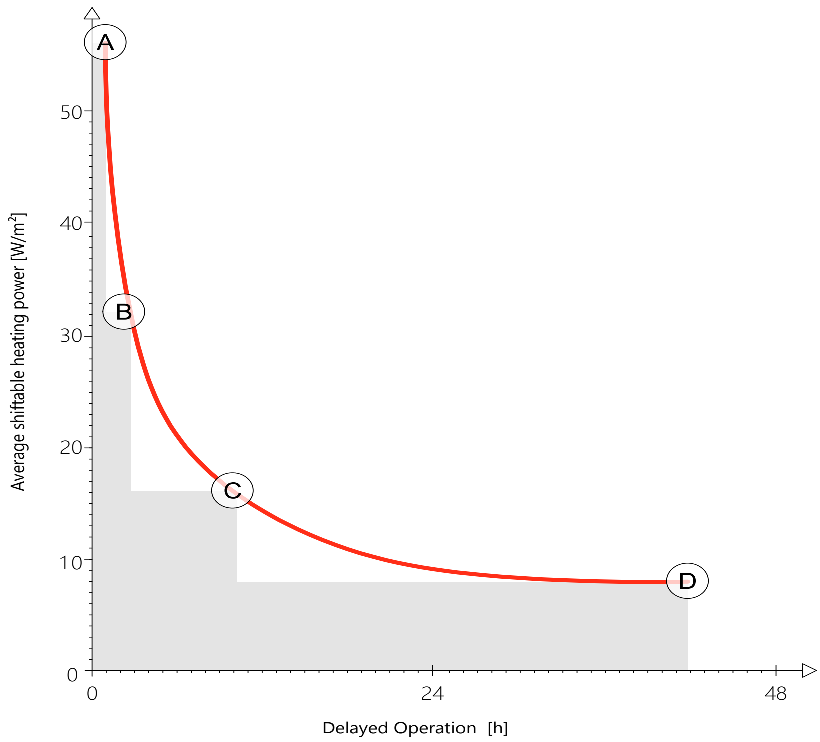

Figure 5 Load duration curves of cases showing the potential of shiftable domestic heating load over time

4.2. Delayed operation – Optimisation

The effect of thermal inertia in relation to energy flexibility has been investigated in detail by (Reynders et al., 2015). Buildings with high thermal mass embedded in the construction, have a huge potential to store heat over long periods. The specific heat storage capacity of the analysed TABULA case studies accounts for approximately 120 Wh/m²K since the buildings all have brick walls and concrete ceilings. Following the primary structure of the case study buildings is changed to a concrete construction (specific heat capacity of construction = 200 Wh/m²K) in the simulation model. Figure 6 shows the effect of increasing the thermal inertia of the building when the heating system is switched off. The larger the storage mass, the slower the building cools down. A heavyweight constructed building in combination with a high insulation standard (case C and D) extends the timespan for thermal load shifting drastically as shown in figure 6. The thermal mass of a concrete constructed building, in comparison to brick buildings, enables it to store more heat.

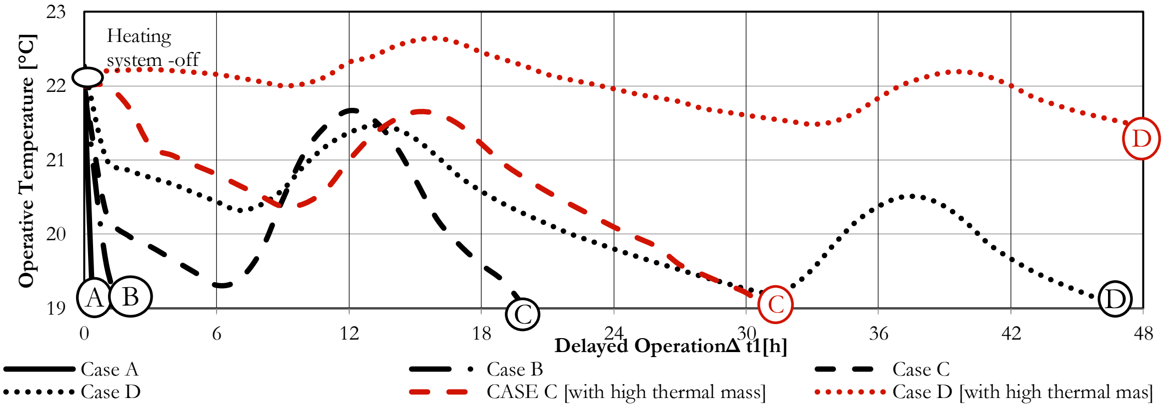

Figure 6 Cooling down time of thecase studies with increased thermal mass for case C and D.

It turns out that the delayed operation time of case study C can be extended from 20 hours up to 32 hours by adding more thermal inertia. This effect becomes even more drastically when adding thermal inertia to the most efficient building, case study D. Here the potential delayed operation time rises by a factor 2.3 from 46 hours up to 102 hours. Figure 7 allows us to explore the influence of shiftable domestic heating loads between heavy and medium-weight constructions, as well as different insulation levels based on the year of construction. The possible off time for case study B, C and C increased considerably, while there is no increase for case A. The latter due to the large losses through the poor thermal envelope.

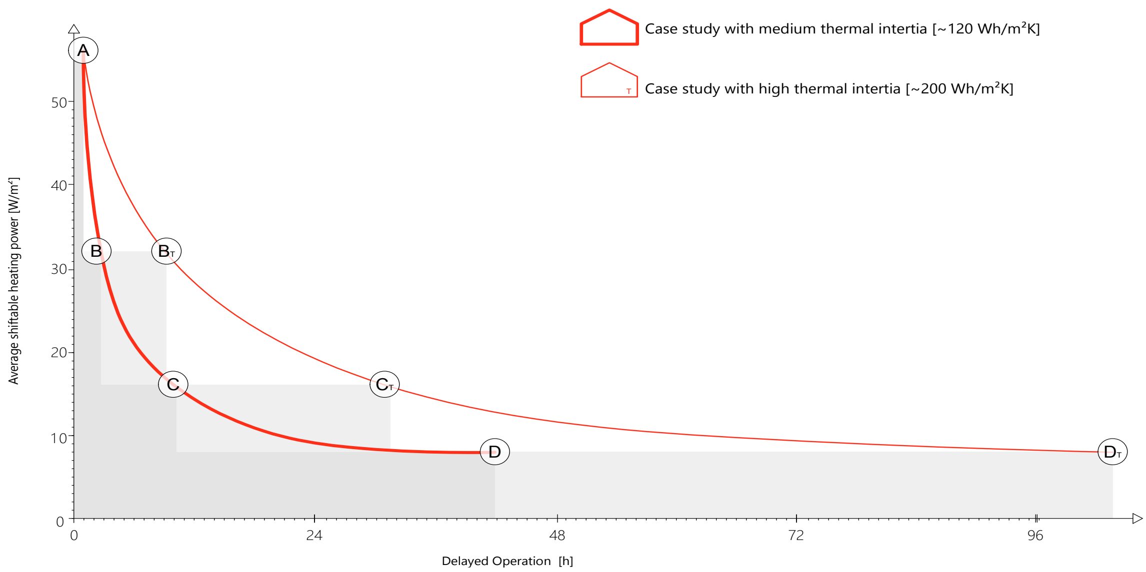

Figure 7 Load duration curves of heavy weight cases - potential of shiftable heating power over time

Even though the load shift period was determined for a typical cold January week, the resulting curve in Figure 7 can theoretically be used for any day/season of the year. If the heating power is known for a certain timespan, the ratio of the average shiftable heating power and the delayed operation time can be estimated depending on the thermal intertia.

In comparison to the investigated load shifting options by modulating the heating system (on/off), state of the art thermal or electrical energy storage systems are a more common way of providing energy flexibility to heating systems. Based on the heating system a state-of-the-art thermal storage water tank of 0.15-0.6 kWh/m² can drastically extend the thermal load shifting potential/ thermal storage potential. These capacities represent a 20-80 kWh thermal storage tank (200-1000 litres) for a typical single-family home in Austria.

The curves in figure 8 show how long a specific thermal power [W/m²] can be provided by different thermal storage system [kWh/m²] after the heat cut-off. It is seen that the load duration curves can be extended drastically by adding thermal storage systems. Figure 9 shows how long a specific electrical power [W/m²] can be provided by three different sized electrical batteries [kWh/m²floor area] after the active power supply has been cut-off. Please notice that this potential seems to rather small because it is assuming a direct electric heating system using each electrical kWh directly as thermal energy for heating the building. If the heating system would be powered by for example, a geothermal heat pump operating at COP 3.5, the load duration curves can be extended drastically. It is essential to notice that batteries can be used all year round for electric energy demand of the building and not specifically only in winter for heating flexibility.

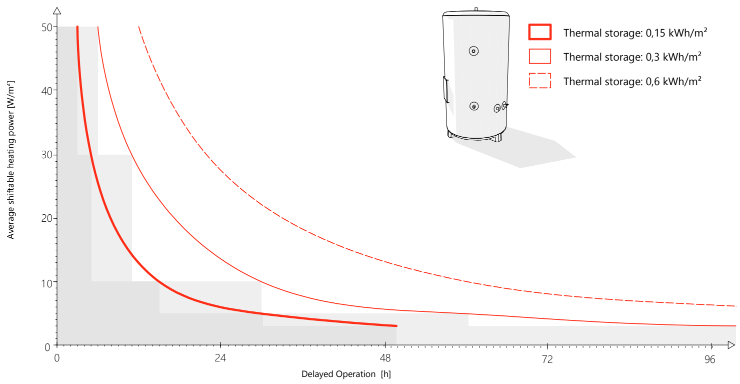

Figure 8 Load duration curves are showing the potential of storeable domestic heating load over time with three thermal storages

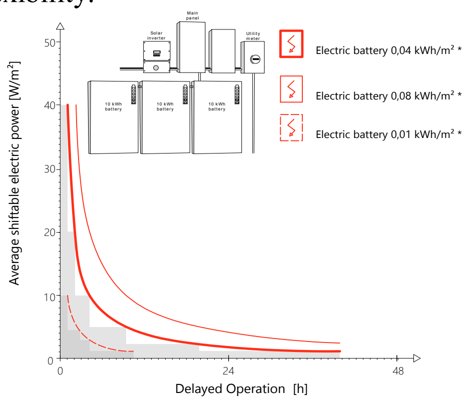

Figure 9 Load duration curves are showing the potential of battery storages to provide for electrical power after power cut-off

4.3. Response - heating-up

Due to the low-temperature heating systems in cases C and D with lower maximum heating capacity, the heating up timespan from the lower temperature setpoint of 19°C up to 22°C usually takes much longer. Also, the sluggishness of low temperature heating systems and modern PI controllers slow down the heating-up timespan. This timespan to reach the original temperature setpoint of 22°C again is referred to as the "response time of the heating system" in figure 10. It is heavily depending on the capacity and the control strategy of the heating system and much more difficult to assume in general than the cooling-down period, which is more related to the physical properties of a building. Figure 10 combines the load duration curves of the case studies showing the potential of shiftable domestic heating load over time for the cooling-down timespan on the right side (delayed operation) with an average predicted heating-up timespan (response) after the thermal load shifting operation on the left side. Also, we can see in figure 10 that from the end of the load shifting period till the heating system reaches the 22°C setpoint temperature again, there is an increase in heating demand since extra power is needed. Old, poorly insulated buildings with slightly oversized heating capacities, can react more quickly and reach the upper setpoint temperature relatively quickly.

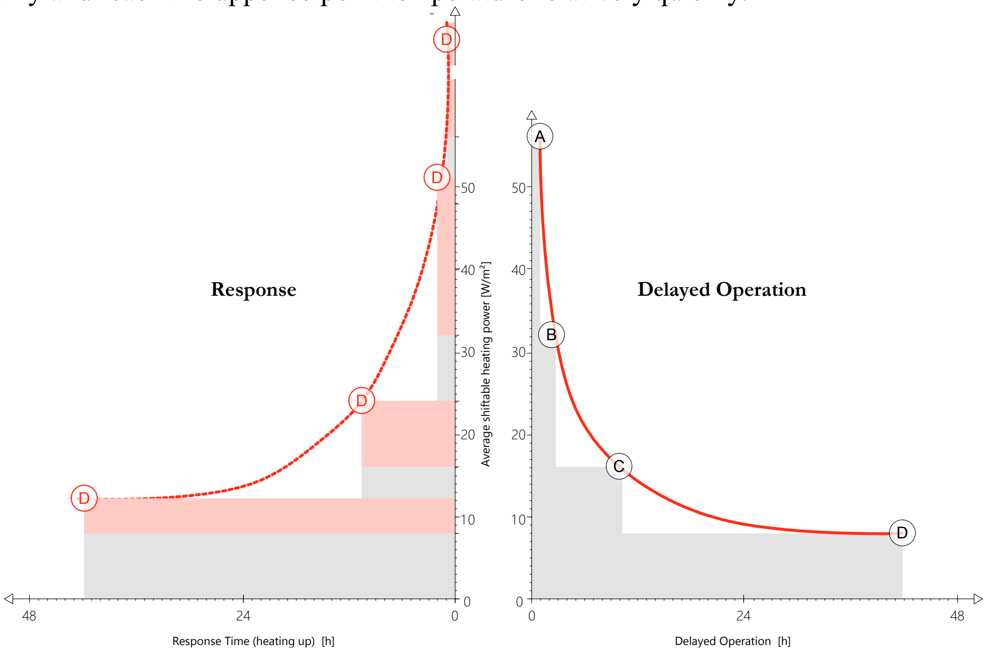

Figure 10 Rebound effect of shiftable domestic heating loads over time delayed operation (Δt1 – right) and response (Δt2 - left).

5. Conclusions

The potential for shifting domestic heat loads from the peak to low demand periods for Austrian building archetypes was investigated, and potentials for optimization were pointed out.

The findings are summarized as follows:

- Old buildings (cases A and B) in contrast to the new (cases C and D) have higher specific loads due to the lower insulation standard. This leads to a higher switchable load, but also a shorter shutdown period. Heat flexibility, therefore, is mainly determined by the buildings' physics-thermal properties. Also, energetic refurbishments of existing buildings can unlock a high load management potential since old buildings usually have high heating loads.
- The total amount of heating energy that can be shifted is beside the thermal quality of the building envelope dependent on the heating set points and acceptable comfort range. Tolerating a larger deviation from the comfort band especially in unoccupied times can significantly extend the load shifting potential of domestic heat loads.
- An increase of thermal mass/heat capacity leads to a damping effect on temperature changes, resulting on average in a 20-30% higher load shifting potential. At least 50% of the domestic heating peak loads can be shifted to off-peak periods during the day for building after 1980 in Austria, also in January, and still reach the comfort band of EN 15251, category II.
- The expansion of electric heating systems on the other side also poses the risk of worsening the seasonal gap of renewables in the grid, leading to higher specific emissions per kWh.
- For all building types, large delayed operation times are possible on days with higher average outside temperatures and high solar irradiation. Also, it is concluded that for four prototypical buildings, it is possible to predict the heating flexibility based on weather conditions – namely outside temperature and solar irradiation. For the older dwellings, the outside temperature has a dominant impact on the heat flexibility, as cooling down times are so fast due to envelope heat losses that these buildings hardly benefit from passive solar gains due to solar irradiance. Especially when the switch-off occurs during periods without solar radiation.

Mobile Tiny Houses – Sustainable and Affordable?

Leindecker H C[1], Kugfarth D R[2]

[1] Professor of Construction Ecology and Building Optimization, FH OÖ, Wels, Austria
[2] Scientific Assistant, FH OÖ F&E GmbH, Wels, Austria

HerbertClaus.Leindecker@fh-wels.at

Abstract. The topic of „affordable accommodations" has affected the construction industry and the politics for many years, not least due to sharply rising real estate prices. Building plots in good locations are just as prohibitively expensive for young people as larger apartments in urban areas, especially in big cities. This raises the question: How much does a person need to live? Energy efficiency, sustainability and regionality are as equally important as coziness, which decisively defines the quality of life of the residents. As part of the "klimaaktiv" regional partnership, the Upper Austria University of Applied Sciences has carried out several research projects concerning the topic of small sustainable homes. In cooperation with an Upper Austrian prefabricated house company, a building technology concept for an innovative modular construction system was devised. The aim here was the development of an innovative, high-quality and inexpensive modular system that does not exclude increased ecological standards. As part of an interdisciplinary project, a group of students developed an energy self-sufficient cabin for almost every kind of application. Based on extensive research on existing building systems, a variety of topics were examined. The focus here was on mobility, modular assembly, ecological materials, self-sufficiency, energy efficiency and the water cycle. In the end, a single-family house, which considers most of the aforementioned aspects, was built.

1. Background & State of the Art

The statements and findings of this publication are largely based on bachelor and master theses of students at the Upper Austria University of Applied Sciences. The main focus was on the master thesis of Lukas Krainz [1] – Development of a building technology concept for an innovative modular construction system – and an interdisciplinary project from the "Eco-Energy Engineering" bachelor's degree programme [2]. Furthermore, research into the topics of small houses ("Micro homes", "Tiny homes"), modular construction, mobility of buildings and urban development was carried out. The cooperation with Wolfthal Zimmerei GmbH during the completion of a bachelor thesis provided important insights into wood-based module construction [3]. Additionally, alternative building concepts of well-known Austrian module construction companies, like "Wohnwagon" [4] and "Genböck's microHOME" were considered [5].

1.1 Mobility of Buildings

The longing for change, flexibility and freedom often makes people dream of mobile micro homes. This longing presents a variety of challenges for architects, civil engineers and technicians. One of these challenges is the balancing act between cost-effective industrial prefabrication and the mobility of the individual building modules. In Austria, the transport of building modules is regulated in the Special Transport Order (SOTRA - Gesamterlass). Depending on dimensions and weight, these transports are classified into four special transport levels with individual legal requirements (see Table 1). Maximum size and weight of a module are dependent on the existing infrastructure and road conditions e.g. road width, load capacity of bridges or height of underpasses [6].

Table. 1: Special Transport Levels and legal requirements for Federal Highways [6]

	Level 1	Level 2	Level 3	Level 4
Width	3,01 – 3,20m	3,21 – 4,50m	4,51 – 5,00m	from 5,01
Height	-	from 4,31m	-	-
Length	22,01 – 25,00m	25,01 – 40,00m	from 40,01m	-
Weight	individual (depending on weight, axle load and requirements of the expert opinion of the road administration)			from 140,01t
Legal Requirements	self-accompaniment	1 Vehicle incl. 1 sworn road supervisory authority	2 Vehicles incl. 2 sworn road supervisory authorities	min. 3 Vehicles incl. min. 3 sworn road supervisory authorities

The single building modules, which are described in the master thesis of Lukas Krainz have a dimension of 18,00 x 5,50m and a maximum weight of 75t (see Figure 1). According to SOTRA, dimensions of this kind would represent a Level 4 Special Transport which requires a minimum of three vehicles including three road supervisory authorities. By combining the single modules, entire single-family houses can be built effortlessly. Mobile buildings in modular construction are usually mounted on screw foundations, which do not negatively influence the soil of the building ground. This guarantees the preservation of the property value and offers the possibility of removing the modules anytime [1].

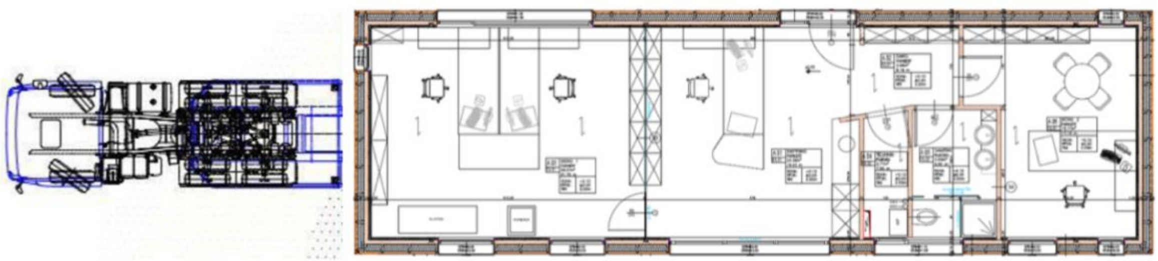

Figure 1. Building in modular design [18,00 x 5,50m] on a truck [1]

1.2 Infrared Heating Systems

For a long period of time, infrared technology was not suitable for use as the main heating system in buildings. This was due to the fact that high-quality energy (electrical energy) is converted into low-quality energy (thermal energy). Due to highly energy-efficient building concepts and the associated low heating requirements, infrared heating systems for buildings can make sense under certain conditions [1].

The most important advantage of this technology lies in the low investment and maintenance costs as well as in the very short heating and cooling phases. These are essential arguments, especially for holiday houses or small rooms that are rarely used. Another advantage is the high proportion of radiant heat, which many people find very pleasant. The high operating costs for buildings with a heating requirement above the passive house standard still represents the most important disadvantage [3].

1.3 klimaaktiv

“klimaaktiv” is the climate protection initiative of the Austrian Federal Ministry for Sustainability and Tourism, which is essentially divided into four main areas - Building & Renovation, Energy Saving, Renewable Energies and Mobility. klimaaktiv Building & Renovation stands for energy efficiency, ecological quality, comfort and execution quality. In order to be able to compare buildings with regard to these criteria, the klimaaktiv building standard was developed. New construction and renovation projects that meet the strict requirements in terms of location & quality assurance, energy & supply, building materials & construction, as well as comfort & indoor air quality are awarded such a designation. A building is assessed for all fulfilled and proven requirements with up to 1000 points, whereby three different quality levels (gold, silver and bronze) can be achieved. In order to ensure a meaningful comparison, a distinction is made between residential buildings and service buildings [3].

2. Implementation & Results

This chapter presents the results of a master thesis and an interdisciplinary project on the topic of "Mobile Micro Homes" written by students of the Upper Austrian University of Applied Sciences. In the end, a single-family house, which considers most of the aforementioned aspects, was built.

2.1 Development of a Building Technology Concept in Modular Design

The construction industry still has high potential in terms of efficiency in the construction of buildings on site. Despite the fact that the average Austrian household size is currently only 2.2 persons, the desire for home ownership is greater than ever. This poses entirely new challenges to the flexibility of the industry. The master thesis entitled “Development of a building technology concept for an innovative modular construction system” was prepared in cooperation with an Upper Austrian prefabricated house company and had the following objectives [1]:

- Preparation of building technology concepts from low to high-tech
- Implementation of a klimaaktiv building declaration for an office building
- Preparation of a building technology document (focus on heating & ventilation)
- Implementation of a photovoltaic simulation

2.1.1 Heating & Ventilation. As already described in the Chapter 1, infrared heating systems only can be economically operated in a building with passive house components. In the context of the master thesis, a modular design based lightweight construction building was considered. The annual heating requirement is 38,1 kWh/m^2a, which is equivalent to a low-energy house.

The annual heating costs with an installed capacity of 70W/m^2 (empirical value) would be € 1993.67 and therefore far above the average heating costs of a water-based heating system. Nevertheless, the implementation of a photovoltaic system (130m^2, 21,6 kWp), which covers nearly 75 percent of the electricity required for infrared heating, significantly reduces the heating costs. By signing a green electricity contract, the ecological aspect is taken into account as well [1].

In accordance with §10 of the "Upper Austrian Air Pollution Control and Energy Technology Law" (From the German "Oö. Luftreinhalte- und Energietechnikgesetzes"), in the state of Upper Austria, electrical resistance heaters may not be used as the main heating system in new buildings, except in justified exceptional cases [3].

Due to the fact that costs and flexibility play an important role in the project, it was decided to concentrate on a decentralized ventilation system. In cooperation with a wholesaler for ventilation units, a suitable concept for the modular building system was developed. The chosen ventilation system comes from a German producer which offers certified passive house ventilation units [1].

2.1.2 klimaaktiv Building Declaration. In order to emphasize the energetic, ecological and economic quality of the building, it was subjected to a klimaaktiv building declaration in the planning phase. The innovative building concept covers a wide range of possible applications. Therefore, two different plans were carried out. In the category Service Building, the (theoretical) bronze award was achieved by satisfying all essential criteria (with a total score of 523). Due to the fact that electrical heating and electrical hot water preparation have a negative effect on the primary energy requirement (PEB_{SK}) and on CO2 emissions factor ($CO2_{SK}$), a klimaaktiv declaration for residential buildings was not possible because these values were too high. The difference between green electricity and mixed electricity also has a very strong effect on the building's primary energy requirement, which should be taken into account when operating infrared heating systems or heat pumps [1].

It must be stated that klimaaktiv recommends infrared heating systems only for true passive houses with heating energy demand lower than 10 kWh/m^2a, including a ventilation system with heat recovery [7]. Further research is necessary to determine whether infrared heating systems in combination with low tech renewable heating systems (e.g. one room pellets stove and intelligent air ventilation management) make sense as a backup heating system for bathrooms and toilets when photovoltaic systems and/or other renewal energy are used.

2.2 Energy Self-Sufficient Cabin

Currently, there is an increased demand for mobile micro homes and module based buildings. An interdisciplinary project offered students from the Upper Austria University of Applied Sciences the opportunity to develop an ecological and economically interesting alternative to standard building solutions. The students had to face a variety of challenges especially in terms of renewable energy, ecological construction materials, energy efficiency and mobility. The project had the following objectives [2]:

- Research into the topic of module construction and mobility
- Substitution of expensive and non-ecological components used in the cabin
- Presentation of a building technology concept including CAD plans
- Optimization of the energy concept
- Economic calculations and comparison with other building concepts
- Construction of an exhibition object (sample wall)

2.2.1 Mobility and Ecological Aspects. The basic construction of the cabin is based on an innovative modular design and can be extended as required, depending on the field of application (see Figure 2). The transportability with a conventional truck (no special transport) had to be considered at every stage of the planning. This requirement means that the floor plan of the individual modules is limited to a maximum floor area of $15m^2$ (length: 5.00m; width: 2.50m). All changes to the interior or exterior wall have a direct effect on the already very limited living space. Therefore, a central problem was the ecological energetic optimization of the exterior walls. The students opted for a lightweight wood construction because it is unrivaled concerning ecology and ensures a healthy indoor climate. The thermal insulation consists of a combination of cellulose and soft-fiber boards. The entire wall construction has a thickness of only 32cm and has a heat transfer coefficient of 0.21 W/m^2K [2].

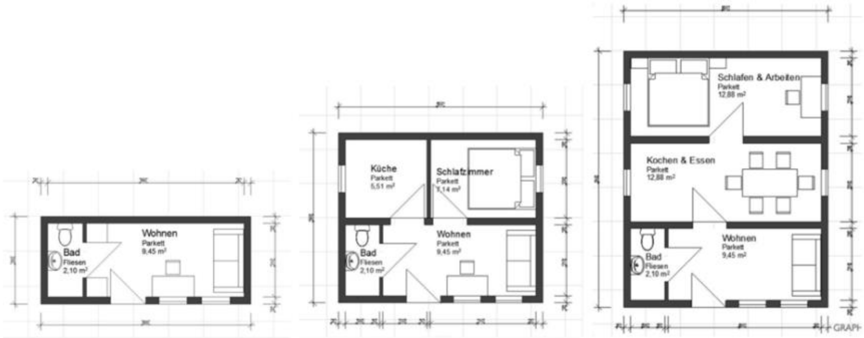

Figure 2. Standard modules for different applications [2]

2.2.2 Building Technology. The self-sufficient cabin contains many innovative ideas, which harmonize in interaction with each other. A well thought out concept that is not only ecological, energy-efficient and practical, but also looks good. Unfortunately, the realization of a 1:1 scale model would have exceeded the time constraints of the project and the budget. A sample wall (see Figure 3) was built, which reflects nearly all aspects of building technology and has already been presented at several internal and public events of the Upper Austria University of Applied Sciences [2].

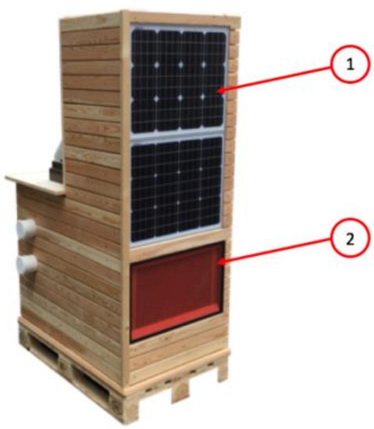

Figure 3. Front view sample wall with PV and cardboard honeycomb insulation [2]

Two integrated 50W monocrystalline PV modules (see Figure 3, No. 1) were installed for the energy supply. In series, they produce 24V direct current, which operates the floor-integrated infrared heating system without conversion loss. If no electrical current is required, the four gel accumulators (34Ah) monitored by the charge controller are charged. To operate household appliances, an inverter (24V DC to 230V AC) and a socket were installed. The cardboard honeycomb insulation (Figure. 3, No. 2) passively uses the sun's rays to generate heat when the sun is low in winter sky and prevents overheating in summer. The single room ventilation unit with an integrated heat recovery system efficiently exchanges the used, low-oxygen air with the fresh air from outside. Compared to manual ventilation systems, 80 to 90 percent of the heat can be recovered. In order to keep heat losses as low as possible, a passive house window was used [2].

2.2.3 Economics of the Cabin. In addition to the two key factors – comfort and sustainability – the cost-effectiveness of mobile tiny homes also plays a decisive role. The total costs for a ready-to-install standard module of the self-sufficient cabin ($15m^2$) amount to € 21,000 (price per m^2: € 1,400). These modules, which are manufactured by a carpenter in the Upper Austrian Ennstal, are also offered turnkey for approx. € 32,400 (price per m^2: € 2,160). At present, the price level is nearly equal to conventional prefabricated houses. In the long term, the price per m^2should fall due to the possibility of industrial production, continuously improved concepts and the increased use of Building Information Modeling [3].

2.3 From tiny homes to modular construction

Fascinated by the concept of mobile micro homes and their modular construction, in addition to the possibility of erecting a house in one day, the first author realized a small single-family home – an extended microHOME [5] with a modular lightweight wooden construction - near the center of a little community, considering most of the aspects of ecological construction (see Figure 4). The main floor of this building consists of 5 modules, which can be replaced later and built up on another site – perhaps introducing a modern way of living in and recycling a building.

Of course it remains to be discussed whether a single family house can be ecological at all. Therefore the concrete foundation level of this building provides space for the next generation. Additionally, this was the only way to fulfill the klimaaktiv essential criteria for heating energy demand because one of the main problems of micro homes is the very bad surface-to-volume ratio.

While redensification in cities is becoming more and more state of the art (e.g. roof extensions), ecological regional planning in rural zones remains the bigger challenge. New approaches are therefore needed, for example the possibility of packing buildings with higher density (e.g. 3-6 tiny homes per 1.000 m^2) in combination with upgrading the public transport systems.

Figure 4. Transport and construction of a module based home [8]

3. Conclusion

Mobility, sustainability and flexibility with regard to private homes are becoming increasingly important. A large number of construction and carpentry companies in Austria already offer mobile living ideas and concepts with a modular construction. More and more start-up companies have also been successfully founded on this basis, which confirms the trend in this direction. One reason for this development is the steady rise in real estate and building land prices, which is forcing both industry and the politics to search for innovative solutions. Mobile homes offer the possibility of renting land for a temporary period of time, allowing them to be adapted to one one's professional and private life changes. Therefore, this living concept can make an important contribution to the sufficiency of real estate.

Due to the continuous development of new housing concepts and work processes - keyword Building Information Modeling - it can be assumed that the costs for modular based buildings will fall in the near future. Nevertheless, a decrease in quality due to series production must be prevented. The flexible use of small residential modules also offers new possibilities for structural redensification in urban areas (see Figure 5). Combined with the consistent use of vacancy (e.g. rooftops, inner courtyards), mobile tiny homes can make a positive contribution to the economic development and the living quality of our cities.

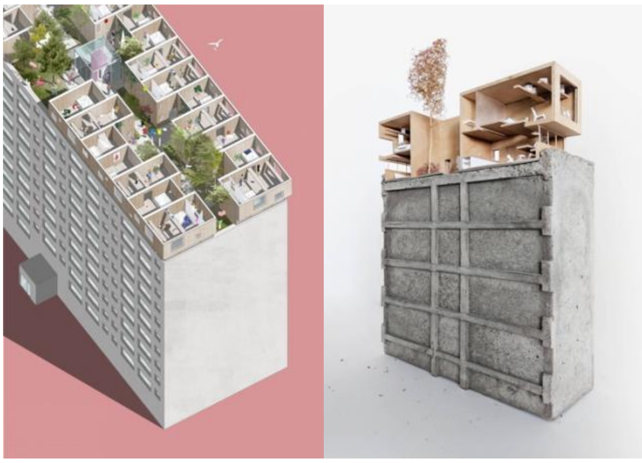

Figure 5. Module based living concept on a rooftop in Berlin, Germany [9]

In terms of ecology and energy efficiency, today's tiny homes are in no way inferior to conventional single-family homes. However, the prerequisites for these are high-quality planning and execution, the use of sustainable construction materials and the use of energy-efficient building technology. The implementation of an infrared heating system in connection with PV and an electrical storage system represent viable alternatives for such building concepts. All of these projects show that modular based building concepts can be produced and operated in an economical and sustainable way. In the end, every person must decide for themselves, whether this living concept contributes to their personal well-being and corresponds to their way of life.

Challenges of retrofitting affordable housing to net-zero carbon in the United Arab Emirates

Mokhtar A

American University of Sharjah, Sharjah, United Arab Emirates

mokhtar@aus.edu

Abstract. Following the Paris Agreement, several governmental bodies in the United Arab Emirates (UAE) started working on further initiatives to improve the energy efficiency of buildings. Some of these hope to target net-zero carbon for new and existing buildings. As in most countries, the stock of existing buildings represents the bigger challenge for this target. In particular, existing affordable housing is the most challenging segment of the building stock. The limited access to expertise and financial resources makes it more difficult for owners of these buildings to retrofit them. Therefore, there need to be appropriate guidelines on how to achieve net-zero carbon in such building typology. This paper identifies both the technical and the financial challenges when trying to develop such guidelines within the context of the UAE. It also discusses the possible solutions that can be used to overcome some of these challenges. The technical challenges include the variation in construction systems, and the quality of construction for these buildings. It also includes energy modelling challenges such as selecting relevant weather data, and defining the patterns of using electricity for the different functions. The financial challenges include the subsidized price for electricity, the cost estimation for various energy conservation methods, and the payback for installing local renewable energy sources. Finally, the paper suggests a path for research activities to address these challenges and to develop the guidelines.

1. Introduction

The United Arab Emirates (UAE) is committed to reducing its per capita carbon footprint. This is reflected in its signing of the Paris Agreement on Climate Change and in various short and medium term strategies published by the country and many of its emirates. One of these strategies is reducing the demand-side of energy. As the building sector is the largest consumer of energy in the country, many regulations and rating systems that support lowering the energy consumption of newly constructed buildings were developed and are being enforced by the different emirates. An example is the *Estidama* rating system in Abu Dhabi [1], *Al Sa'fat* rating system in Dubai [2], and *Barjeel* regulations in Ras Al Khaimah [3]. The retrofitting of existing buildings is also an important aspect of the strategy. For example, Dubai is targeting the retrofitting of more than 30,000 existing buildings and developing a market for Energy Service Companies (ESCO) to achieve its target.

Housing represents an important section of the stock of existing buildings in the UAE. In Dubai, for example, statistics show that individual villas represent about 77% of the number of buildings [4]. Residential consumption is about 32% of the energy consumed in that Emirate [5]. Affordable housing is a segment of these residential buildings. The term "affordable" housing is a relative term and depends on where it is used. For the purpose of this work, an affordable house is a house that is owned by a UAE citizen through government support. This support can be through providing land and/or finances. Tens of thousands of such houses were built and are being built through some government programs [6], [7]. An affordable house for a UAE citizen is typically a detached or semi-detached villa of one or two floors occupying roughly 30% to 45% of its plot. The area of a villa is roughly between 250 to 500 m^2. The cost is roughly in the range of US$ 300K to 600K. Figure 1 shows a sample of a group of these villas forming a small community. Electricity is also subsidized for the occupants of these houses in most emirates. The subsidized charge is about US$ 0.02 to 0.03 per kWh. In addition, regulations regarding energy efficiency were non-existing for a long period of time resulting in high consumption of electricity in these villas. A study by Al Awadhi et al. for five villas in the UAE, each representing the most common types of villas in each decade starting from the 1970s until the 2010s shows energy use intensity (EUI) from 602 to 371 kWh/m^2/year [8]. The same study showed a potential saving that can reach 30% if these villas were built with a reasonable level required by the green building codes available at the time of the study.

Figure 1 A Google Map for a sample of a residential community in the UAE.
(Image © 2019 DigitalGlobe, Map data © 2019 Google)

The potential for energy saving by retrofitting these buildings is high. However, there are many challenges in trying to realize this potential. This paper discusses these challenges and the possible solutions to overcome some of them. The paper starts with examining the feasibility of achieving different low energy targets for a house in the UAE. It then discusses the technical and financial challenges to achieving a target. Finally, it recommends a line of studies that support developing guidelines to define and achieve the target.

2. Feasibility of Zero Net

It is important to define the terms that are used as targets before studying the feasibility of achieving such target. In this paper, the following terms are defined as:

A Zero Energy (or a Zero Net-Energy) (ZNE) building is an "*ultra-low energy building that consumes only as much power as is generated onsite through renewable energy resources over the course of a year*" [9].

A Zero-Net Carbon (ZNC) is "*a highly energy efficient building that produces on-site, or procures, enough carbon-free renewable energy to meet building operations energy consumption annually*" [10].

A Nearly Zero Energy Building (nZEB) is defined by the Emirates Green Building Council for the case of the UAE as "*a highly energy efficient building with a site EUI less than 90 kWh/m^2/year and covers a significant portion of its annual energy use by renewable energy sources produced on-site or off-site*" [11].

The difference between a ZNE and a ZNC building is that the latter can procure renewable energy from off-site sources while the first cannot. The difference between a ZNC and an nZEB building is that the latter can use energy generated from non-renewable sources while the first cannot. All these buildings are connected to an electric grid and the calculations of net-energy are done on an annual basis. The author starts by examining the feasibility of having a ZNE house in the UAE. This is followed by examining the possibility of having a ZNC house. Finally, it discussed the possibility of having an nZEB.

2.1. Zero Net-Energy

To examine the feasibility of having a ZNE house in the UAE's harsh climate and high standards of living, one needs to find a reasonable number to represent the EUI for an affordable house in the country. Unfortunately, very little information is available on this. However, some studies were done on existing residential villas that can give some guidelines on a possible EUI in the UAE.

Friess et al. studied a villa that was constructed in 2009 from a project that had one thousand villas with the same model [12]. It is a two floor, semi-detached villa with an envelope that followed the municipality requirements at the time. They considered this villa to be representative of villas built in Dubai at the time. They found out that the EUI is 194 kWh/m^2/year from the utility bill. They were able - through simulation - to reduce this EUI by about 23% by just insulating the reinforced concrete elements that represented thermal bridges in the envelope (e.g. R.C. columns). Adding 160mm of external insulation reduced that further to almost 30%.

The author studied the energy bills for 132 attached villas of various sizes. They are all with two floors and located in Sharjah, UAE. They were built in a span of 10 years starting from 1997. The results show that the older villas use an average of 185 kWh/m^2/year while the newest ones that used a bit more insulation use an average of 140 kWh/m^2/year.

The Emirates Green Buildings Council conducted a study using estimated energy consumptions from five villas that were to start being built in 2017 [11]. The range of EUI varied from 44 to 119 with a median of 98.8 kWh/m^2/year. The study also included a survey of professionals about the feasible level of EUI in the UAE. They concluded that 90 kWh/m^2/year is achievable for residential and office buildings.

Another study for the feasibility of achieving ZNE buildings in the UAE climate category concluded that it is feasible to reach 95 kWh/m^2/year for an apartment building (not a villa) [13]. The study used 30 energy efficient measures to minimize energy use without considering their cost implications.

From the mentioned values for EUI in different studies, it seems reasonable to consider the value mentioned by EGBC (90 kWh/m^2/year) as a feasible EUI value for a low-energy villa in the UAE.

From the other side, one needs to estimate the possible energy that can be generated/captured on a site in the UAE. Villas are typically able to do that through solar energy only. This can be in the form of photovoltaic (PV) panels or thermal solar collectors. For simplicity, we will assume the use of PV panels only.

The study by the EGBC mentioned that the five newly built villas in the UAE that voluntarily reported their data showed electricity generations of about 0, 55, 80, 95, 115 kWh/m^2/year. It is not clear how the volunteers calculated these values for their villas. With such large differences, it is expected that this is the electricity each generated divided by the total floor area of the villa. We are interested here in calculating the potential of generating electricity on one square area of a horizontal building roof. To do this, the author uses the PVWatts Calculator tool developed by the National Renewable Energy Laboratory [14]. The weather data of Abu Dhabi (the capital of the UAE) airport is used and horizontally installed fixed standard PV panels are assumed. Default data for system losses and efficiency are used. The result shows that producing about 210 kWh/m^2/year of alternative electric current is expected from the PV panels. This estimation for electricity generation can be used in relation to the considered EUI value of 90 kWh/m^2/year (of total floor area). By dividing 210 by 90, one can conclude that it is possible in the UAE climate for roof-installed PV panels to provide the electricity needs for a villa with two floors. Hence, it is feasible - at least in theory - to operate such a villa as a ZNE villa.

It is worth mentioning that a villa named the "Passive Autonomous House of Mohammed Bin Rashid Space Center" is in operation in Dubai [15]. It is a two-floor villa and fully operational off-grid using the PV panels installed on its roof. It was built for demonstrating the possibility of such operations and the cost did not seem to be an issue.

2.2. Zero-Net Carbon

In their study of existing - and relatively old - affordable villas in the UAE, Al Awadhi et al. reported an EUI of 371 to 602 kWh/m^2/year [8]. These are very different EUI's than the 90 kWh/m^2/year mentioned by the EGBC for newly constructed villas. This is why there is a large potential for energy saving through retrofitting these types of buildings in the UAE. Yet, it may prove to be cost prohibitive for many of the existing buildings to reach the EUI value of 90 kWh/m^2/year and install PV panels to become ZNE buildings.

Therefore, it is expected that many of the retrofitted villas will require procuring renewable energy from outside the building site and hence become ZNC buildings. In the UAE, procuring renewable energy can be done in a variety of ways:

1. Using roads solar panels to generate energy at the community level. This seems to be promising considering that neighborhoods in the UAE tend to have no or very little trees that cast shadows on the street (see Figure 1). This can provide about 50% additional solar energy to those provided by PV panels installed on the roof for a typical arrangement.
2. Using solar panels installed on buildings in the community that have large roofs and seasonal use such as local schools.
3. Using solar panels installed on parking areas of buildings with cyclical use such as local mosques and recreational centers.
4. Making use of a program in Dubai that provides renewable energy credits. The program allows building owners to buy these credits and cover the energy that they cannot generate on their building site [16]. This program should be viewed in relation to the operation and continued construction of a 5000 MW solar park in Dubai. The park will provide many of these credits.

Because of the abundance of solar energy in the UAE, it seems feasible to retrofit many of the existing residential buildings to ZNC. The cost implication certainly needs to be studied.

2.3. Nearly Zero Energy Building

An nZEB can use non-renewable energy to cover its needs. However, according to the definition by the EGBG, such a building in the UAE should not be using more than 90 kWh/m^2/year. It may prove cost prohibitive to retrofit old villas to that level of EUI.

From the above discussions of ZNE, ZNC, and nZEB, the author believes that having ZNC as a target would be the most feasible for retrofitting affordable housing in the UAE. Yet, this needs to be further studied to reach a definite conclusion.

3. The challenges of retrofitting

Many of the affordable houses in the UAE were built at times when energy conservation was not an issue of consideration. Building regulations that aim to conserve energy hardly existed in the UAE before the year 2000 and it took about 10 years after that to reach adequate standards. These regulations are getting better with time. Now with government commitments to reduce countries' carbon footprint and adhere to the Paris Agreement goals, retrofitting of these houses needs to be addressed.

The author suggests an approach where the current stock of affordable housing is classified into categories. Each category includes houses that were built using certain construction materials and building technology. It is common that during a period of time, a limited number of materials and technologies dominate the affordable housing market because of a variety of reasons including the cost. For each of the identified categories, a cost-optimal level should be defined following the example of the European Union [17]. This is combined with a retrofitting strategy that defines a set of energy conservation measures suitable for the category.

The author is investigating the possibility of using this approach for a group of 48 identical villas. These are attached two-floor villas in 8 separate clusters and with four different orientations. They were constructed between the years 1998 and 2000. Energy modeling is used to simulate the energy behavior of a representative villa (reference building). Several energy conservation measures are identified and tested. While this research is still ongoing, there are clear challenges that appear in the process. These challenges will face any efforts to address the retrofitting of housing projects in the UAE. The challenges can be categorized into technical ones and financial ones even though some of these challenges cross both categories.

3.1. The technical challenges

The availability of the technical data is an important challenge. The villas were constructed from very simple drawings with hardly any details or written specifications. The trades' rules-of-thumb were used. Through the author's interviews with contractors working in the country at the time, information on walls and roof layers were collected to a reasonable quality. Properties of glass and window frames are estimated through visual investigation. Air leakage values were roughly estimated through visual appreciation of building components such as gaps in the window frames. Certainly, with more resources, these technical data can be identified more accurately using various technologies. Then, a reference building can be constructed digitally from this data. It would be reasonable to assume that this reference building represents most villas built at the same time. The impact of factors such as building orientation, size, and external shading elements should be studied and some correction factors may be used for a specific villa under study.

The more challenging aspect is estimating occupants' behavior in terms of plug loads, schedules of use, and control of systems (e.g. thermostat setting). Within the 48 villas studied, there are significant differences in electricity bills even with buildings having an identical orientation and similar external shading elements. The difference can be attributed mainly to variations in occupants' behavior. The UAE does not have relevant surveys similar to the "Household Electricity Survey" of the UK [18] or the "Residential Energy Consumption Survey" of the USA [19]. There is also no existing research work to estimate occupants' behavior like that done for Egypt [20]. Collecting this data seems to be a pressing issue for the UAE to support an appropriate retrofitting strategy. The author suggests that this is done first by categorizing affordable housing into groups based on aspects such as the number of occupants, building size, and household income. Then, sub-meters and other measurement tools are used to monitor energy related to users' activities in sample buildings within each category. The data is analyzed and patterns of occupants' behavior are defined for each category.

Sub-meters are also useful to measure the electric consumption of different systems, sub-systems, and specific equipment in sample buildings. This detailed data are very useful in performing the very challenging task of calibrating an energy model. Software are available now to make use of the detailed measurements to adjust various data in the energy model to be as close as possible to the modeled building. A well-calibrated model is necessary to estimate the energy saving impact of any combination of energy conservation measures. The estimated saving is key in determining the cost-optimal level and the retrofitting strategy for each category of housing.

The availability of the hourly weather data - needed for energy model calibrations - is less of a challenge now for the UAE as all major cities has commercially available historical hourly data. However, files with future expected typical weather that reflects the impact of climate change are limited.

3.2. The financial challenges

The major hurdle in retrofitting affordable housing is the heavily subsidized price of electricity. With the exception of Dubai, which has electricity prices comparable to the average price in the USA, all the emirates charge only 20-30% of that price to citizens. The author's initial investigation with different energy conservation measured found that almost no measure would make economic sense with the subsidized prices.

The author suggests that the actual cost of electricity – borne by the government – should be used to investigate the cost-optimal level and hence the retrofitting strategy for each identified category of affordable housing. Following this, the government should initiate programs that gradually shift its subsidy for consumed electric energy to a subsidy for energy conservation measures. The suggestions in the following paragraphs illustrate this approach.

To reduce the consumption of artificial lighting, the government can develop a program to replace existing light bulbs with LED. It can make it a condition to continue the electricity subsidy, remove other light bulb types used in houses from the market, and imbed the replacement cost in the electricity bill for a few years. The number of years should be calculated so the owners of the houses do not see a difference in their bills. The program may also include installing occupancy and daylight sensors for light control.

A similar program can be used for replacing old appliances with high efficiency ones. As an added incentive, the government can buy back old appliances. It can recycle/upgrade them to recover some of the cost.

It also takes a very long time to recover the cost of installing PV panels on villas. To overcome this problem, installing PV panels should also be a condition for continuous electric subsidies. However, the government should allow buying back the electricity generated from them. For a few years, it can pay a price per kWh that is similar to its actual cost to generate electricity. The number of years is calculated to allow the user to recover the cost of the PV installation.

Certainly removing the subsidies on consumed energy will be very beneficial for any retrofitting program. Yet, it does not seem to be happening soon. However, it may be possible to subsidize each housing unit up to a particular EUI. This keeps the government's commitment to its citizens but also encourages them to consume energy more consciously. Spending part of the money allocated to the subsidies on school educational programs and awareness campaigns to encourage energy conservation may also prove to be cost effective.

4. Conclusion and Recommendations

It will be difficult for the UAE to retrofit its existing stock of affordable housing for the purpose of minimizing its energy consumption. This is due to various challenges. Perhaps the biggest challenge is the subsidized energy cost which makes improving any aspect of the energy performance of a house makes no sense for the owner. Yet, it is the quickest challenge to overcome if the government decides to change its pricing strategy. The author would argue that it is better for the government to provide its citizens with current subsidies in the form of cash payments and to raise the electricity price to actual cost. This would generate an incentive to reduce consumption and to invest in retrofitting.

Yet, even with overcoming this challenge, owners need to know where best to invest their retrofitting investments. Individual owners lack the expertise and soliciting such expertise would be too costly. Therefore, the author suggests the following studies to be done for the UAE housing stock:

1. Categorize affordable housing units based on criteria identified through the analysis of the housing stock.
2. For each category, collect the technical data needed to create a quality reference building model. This would be through studying several representative villas and should include:
   a. Identifying the material properties through invasive and/or non-invasive technologies.
   b. Using standard techniques to identify a representative value for air leakage.
   c. Installing sub-meters and other measuring equipment to understand the patterns of users' behavior and the efficiency of the available systems.

   d. Identifying energy conservation measures and the cost of each measure. This should take into account the impact of having a new and large retrofitting market on lowering some prices and increasing others.
   e. Building a reference model, applying the different energy conservation measures, identifying a cost-optimal EUI, and defining a retrofitting strategy.
3. Test the retrofitting strategy on sample buildings for each category and make any necessary corrections.

From the above studies, guidelines can be developed for each category of housing. These guidelines certainly need to reflect the government's intended strategy to price electricity.

Towards developing a building typology for Sudan

Ismail Ahmed Ali S, Szalay Z

Budapest University of Technology and Economics, Budapest, Hungary

Suha8896@hotmail.com

Abstract. Sudan suffers from hard summers with temperatures approaching 42 0C in the South and 48 0C in the North. In spite of that, the technical solutions in buildings for protection against solar radiation and natural ventilation are generally beyond reach. There isn't sufficient information provided on the characteristics of the building stock, building physics and energy use of buildings in Sudan. The main objective of this research paper is to collect the data from the population and housing census, scientific research papers and different reports, and to use these in preparing a building typology table. The climate in Sudan is divided into three zones: warm desert climate, warm semi-arid climate, and tropical savanna climate zone. The building varies according to the climate zones, geographical feature, and urbanization levels. Building materials range from natural ones like straw, wood, and mud to moderns one like bricks and concrete. Building typology varies from structures to provide temporary shelter to the permanent single or multi-family houses. The main result of this research paper is to identify a building typology in Sudan with reference buildings. This is the first paper that introduced the typology table of Sudan.

1. Introduction

We are living under the mercy of climate. Climate shapes us, it means that our habits, clothing, food, and buildings need to adjust to climate conditions. There are four main climate zones on Earth: cold, temperate, hot-arid and hot- humid zones [1]. Traditional architecture responded to the climatic challenges in every climate zone with locally available solutions.

As the hot-arid climate area where Sudan is located is characterized by excessive heat and glaring sun, there is a focus on designing a shelter to reduce heat impacts and provide shade. Structures in this area were traditionally constructed of massive roofs and walls of adobe. In many developing countries, development efforts often focus on the construction sector to achieve the required level for urban shelter. Sudan as a developing country is still far from providing an adequate level of shelter to its citizens. The harsh environmental and climatic features, worsening economic situation, shortages and the big gap in the scientific data and research prevented the proper adaptation of building materials and technology. On the other hand, there is an incompatibility between the modern building materials and techniques and the country's features and design parameters.

The main purpose of this research paper is to introduce the general features of the Sudanese geodemographic and climate characteristics and to analyze how these features influenced the building stock in the past and in the present. The main goal is to compile relevant information on the building stock of Sudan for establishing a building typology that can be used for further assessment. According to our knowledge, no such building typology existed before in the country, so this can be considered as a first trial effort. A building typology with reference buildings is a useful starting point for energy performance calculations, comfort evaluations, and strategic planning [2].

2. Methodology

The method used in this paper was to collect statistical data from the different authorities and information from the previous research, and using the data to illustrate and analyze the building typology of Sudan according to the different parameters. First geographical, climate and demographic features are introduced, and the relevant information on the housing stock is described.

2.1 Geographical features

Sudan is located in North- East Africa. It is bounded by the Red Sea and Egypt from the North, Ethiopia, and Eritrea from the East, South Sudan from the South, Central African Republic, Chad and Libya from the West. Before 2011, Sudan was the largest country in Africa, but due to the secession of South Sudan, its current area is about 1.886 million km² making it number three in Africa and number 16 in the world. Sudan has many wealth resources of water, livestock, fertile lands, diverse forests, minerals (gold and copper), and oil production. The soils of Sudan are classified into six main categories according to their locations and construction: i) desert; ii) semi-desert; iii) sand; iv) alkaline catena; v) alluvial; and vi) ironstone plateau. There are many local variations due to drainage conditions [3], [4].

2.2 Climate of Sudan

Sudan has a composite climate between hot, cool and rainy seasons. The principal climatic elements which affect the building design and comfort are solar radiation, temperature, humidity, wind speed and direction and precipitation [5].

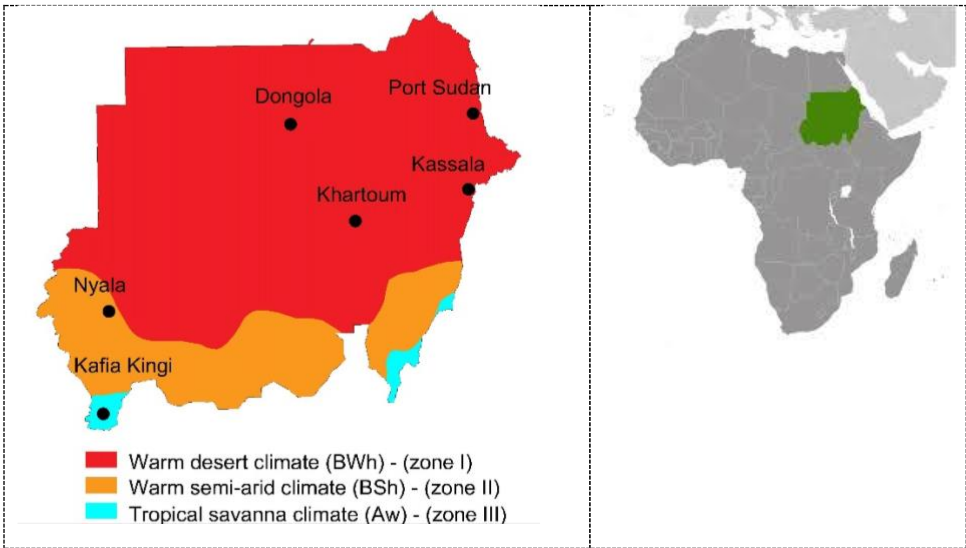

Figure 1. a) Sudan climate zones b) Location of Sudan in Africa,

Source: Based on Koppen [6], and Sudan Meteorological Authority (SMA) [7]

Sudan is classified into three climatic zones (Zone I: warm desert climate, Zone II: warm semi-arid climate and Zone III: tropical savanna climate) as shown in (Figure 1) [6], [7].

In the Northern Part (zone I) warm desert climate zone summer temperatures exceed 43.3 degrees Celsius in the desert zones and rainfall is negligible except in the center, such as the capital Khartoum and Gezira city where rainfall is common between June and September. Dongola, Port Sudan, Kassala, and Khartoum are examples of some cities in this zone (See Figure 1 and 2). The maximum mean temperature registered the highest values in Dongola and Khartoum cities, (Figure 2(a) and Figure 2(b)), while the highest values of humidity are in Port Sudan city because of its coastal location close to the Red Sea (Figure 2(c)). In the capital Khartoum, the average annual temperature is about 26.7 °C;

and the annual rainfall is about 254 mm. The northern part of Sudan has a harsh climate compared to the other parts.

Nyala is located in the South Western warm semi-arid climate zone area (zone II), it has moderate summer and winter temperature and high rainfall and relative humidity values (see Figure 2(c) and Figure 2(d)), this is because its location is close to the tropical savannah region (zone III) [8].

The greatest amount of solar radiation in Sudan is found between 15 and 35 latitude north. Wind speed and direction vary with seasons. In winter, the wind speed ranges between 0.54 m/s to 1.54 m/s in N and NW direction, while in the summer season winds are usually locally supplemented by dust and sand in the direction of NW to SW. Dust storms frequently occur in the desert zone. High temperatures also occur in the southern part, but the humidity is generally high [9].

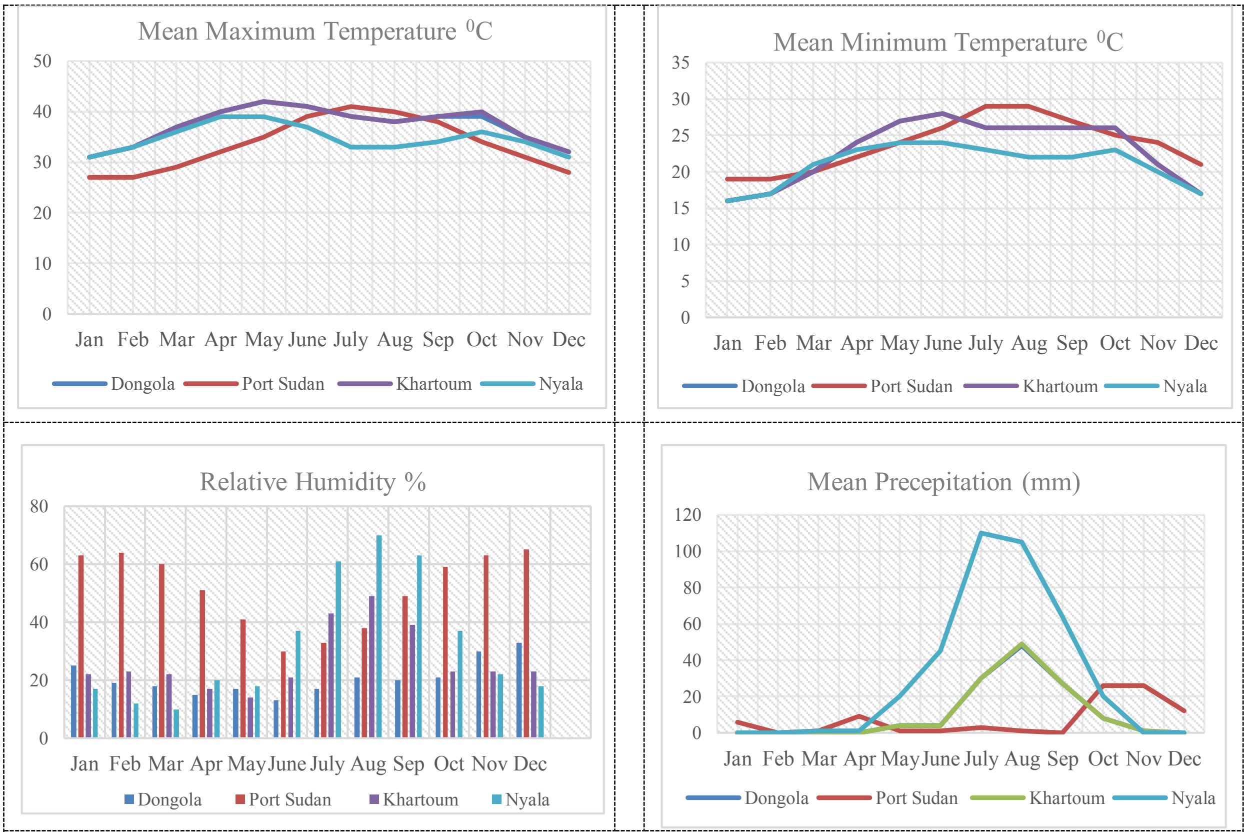

Figure 2. Metrological data of Dongola, Port Sudan, Kassala, Khartoum, Nyala for the: (a) mean maximum temperature for 30 years period (b) mean minimum temperature for 30 years period (c) annual relative humidity in 2009 (CBS) (d) mean precipitation (mm) for 30 years period

Source: World Metrological Organization, Sudan Metrological Authority and Central Bureau of Statistics [8].

2.3 Demographic

The population of Sudan has increased by 49.5% in the past 25 years, reaching 41 511 526 million in 2018, growing at 2.8% rate per annum. The urban population is estimated at about one-third (34.6%) of the total, which indicates that Sudan is still predominantly rural. With this rate of increase, the population could double in about 16 years [10], [11].

Sudan's population pyramid is young and growing, so it belongs to the expansive type (Figure 3). In the population distribution, around 41% of the population is under 15 years, 56% is between 15 to 64 years and 3% of the population is more than 65 years old. Life expectancy is low due to the health and economic system. Most of the population is confined to two climate zones. About 52% of the population lives in the warm desert climate zone and 48% in the warm semi-arid climate zone. Only 0.04% live in the tropical savannah climate (Figure 4 and 1). A conflict region between South and North Sudan in this area (Kafia Kingi City) due to the rich natural resources there [12].

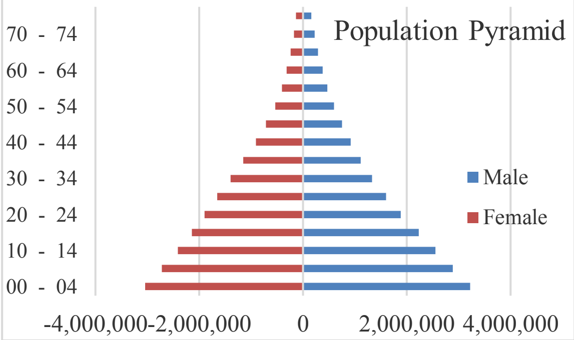

Figure 3. Population pyramid

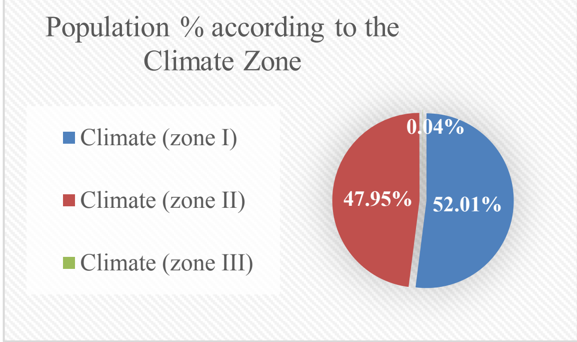

Figure 4. Population percentage according to the climate zone, Source: Annual Health Statistics Report

Source: Annual Health Statistics Report 2017 [12]

2.4 Tenure status of dwellings

Most Sudanese live in simple houses of their own or rent from landlords or agricultural-scheme authorities. Housing can be classified into four types according to tenure status as shown in Figure 5: owned, rented, provided as part of work and free dwelling.

Figure 5 illustrates that most of the dwellings are owned, about 86%, while housing provided as part of work registered the lowest value. The government doesn't play a big enough role in supporting affordable housing [13].

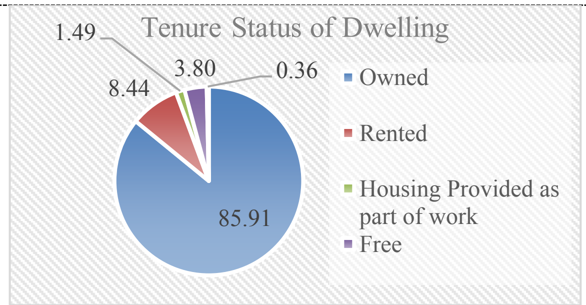

Figure 5. Tenure status of dwelling, Source: Central Bureau of Statistics 2008 [13]

2.5 Building materials in Sudan

The building materials in Sudan are classified into three types: (a) modern materials: i.e., concrete, red brick with cement mortar, cement bricks and corrugated iron sheets; (b) traditional permanent materials: red bricks combined with mud bricks for wall construction, mud construction for walls and roofing made from sticks, thatch and mud; and (c) traditional materials: i.e., thatch used for roofing and for walls. In first class areas (classification according to the residential area level), residential buildings are made of red bricks with clay or cement mortar, reinforced concrete ceilings, and roofs or corrugated iron sheets for roofing [14].

Residential buildings may be classified according to the building materials into straw huts, mud and adobe houses, red bricks houses and apartment houses (Figure 6 (a)). About 65% of the houses are from mud and adobe material, and a very low percent of the houses are apartments. This reflects the low level of urbanization in Sudan.

Another classification is according to the residential area level (Figure 6 (b)). The first and second class residential areas should be durable materials, while the houses in the third class residential areas can be constructed of semi-durable materials. Most of the houses are at the medium level, “the third class housing “and the percentage of the illegal houses are very high. This reflects the slow urban planning process. The top materials that have been used in houses are mud and adobe for wall, straw and palm leaves for roof construction (Figure 7 (a) and figure 7 (b)). Concrete and cement blocks registered the lowest percentage [15].

* Note: the data about the building materials, residential area classes and wall and roof materials of the house are rather old (from 1968). The main reason is to show the classification and the materials that have been used in the past. This survey is used by several authors [16]. According to our knowledge, there is no new data available.

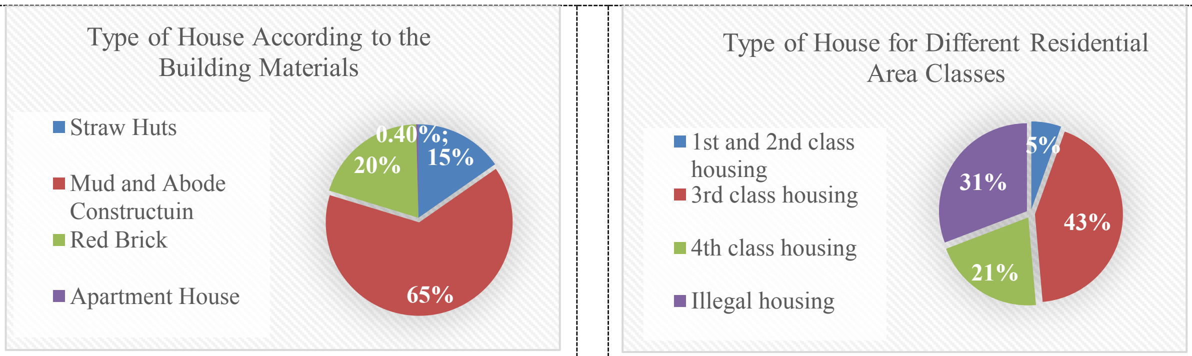

Figure 6. Type of house according to the: (a) building materials. (b) residential area classes Source: Household Sample Survey 1968

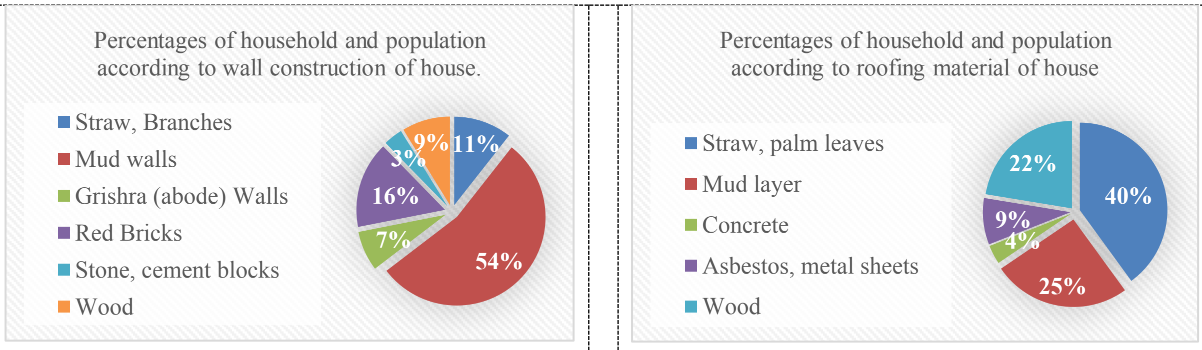

Figure 7. Percentage of household and population according to the (a) wall construction of the house (b) roofing material of the house. Source: Household Sample Survey 1968

2.6 Building construction development in Sudan

There is a big difference in the level of construction activities in Khartoum, the South, and North Darfur. The region of the Southern part and Darfur suffer from the low level of their built environment, due to the war, conflicts and the lack of economic development. There is a shortage of building materials due to draught and the huge need for shelter [17]. The most common houses in the rural part are the so-called Gottiya made of straw or millet stalks covering a wooden skeleton.

At the last census in 2008, over half of all housing units were Gottias (single rooms with round mud walls and a conical straw roof); about one-third were Menzils (multi-room houses with toilet facilities). Almost every house, even in the cities, has a walled courtyard or garden [18].

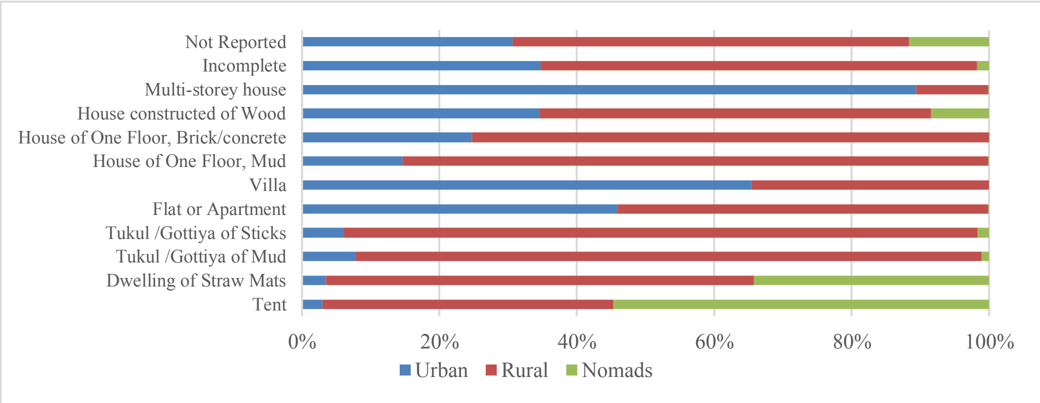

Figure 8. Household and population by type of dwelling
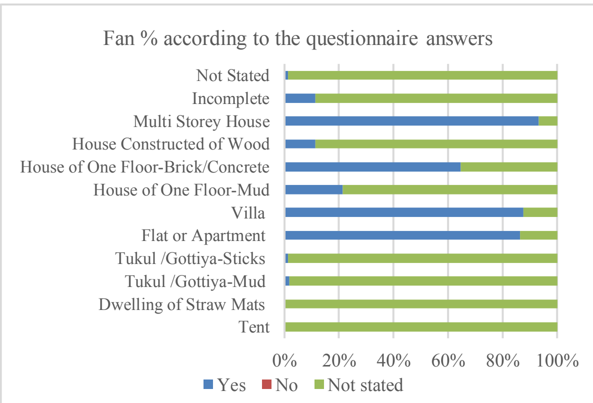
Source: Central Bureau of Statistics Census 2008 [13]

According to the collected data from 2008 census reports, dwellings in Sudan are classified into different types: tent, dwelling of straw mats, Tukul or Gottiya of mud, Tukul or Gottiya of sticks, flat or apartment, villa, single-storey mud house, single-storey brick or concrete, house constructed of wood and multi-story house. Most of the urban population live in a multi-story house and the rest in temporary and traditional houses. In the rural population, one-floor mud houses and Tukul or Gottiya stick houses are the common types, while multi-story houses rarely exist (Figure 8). The nomadic population depends on temporary materials, like straw mats and other temporary materials.

2.7 Heating and cooling devices:

Simple devices like fans and air coolers are used for cooling in Sudan. The data showed that these devices are used by about 18.17% of the total population for fans and 3.94% for air coolers. Most of these devices are used by the urban population rather than the rural population (Figure 9 and Table1). The data in Figure 9 may be unreliable due to a large amount of not stated answers.



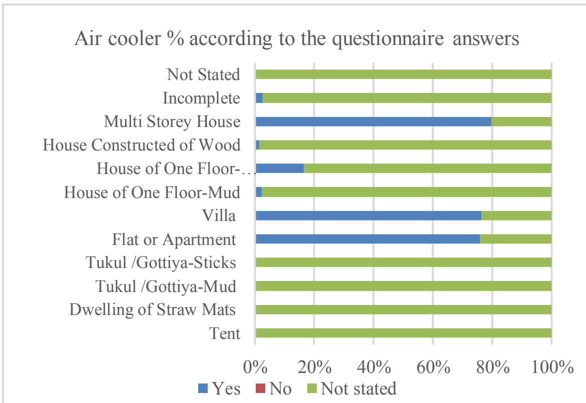


Figure 9. Percentage of fans and air coolers for different dwelling types according to the questionnaire answers, Source: Central Bureau of Statistics Census 2008 [13]

Table 1: Percentage of fans and air coolers of the total population

Item	Households%		
	Total %	Urban %	Rural %
Fan	18,17	40,22	9,3
Air Cooler	3,94	11,05	0,77

Source: Central Bureau of Statistics Census 2008 [13]

In temporary, old and traditional buildings fans and air coolers are rarely used, while they are more common in one-floor brick, concrete dwellings, single or multi-story houses and apartments (Figure 9). Most of the modern houses from reinforced concrete and bricks contain either simple or advanced cooling devices, due to the fact that concrete as a building material is not compatible with the Sudanese environment. Heating devices are not applicable in Sudan, except in a few houses in the northern part where electrical heaters are used for a few days in winter [13].

Table 2. Building typology table.

Construction Time	Temporary	Single Family Dwelling Detached			Multi-family Dwelling
		Climate Zone I (warm desert climate)	Climate Zone II (warm semi – arid climate)	Climate Zone III (tropical savanna climate)	
Very old (1900-1950)[1,2]		 House of One Floor Mud (Adapted)		 Tukul/Gottiya Mud	
Old (1956-2000)[3]	 Tukul /Gottiya Sticks	 Tukul/ Gottiya Mud	 House of One Floor Brick/ Concrete	 Dwelling of Straw Mats  Wooden Dwelling	 Flat or Apartment
Modern (2000- till now)[4]	 Tent  Tukul /Gottiya Sticks	 House of One Floor Mud	 Villa		 Multi Storey House

[3] The Post-Independence Era (1956–2000)
[4] Architecture from 2000 onwards [19]

3. Results

The aim of the research was to present an overview and create the building typology of Sudan based on the data collected according to the different parameters: construction time, climate zone, construction materials, durability, tenant status of the dwelling and the building capacity.

From the collected data we could arrange the building typology table (Table 2) according to construction time, different climate zones, the durability of the material and the family size. A short description of each type is as follows:

The Tent is a very old, temporary and easy to move dwelling, which is used by nomads. It is made from the local materials. ***Dwelling of Straw Mats*****:** a traditional dwelling which is made from pieces of mats connected together to form a room shape which is used as a shelter, it could be as a hut or a rectangle shape. ***Tukul/ Gottiya of Mud:*** a mud hut or house which is made essentially from the mud. (Tukul is a simple room made from traditional materials, some people use it as a place for cooking, while Gottiya is a single room with round walls and a conical roof.). ***Tukul/ Gottiya of Sticks:*** it's a temporary stick room, which is made essentially from sticks as supporters for the dwelling. ***Flat or apartment:*** made of modern buildings materials, such as bricks and reinforced concrete. ***Villa:*** includes a large amount of land and often barns, garages, or other outbuildings as well. ***House of one floor, mud:*** a traditional house with one or many rooms. It is made from mud as an essential material. ***House of one floor, brick/ concrete:*** a one family house with many rooms which is made from bricks and concrete. ***House constructed of wood:*** a single family house which is made from wooden elements. ***Multi- Storey House:*** a multi-family dwelling which is made from modern materials such as red bricks, reinforced concrete, cement block, and others.

4. Conclusions

The collected data from the country censuses, surveys, reports, and research papers had a lot of information about the climate, topography, building materials, and building technology of Sudan. A building typology table was prepared from the different collected data and with different parameters, such as construction time, the durability of the dwelling, and building capacity.

From the analysis the following points could be concluded:

- Climate change has a deep effect everywhere. In Sudan, the hot-arid areas have advanced southward, especially in the vulnerable areas surrounding Al Fashir and Nyala. This climate change caused a strong food scarcity, draught and affect the thermal comfort of buildings.
- The means of cooling and heating devices, such as air-conditioning is rarely used in Sudan because of the high cost of the operation, the price of the equipment and the low income of the majority of the urban population.
- The research on building typology was a starting point to better understand the features of Sudan's climate and to study and organize the building typology. These typology results should be improved and transferred into practical results.
- Data from Sudan's fifth population and housing census in 2008 were used, because it was the most recent, although there was some shortage of information on housing and building materials in the data. Due to this reason, some of the information applied in this paper is rather old but at least it was helpful in the classification and analysis procedure. Future research and updating the information will be much easier in the future.

5. Acknowledgment

Project FK 128663 has been implemented with the support provided from the National Research, Development and Innovation Fund of Hungary, financed under the FK_18 funding scheme. The research reported in this paper was also supported by the FIKP grant of EMMI in the frame of BME-Water Sciences & Disaster Prevention (BME FIKP-VÍZ).

Abstract. The current focus on climate change mitigation is reflected in policy goals to reduce the energy use of buildings. However, buildings are not only responsible for a large share of energy use and corresponding GHG emissions, they moreover require a lot of resources, produce a lot of waste, and emit harmful substances. In this paper, an approach is developed to investigate the most preferred renovation strategies for social housing, considering various parameters such as efficiency of the current and future heating system, service life of the heating system and insulation level of the building envelope. Moreover the reduction in life cycle environmental impact due to the replacement of heating systems by systems with increased efficiency is studied. The results show that for non-insulated buildings an increase of the thermal resistance of the building envelope is more effective than replacing the heating system while for, even poorly, insulated buildings the efficiency of the heating system is more important. A holistic Life Cycle Assessment approach is preferred to assess renovation scenarios as focussing on energy reduction might lead to an increase of the life cycle environmental impact of the building. Although this paper focuses on social housing, the approach is broadly applicable.

1. Introduction

Buildings are responsible for a large share of energy use and GHG emissions in Flanders [1] [2], require a lot of resources, produce a lot of waste and emit harmful substances [2] [3]. Despite these insights policy currently focusses merely on the reduction of energy use in buildings. The current draft climate policy plan for Flanders aims for a compliance of all residential buildings with an Energy Performance Certificate (EPC) level A by 2050 [4], [5]. An EPC shows the energy score of the building compared to other buildings [6] and is calculated using a standardized method [7]. To reach this goal the energy use in residential buildings should decrease 76% compared to 2012 by 2050 [5] and therefore Nearly Zero Energy Building (NZEB) renovations are put forward [8] [4]. Social housing companies face an important challenge in renovating their existing housing stock to a level compliant with these policy goals [1] [4] [8] as they have limited budgets. Although operational energy use is causing an important impact on climate change [9], a narrow focus on energy reduction should be avoided. This paper therefore evaluates renovation scenarios using a Life Cycle Assessment (LCA) approach, considering multiple environmental impacts. The most preferred refurbishment strategies for social housing are investigated, considering various parameters such as efficiency of the current heating system, service life of the heating system and (increased) insulation level of the building envelope. Typically, LCA studies are static studies, meaning that the impact of the interventions of to date are included in the assessment, but that future improvements during the service life of the building are not considered. In this paper, a dynamic approach is developed that takes into account future improvements such as expected improvements of heating system efficiency for every future replacement.

2. Description of the method

2.1. Estimation of the energy use

In a first step the energy use for spatial heating of the building is estimated based on the equivalent degree day method [10] [11](1). Ventilation losses and solar and internal gains are assumed to be constant for the various refurbishment strategies as data collection on these aspects is not yet finalised.

$$Q_t = \left(0{,}024\ \sum_{q=1}^{w} \frac{S_q\, a_q}{R_q}\right) Eq°d\ \frac{1}{\eta} * L \tag{1}$$

Table 1. Parameters to estimate the energy use to compensate transmission losses over the service life of the building.

Q_t	Heating energy over the building service life (kWh)	
Sq	Surface of each element (m²)	Input
a_q	Correction factor heat losses	Input [12]
Rq	Thermal resistance of each element (m²K/W)	Input [12]
Eq°d	Equivalent degree days (K d)	1200 [13], [14]
η	Global system efficiency (%)	Input [15]
L	Building service life (years)	60

For the energy calculation (and related environmental impact assessment), a dynamic approach is used whereby a more efficient heating system is assumed each time the system is replaced. As future efficiencies are unknown, estimates are made based on the analysis of historic data. The estimated efficiency of the heating system installed in the year of the replacement ($\acute{\eta}_t$) is based on the efficiency in year 0 ($\acute{\eta}_0$) and the annual growth rate for efficiency ($g_{\acute{\eta}}$) (2). The latter is assumed to be 0,5%. Sensitivity analysis on this parameter is foreseen in a future step of the research.

$$\acute{\eta}_t = \acute{\eta}_0 * \left(1 + g_{\acute{\eta}}\right)^t \tag{2}$$

2.2. Assessment of the environmental impact

The environmental impact of the materials used for the renovation measures and of the energy use for heating is assessed through a Life Cycle Assessment (LCA) [16] [17]. The Belgian LCA method for buildings and building elements [13] is used. This method considers seven impact categories in line with the European standard EN15804+A1:2013 [18] and ten additional impact categories in line with the Belgian legislation [19].

For the inventory of the data, the Ecoinvent database version 3.3 [20] is used. Scenarios for transport to the building site and installation, as well as scenarios for cleaning, maintenance, sorting, transport to the End Of Life (EOL) treatment and the EOL treatment itself are based on the Belgian LCA method [13]. The dismantling of materials is assumed to be manual and therefore no impact is included. In case the elements are still in a good condition, the existing element is maintained. In case the element is renovated, both the impact of the new element and the impact for the EOL treatment of the existing element (E_0) are taken into account. It is furthermore assumed that the service life of some components is lower than the service life of the building and hence require replacements during the building service life. More specifically, it is assumed that 10% the roof tiles and the entire internal roof finishing are replaced each 30 years. These are assumed to be replaced by identical materials (with the same environmental impact as to date). The estimated service life of the windows is assumed to be 30 years and these are replaced by better insulating windows. The service lives of elements are based on literature [21]. At the end of the service life of the building, here 60 years, the impact of the EOL treatment of all elements is included. The assumptions for the EOL treatment of the elements and systems are presented in Table 2.

Table 2. Overview of EOL treatment **[13]**.

	On site Sorting on site	Fractions landfill	allocated to incineration	specific EoL recycling
Waste glass sheet (window)	70%	5%		95%
Wooden products (window)	40%		85%	15%
Ceramic roof tiles	75%	95%		5%
Fibre cement slabs	75%	100%		
Gypsum plasterboard	50%	80%		20%
System (metals)	100%	5%		95%

2.3. Assessment of the Environmental Life Cycle Cost

The national LCA method in Belgium includes the option to aggregate all impact categories in a single score by calculating an external environmental cost in euro, the E-LCC, presented in Table 3 [22]. This represents the costs to avoid or compensate the environmental impacts caused. To make straightforward decisions in case of contradictory indicators, the E-LCC is used to compare the renovation strategies.

Table 3. Overview central monetary values [22, table 3 and 4, p 12]

Environmental indicator	Unit	Monetary value (€/unit)	Environmental indicator	Unit	Monetary value (€/unit)

3. Results and discussion

3.1. Description of the case study building

The case study building is a terraced family house of two floors with three bedrooms for four people. The building is constructed in 1983. The external walls and roof are insulated with 6 cm of mineral wool insulation. Currently no ventilation system is installed. The present heat production system is a gas boiler with a production efficiency of 85%. The default values of the Flemish EPB standard [15] are assumed for the efficiency of the other system components (emission, regulation and distribution) which results in a total system efficiency of 69%. The surface area and composition of the building elements being renovated are presented in Table 4.

Table 4. Composition of building elements being renovated.

Element	Construction	U value (W/m²K)
Floor on grade 86,85 m²	- Concrete slab - Support layer - cement based screed - Ceramic tiles	2,89
External walls 83,20 m²	- Gypsum plaster - Loadbearing brickwork - Mineral wool insulation (6 cm) - Brick veneer	0,45
Pitched roof 83,70 m²	- Roof tiles - Wind and water barrier - Mineral wool between wooden beams (6 cm) - Gypsum board	0,55
Windows (27,88 m²) and roof windows (3,15 m²)	Wooden frame with double glazing	3,30

3.2. Description of the renovation scenarios

The renovation scenarios for the building envelope are presented in Table 5. For each scenario several thicknesses of the insulation material are considered. For the external walls the first scenarios is adding external mineral wool insulation with a finishing of façade tiles on a wooden frame. In a second scenario external EPS insulation is added to the walls, finished with a mineral rendering. It is assumed that the service life of the external rendering is 30 years and that it is then replaced by an identical one.

Table 5. Description of renovation scenarios.

For the renovation of the pitched roof, again two scenarios are considered: (1) insulating with mineral wool between the existing wooden structure and (2) adding PUR insulation boards on top of the existing structure. The finishing for both roof scenarios is assumed to be with new ceramic roof tiles. For the heating boilers three options are considered: (1) the existing boiler was recently replaced and hence can be used for another 10 years, (2) the boiler is replaced by a new one with a service life of 30 years and (3) the boiler is replaced by a new one with a service life of 20 years. After 10, 20 or 30 years the boiler is replaced by a new system with a better efficiency and the EOL treatment of the previous system is included. For the scenarios where the heating boiler is replaced in year 0. The efficiency of the new heating boiler (in year 0), is assumed 97% or 104%, resulting in a heating system efficiency of 78% or 84% respectively. As mentioned in section 2.1, the efficiency of the replaced boilers at year 10, 20 or 30 is assumed to be higher than to date according to formula (2).

3.3. Analysis of the influence of the insulation level of the base case

As the housing stock of social housing companies in Flanders is divers and consists of buildings with different construction periods, it would be interesting to see whether this would affect the selection of the renovation scenarios. To provide this insight, the assessments are done for the case study building as described in section 3.1 and for a hypothetical case assuming the building is not insulated.

3.4. E-LCC and energy demand for several renovation scenarios

3.4.1. The effect of including the efficiency increase for future replacements of the heating system. To gain insight in the importance of using a dynamic LCA approach, the results of the dynamic approach are compared with ones using a static approach (i.e. efficiency of the heating system is kept constant during the whole service life of the building). For this comparison it is assumed that the existing boiler was recently replaced and will be replaced in 10 years by one with a higher efficiency and a service life of 30 years. The results for both the case study and the hypothetical uninsulated house are presented in Figure 1 per building element and in Figure 2 per impact category. A decrease of the total E-LCC of 5,47% for the poorly insulated building and 8,99% for the non-insulated building is noticed when the dynamic approach is used. This is due to the decrease of the energy use needed for heating the building and a corresponding decrease of the impact on global warming. This confirms that a dynamic approach is important.

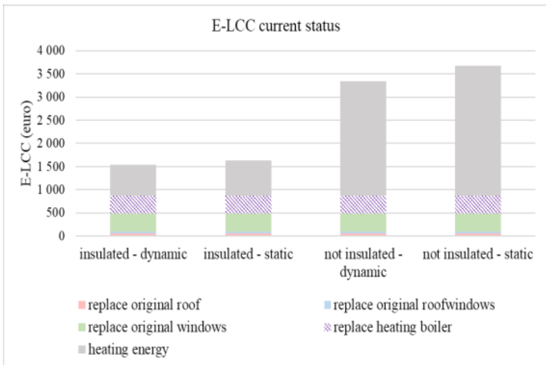

Figure 1. E-LCC per element of the case study building and hypothetical uninsulated building using a dynamic and static LCA approach

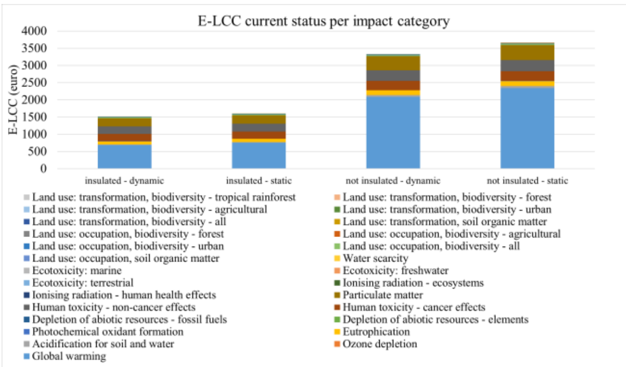

Figure 2. E-LCC per impact category of the case study building and hypothetical uninsulated building using a dynamic and static LCA approach

3.4.2. E-LCC results of the renovation scenarios. The E-LCC of several renovation scenarios for the poorly insulated case study building and the non-insulated hypothetical situation are presented in Figure 3. Table 6 shows a description of the renovation scenarios studied in Figure 3.

Table 6. Description of the renovation scenarios studied in Figure 3

	Insulated	Not insulated
Current status	6 cm mineral wool wall insulation 6 cm mineral wool roof insulation Roof windows U 3,30 W/m²K Windows U 3,30 W/m²K Heating 69% efficiency, 30 year service life	No wall insulation No roof insulation Roof windows U 3,30 W/m²K Windows U 3,30 W/m²K Heating 69% efficiency, 30 year service life
Minimal investment	6 cm mineral wool wall insulation 6 cm mineral wool roof insulation Roof windows U 3,30 W/m²K Windows U 3,30 W/m²K Heating 78% efficiency, 30 year service life	No wall insulation No roof insulation Roof windows U 3,30 W/m²K Windows U 3,30 W/m²K Heating 78% efficiency, 30 year service life
Minimal energy use	18 cm EPS wall insulation 16 cm PUR roof insulation Roof windows U 1,47 W/m²K Windows U 0,90 W/m²K Heating 104% efficiency, 20 year service life

NZEB 1	18 cm stone wool wall insulation 18 cm stone wool roof insulation roof windows U 2,45 W/m²K windows U 1,50 W/m²K Heating 84% efficiency, 30year service life	
NZEB 2	12 cm EPS wall insulation 10 cm PUR roof insulation Roof windows U 2,45 W/m²K windows U 1,50 W/m²K Heating 84% efficiency, 30year service life	

One of the current renovation measures in social housing is replacing the existing heating system by a better one, represented in Figure 3 as the scenario “min investment”. For the case study building this results in an E-LCC decrease of 4%, while for the non-insulated building the effect is higher, namely 7%, due to the higher original heating demand. The results show that (1) the effect of improving the heating system is lower when the building is better insulated and (2) that it is more interesting to improve the insulation level of non-insulated buildings than replacing the heating boiler.

The renovation scenario minimal energy use in Figure 3 leads to the lowest heating demand for the poorly insulated building. For this renovation scenario a reduction of the energy use of 64% is obtained, however, the E-LCC for this scenarios increases with 88% compared to the current status. Apparently the reduction of the impact for heating the building due to the extra insulation and more efficient heating boiler cannot compensate the additional impact for the new materials and the new boiler. On the other hand, for the non-insulated building a reduction of the energy use of 89% is shown for the scenario leading to the lowest energy use, which results in a reduction of the E-LCC with 19%. Striving for a minimal energy use is hence not the best approach for all buildings to reduce the environmental impact.

The renovation scenario resulting in the lowest E-LCC for the poorly insulated case study building results in a reduction of 7% of the E-LCC and a reduction of 15% of the energy use. This scenario only includes a replacement of the heating system. Further increasing the insulation of the building envelope does not result in a sufficient reduction of the heating demand to compensate for the additional impact of the new materials. For the non-insulated building a much higher (44%) reduction of the E-LCC is achieved for the scenario leading to the lowest E-LCC. The further energy reduction due to additional replacement of the windows is insufficient to compensate for the additional environmental investment costs.

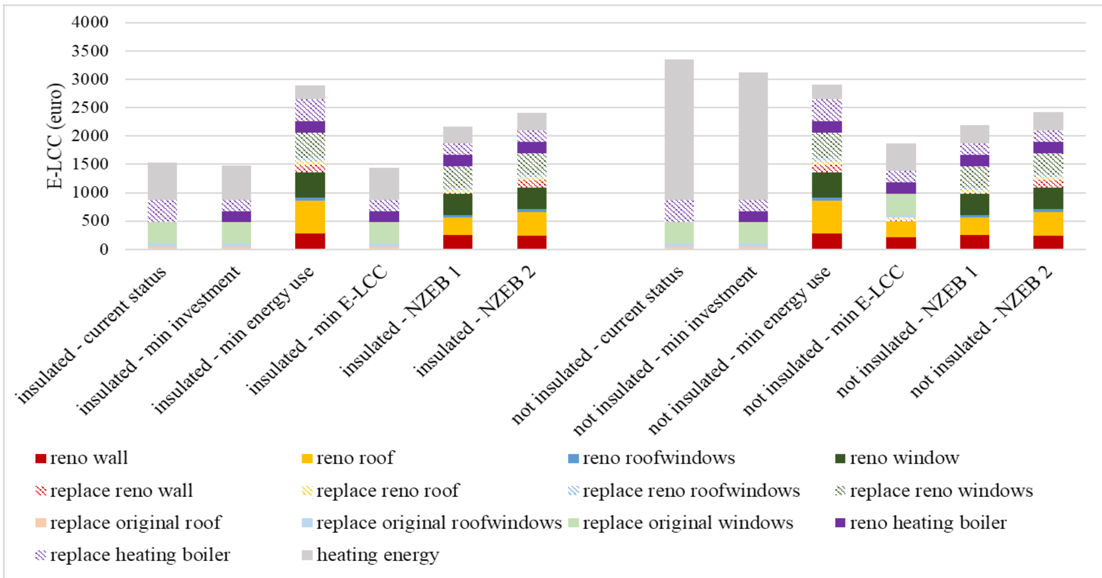

Figure 3. E-LCC for several renovation scenarios for the poorly insulated case study building and the hypothetical non insulated situation

3.4.3. E-LCC results of two NZEB scenarios. The requirements for NZEB renovation are based on U values for the building elements *[8]*. However, the environmental impact of buildings is not merely related to the impact of the energy use, but moreover the impact of the materials can be important. To gain insight in the E-LCC of NZEB buildings compared to the analysed renovation scenarios, two scenarios for NZEBs, with different materials, were defined. The results are presented in Figure 3 for both the poorly insulated case study and the hypothetical uninsulated building.

For the poorly insulated building the reduction in energy use of the two NZEB scenarios is similar, 54% and 53%. Although the E-LCC is increased for both scenarios the magnitude of the increase is slightly different due to the different impact of the insulation and finishing materials used in each scenario. For the scenario with mineral wool insulation the E-LCC has increased with 41%, while for the scenario with EPS and PUR insulation the E-LCC has increased with 56%. This can be explained by the difference in the impact of the production process of both the insulation and the finishing materials and in the difference in service life of the chosen finishing [21]: the rendering needs to be replaced once entirely during the service life of the building while the façade tiles need only one partial replacement. For the non-insulated building the NZEB renovation scenarios lead to a decrease in energy use of 87% and 86% and a decrease in the E-LCC of 35% and 27% respectively.

For the case study building, the NZEB renovation scenario leads to an increase of the E-LCC of the building compared to the current status, while for the non-insulated building the NZEB renovation scenarios lead to a decrease in the E-LCC, although other scenarios lead to an even further decrease.

Table 7. Overview of the effect on energy use and E-LCC of the various renovation scenarios.

	Insulated building		Non-insulated building	
Scenario	Energy use (kWh)	E-LCC (euro)	Energy use (kWh)	E-LCC (euro)
Current	100%	100%	100%	100%
Min. investment	-9%	-4%	-9%	-7%
Min. energy use	-64%	+88%	-89%	-19%
Min. E-LCC	-15%	-7%	-80%	-44%
NZEB 1	-54%	+41%	-87%	-35%
NZEB 2	-53%	+56%	-86%	-27%

The effect on the energy use and E-LCC of the various renovation scenarios is presented in Table 7. The policy goal to reduce the energy use with 76% seems not possible for the case study building. However as the case study building is already insulated, this goal is possibly to strict. Based on the current EPC score (241) for the case study building [23], only a reduction of 42% is needed to reduce the EPC score to 100. Based on the results presented in Table 7, a 42% reduction can be achieved although resulting in a higher E-LCC and thus leading to a higher environmental impact. If the case study building would not have been insulated, all energy renovation scenarios would lead to a lower E-LCC, however important differences in the magnitude of the reduction of the E-LCC are noticed.

4. Conclusions and further outlook

This paper studied whether a future increase of the efficiency of heating systems has an important impact on the estimation of the life cycle environmental impact of a building. Furthermore the most preferred renovation strategies for social housing are investigated.

Considering that replacements of heating boilers during the service life of a building will include a higher efficiency at each replacement, results in a decrease in the Environmental Life Cycle Cost (E-LCC) of 5,47% for a poorly insulated building and 8,99% for a non-insulated building. As improvements in the emission and distribution components of heating systems as well as coupling with other systems, such as for example heat pumps can be expected, it seems interesting to further study possible improvements in technology for heating in detail. Besides the effect of efficiency increase of heating systems, the effect of the service life of the system on the E-LCC of the building is studied. As a shorter service life of the heating boiler results in more replacements and the corresponding increase in E-LCC linked to the investment in new systems, it is preferred not to replace the heating system before the end of its technical life.

The most preferred renovation strategy for a non-insulated building proved to consist of improving the thermal resistance of the building envelope rather than replacing the boiler by a more efficient one. For poorly insulated buildings, the opposite was found: for these buildings it is more interesting to replace the heating boiler by a more efficient one.

The analysis of NZEB renovation scenarios as proposed by policy revealed that these lead to an increase in the E-LCC for the poorly insulated building, whereas for the non-insulated building this scenario leads to a reduction of the E-LCC compared to the current status of the building. However renovation scenarios with a lower insulation level lead to an even lower E-LCC. Striving for a minimal energy use results in a higher E-LCC for the poorly insulated building because the E-LCC of the additional materials to insulate the building envelope cannot be compensated by the reduction of the E-LCC for energy. It seems therefore more efficient to focus in the E-LCC of renovation scenarios rather than on the reduction of the energy use.

As the impact on global warming is linked to the amount of energy from natural gas needed for heating the building it seems interesting to study the effects of a shift to renewable energy. Therefore estimations on the energy use needed to prepare sanitary hot water and the electricity use should be included in future research to assess the effect of renewable technologies such as solar collectors or PV panels.

Abstract. This paper presents a case study of environmental evaluation of innovative shell-nexorade hybrid timber construction system designed within fabrication-aware technic and fabricated using robotic construction technology. The life cycle assessment of construction phase of the system has been performed; a sensitivity study of the robotic system's outlay has been effectuated. The results show that the contribution of robotic construction system to the overall result is fairly significant and, in some figures, can even exceed the material's one.

1. Introduction

The ongoing development of digital design and fabrication techniques has explicitly changed the way architecture is thought, designed and produced. The emergence of the non-standard movement in the early 2000 was explicitly arguing for the beginning of the new era based of mass-customization paradigm, that was supposed to bring some spectacular changes to construction industry by releasing its production from the curse of standardization [1],[2].

Therefore, empowered by computation, a whole generation of highly optimized forms appeared, spreading a belief into the sustainable character of those as well as the potential of digital technologies in the field of environmental performance of the sector.

Nevertheless, most of optimization and rationalization technics are principally focused on a single phase of life cycle of a product or a single impact indicator. Today's most of energy-efficiency policies are focused on the operational phase of a building, e.g. heating, cooling, etc [3]. And a recent slight progression towards life cycle performance generated a hot discussion amongst practitioners on ecological character of different construction materials, with a succeeding popularity of timber high-rise buildings.

Regarding the academic trends, multiple lightweight construction systems were developed within digital design-to-production workflow [4], [5]. A significant reduction of construction materials in various building elements was achieved, strengthening the credence into the sustainable potential of digital fabrication.

In this paper we question the environmental performance of morphologically optimized and numerically produced construction system. The use of life-cycle assessment method is proposed to evaluate the question. An innovative timber construction system - shell-nexorade hybrid is taken as a case-study.

The purpose of the study is twofold: in the first place, the environmental impact of the construction system is assessed, secondly the impact transfer of the system is investigated. In other terms, the fundamental question of this work is the possible trade-off between efficiency of the structure and environmental load of robotic construction system.

2. Description of the structure

2.1. Design

The structure was built for the occasion of 20 years of the new site of Ecole des Ponts ParisTech, by the team of Navier Laboratory. Also known as R2 pavilion, the structure incorporates manifold researches on structural morphology and architectural geometry conducted in laboratory.

Figure 1. *R2 Pavilion* built with shell-nexorade hybrid structural system

The structural type of the pavilion was baptized as shell-nexorade hybrid, due to the elegant blend of both principles. Nexorades, are largely known as reciprocal frames. They are constituted of load bearing members which support each other in a cyclic manner along their sides [6]. This specific arrangement of members makes them connect by pairs, creating a significant simplification of assembly, which is a general problem of classical space structures and gridshells. However, the simplification of assembly technics comes along with an increase of geometrical complexity, which is usually solved by a form-finding method as far as design part is concerned [7].

The membrane behaviour was achieved by introducing the flat panels that act like bracing elements and transform the grid of beams into the shell structure. Therefore, with an additional 30% of material mass the structural stiffness was multiplied by 10.

The planarity of the bracing quad panels was held within marionette method [8] in order to ensure their fabrication flair as well as to avoid the coupling between bending and axial forces. Therefore, the initial surface was meshed with planar quads, then using translation method [9] the T-joints were generated, preserving the planarity of the quads.

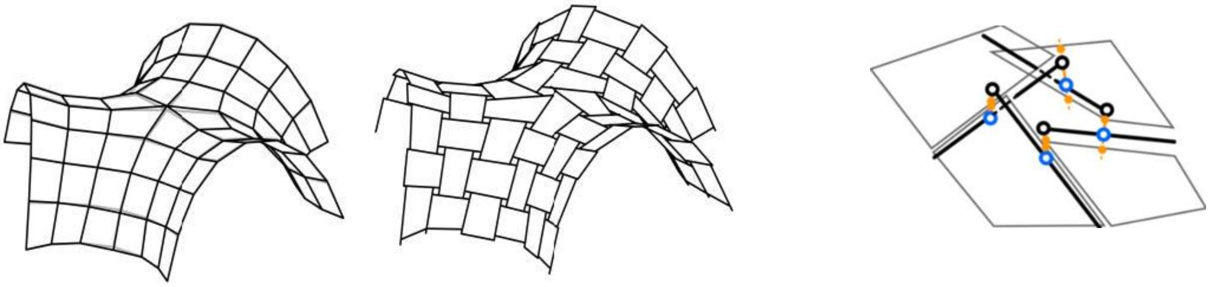

Figure 2. PQ-mesh transformation to Reciprocal Frame(left); Marionette technic for planarity of quads (right) **[10]**

2.2. Fabrication

Most of design choices of the project were made within the fabrication-aware strategy [11] , which could be briefly described as the geometry rationalization principle focused on manufacture constraints. Thus, the final structure is composed of 102 straight glulam beams and 48 flat plywood panels, each of which is non-standard. The totality of formal and manufacturing complexity was brought into beam's geometry (Figure 3), to be held with 6 axes robotic milling. As follows, the panel fabrication was abridged to a mere CNC cut.

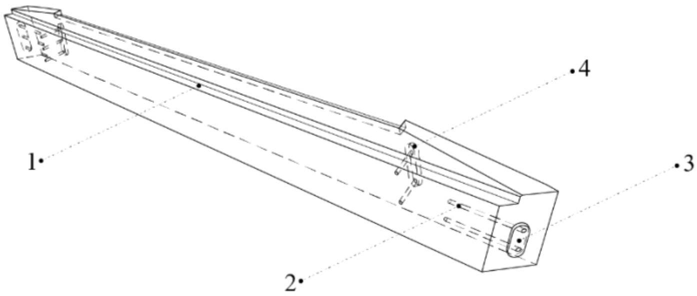

Figure 3. Example of beam element:

1. Reservations for panels
2. Screws to set place
3. Tenon
4. Mortise

The layout scheme of the robotic platform of Ecole des Ponts ParisTech is shown in Figure 4. It is composed of two collaborating 6 axes robotic arms (1): one is mounted on a 9 m track (2) and referred as gripper robot (1a), the other is fixed and referred as fixed robot (1b). The milling head (3) is mounted on fixed robot and the pneumatic gripper (4) is fixed on gripper robot. Next, eight independent operations were effectuated with stationary fixed tools dispatched around the track (cf.[12]).

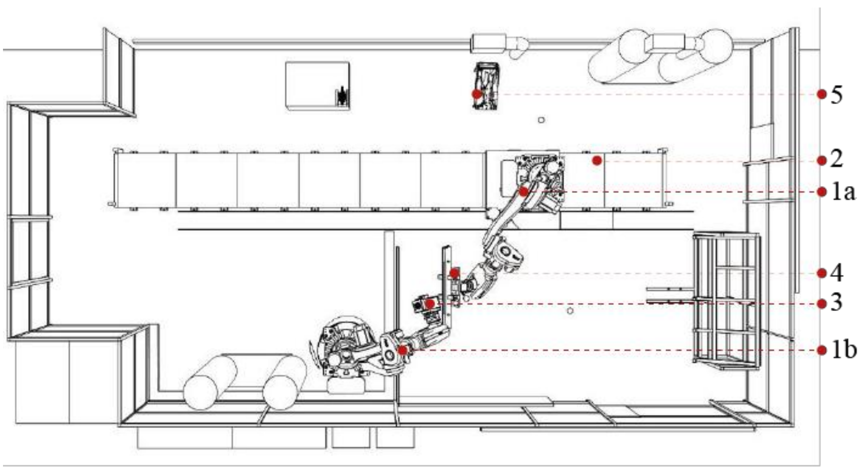

Figure 4. Top view of layout of robotic fabrication platform: 1a _Gripped Robot; 1b _Fixed Robot; 2_Track; 3_Milling head; 4_Pneumatic gripper; 5_Circular saw [10]

2.3. Assembly

The assembly technic of the structure represents the most low-tech part of the construction process. It basically demands some drilling skills and some specific crews, that can be set against the wood fibres [13] (Figure 5).

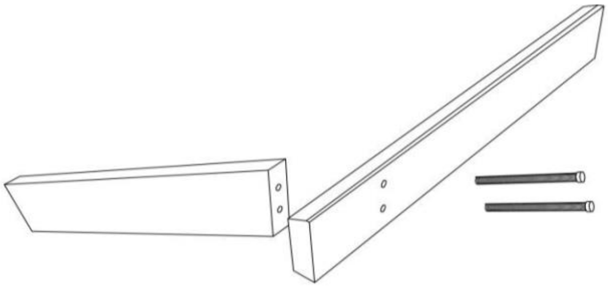

Figure 5. Scheme of T-connections assembly of Beams [12]

All the construction elements of a structure were prefabricated off-site and assembled in-situ, which demands an approximately zero tolerances of fabrication and assembly processes. The assembly sequence starts from the construction of a hexapod from the central node and then progresses to the boards. Geometric control of connections was ensured through the tenon/mortise system milled on the beam's extremities (Figure 3) and the adjustment of the bracing panels (cut with a tolerance of 2 mm on each side). Authors claim that the assemblage part can be handled by 2 persons [12], back in time though the human resources needed to figure one were 6 PhD students, 2 Academic Researchers and 1 Professor.

3. Methodology

In order to evaluate the environmental character of the structure, the Life Cycle Analysis method is used [14], [15].

A few academic works have already explored a similar problem. Agusti-Huan et al. have effectuated a foremost work in the field, comparing digitally fabricated elements with ones fabricated conventionally [16], [17], concluding that digital fabrication processes do not really count in total results, comparing to the potential in terms of material reduction they bring. The system boundaries of the analysis were cradle-to-gate, without consideration of end of life phase.

Krieg et al. have also performed an LCA study of an innovative timber structure [18]. The constructive system was compared with its alternatives, differentiating materials and fabrication technics. The stiffness of the structure was referred as functional unit and only the GWP indicator was considered. The results show that even if the embodied carbon of materials is still more important than the one of robotic construction system, the second does contribute to global result. It seems that only energy consumption of the robot was taken into account.

In present case study we focus on the methodology for taking into account robotic construction system. Therefore, a detailed life cycle model of robotic fabrication system was assembled, taking into account the maintenance and the replacement of components during service period that was set for 12 years. Then, a sensitivity study of the outlay of the construction system to the referenced process was effectuated, ranging a working period of machines within three scenarios (Table 1) in order to investigate the difference it will bring to global result. The outlay calculation follows the expression below:

$$\frac{\text{Working Period of Machine}}{\text{Lifespan of Machine}}\ 100\%$$

The first one considers uniquely the fabrication time which is around 20 minutes by beam and one hour for panels. The second one reflects an idealistic scenario of the entire production process: one week by machine, which still is greatly optimist for the research project. The third scenario accounts an actual duration of parametrisation and set up period needed at the time: two months for robotic cell and two weeks for CNC cell. It is important to note that the energy consumption remains the same in all three scenarios.

Table 1. Three scenarios of machines' outlay

	1st Scenario	2nd Scenario	3rd Scenario
Robotic Cell's Outlay	**37.62 H** / 105120 H = 0,04%	**120 H** / 105120 H = 0,1%	**1440 H** / 105120 H = 1.4%
CNC Cell's Outlay	**1 H** / 175200 H = 0.0006%	**120 H** / 175200 H = 0,07 %	**576 H** / 175200 H = 0,3 %

In order to have comparable results regarding other construction technics, the cradle-to-gate stages were set as system boundaries (A1-A3 cf. EN 15804).
Recipe Midpoint (H) method of impact calculation was chose, following to the ILCD Handbook recommendations [19]. The EcoInvent 3.2 cut-off database was used for inventory within OpenLCA software. Finally, the life cycle model of the system is depicted in Figure 6.

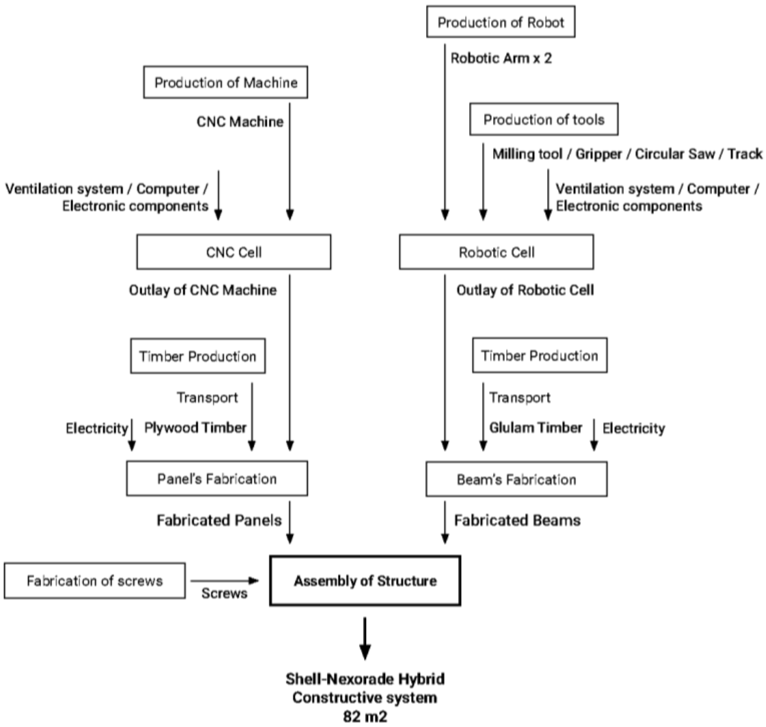

Figure 6. Life-Cycle Model of Shell-Nexorade Hybrid Construction System

4. Results and Discussion

The environmental impact of the shell-nexorade hybrid construction system is presented on the Figures 7 and 8. The variation in results is related to different outlay calculation of robotic and CNC cells to the process of reference. In other terms different working time of machines were considered in order to investigate the sensitivity of the parameter.

The present study illustrates that digital fabrication processes contribute significantly to the overall environmental impact of the system, which means that optimisation design strategies based on robotics technology for the production part should take into account the environmental load of the last.

The same hypothesis needs to be verified for the structure of larger scale containing more elements. Considering the important amount of time needed for the parametrization of production sequence versus the rapid execution, the environmental load of digital fabrication may be insignificant for larger production series. Finally, the present results need to be compared with an alternative construction system fabricated without robotic technology, in order to have the complete vision.

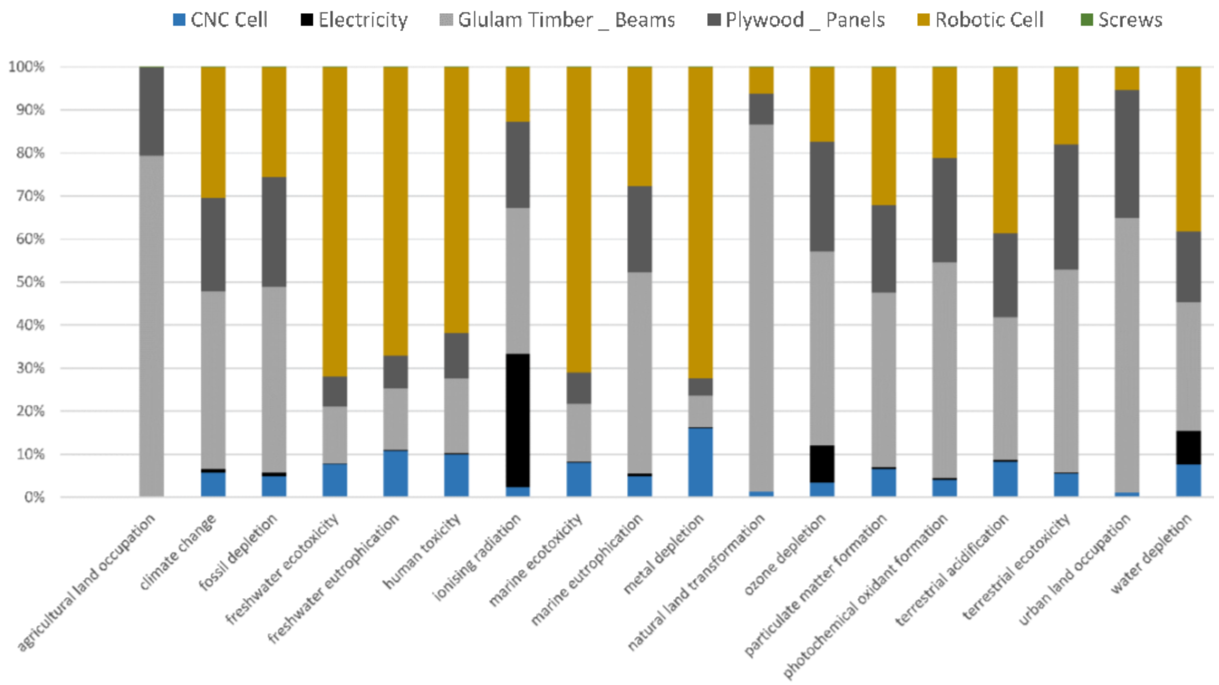

Figure 7. Environmental Impact of Shell-Nexorade Hybrid _ 3rd Scenario

5. Conclusion

This LCA study of innovative timber construction system designed within the fabrication-aware strategy and produced using digital fabrication technics demonstrates the occurring of an important impact transfer in the life cycle of the system caused by robotic fabrication technology. The sensitivity analysis of the outlay of machine's working time has confirmed the significance of this parameter in the overall result. Consequently, depending on the accountment method the contribution of digital fabrication system can be almost as important as the one of the materials, which answers the fundamental question of this work on the possible compromise between those two.

In closing, automation in construction is today's one of the most major research topic in building sector. In early 2000, numerical controlled machines were theorised as the solution for the differentiated mass production, in middle 2010, robotics begun to be seen as the solution to the environmental problem of the sector. Yet, for multiple reasons of legal and technological inertia of the industry, the mass-customisation is barely ready to advent, and the environmental performance of automation remains to be developed within the appropriated theoretical agenda.

Abstract. Many strategies have been investigated seeking for efficiency in construction sector, since it has been pointed out as the largest consumer of raw materials worldwide and responsible of about 1/3 of the global CO_2 emissions. While operational carbon has been strongly reduced due to building regulations, embodied carbon is becoming dominating. Resources and processes involved from material extraction to building erection should be carefully optimized aiming to reduce the emissions from the cradle to service. New advancements in timber engineering have shown the capabilities of this renewable and CO_2 neutral material in multi-storey buildings. Since their erection is based on prefabrication, an accurate construction management is eased where variations and waste are sensible to be minimized. Through this paper, the factors constraining the use of wood as main material for multi-storey buildings will be explored and the potential benefits of using Lean Construction principles in the timber industry are highlighted aiming to achieve a standardized workflow from design to execution. Hence, a holistic approach towards industrialization is proposed from an integrated BIM model, through an optimized supply chain of off-site production, and to a precise aligned scheduled on-site assembly.

1. Introduction

For the first time in over 20 years of United Nations (UN) negotiations, a global agreement on climate dealing with the reduction of greenhouse-gas (GHG) was established in Paris in 2015 within the 21st Conference of the Parties (COP 21) of United Nations Framework Convention on Climate Change (UNFCCC) and the 11th session of the Meeting of the Parties (CMP) to the 1997 Kyoto Protocol.

The main long-term goal of the so-called Paris Agreement is to maintain the global temperature increase bellow 2°C related to pre-industrial levels through reducing GHG emissions [1], what would substantially help to mitigate the irreversible effects of a climate change. However, a report from the United Nations Environment Programme (UNEP) has concluded that such a goal is not achievable under current circumstances. According to the report from the UNEP, the energy intensity per square meter of the global buildings sector needs to improve on average by 30% by 2030 compared to 2015 to meet the ambitions from the Paris Agreement [2].

Building sector has here a decisive role since accounts for 36% of global final energy use and 39% of energy-related carbon dioxide CO_2 emissions [2]. Obviously there is an environmental need to reformulate construction implementing a better use of resources and avoiding wasteful practices.

2. Why timber?

Since building regulations have become more restrictive in terms of energy consumption in use stage, operational carbon has been considerably reduced. Consequently, the CO_2 emissions produced by building product manufacturing and construction phases (A1-A5), called embodied carbon, have assumed a main role when reducing global emissions. By using low-carbon materials and employing more-efficient design and construction processes, the CO_2 emissions could be reduced up to 30% [3].

Lifecycle Assessment (LCA) is a standardized method to quantify environmental impacts of buildings throughout the whole life cycle stages, from material extraction and product manufacturing (A1-A3) through construction (A4-A5), use and maintenance (B1-B7), and end of life (C1-C4). Even supplementary information beyond the building life cycle can be quantified meaning the benefits and loads beyond the system boundary (D) [4]. Following this discourse, for the life cycle assessment of two variations of concrete and two types of construction timber, the Global Warning Potential GWP [kg CO2 –eq] over a time horizon of 100 years was analyzed (s. Table 1) according to the European standard EN 15978 [5]. The system boundaries for the calculation is based on the general LCA framework [5] and following stages are included:

A1-A2-A3	Product stage: Raw material supply – transport – manufacturing
C2	End-of-life stage: Transport
D	Benefits and loads beyond the system boundary stage: Reuse, recovery, and recycling potential

Table 1. LCA indicators of building materials Global warming potential GWP [kg CO2 –eq] per m³

	A1-A3	C2	D
Concrete C25/30	211.1	12	-21.4
Concrete C35/45	265.1	12	-21.4
Glued laminated timber	-652.6	0.46	-372.6
Cross Laminated Timber	-633.4	0.44	-357.6

The life cycle assessment (LCA) is based on the data coming from EPD (Environmental Product Declarations), containing transportation, set to truck, during extraction/production (module A2) which is included in the EPD module A1-A3 and transportation to waste disposal (C2).

Attending to the environmental impact of the selected materials, the ecological advantages of timber compared to conventional concrete is highlighted underlining the potential for further developments, since its production is less carbon intensive, it is renewable and stores carbon for the long term contributing positively to the global warming control. Its strength-to-weight ratio makes timber an attractive material to build with since transport emissions are reduced, as so is the size of the foundations, while the workability increases.

Besides material selection, a leaner approach needs to be implemented to avoid the wasteful practices, which have put construction sector as the largest consumer of raw materials and responsible for about 1/3 of the global waste annually. Since the focus of the so-called Lean Management relies on eliminating waste, minimizing material use, avoiding errors and increasing accuracy and efficiency, a low-emission building site is therefore achievable through its implementation.

3. Methodology of research

Off-site construction may be the most positive factor when building with timber. Though prefabrication exists since decades, it is at present when it is not anymore linked to mass production, where all elements look alike with no customization, but to a systematic working methodology where sub-pieces, when combined, form an end-product with bare constrictions. Implementing off-site timber construction, overall time can be reduced by 25% [6] since the erection on site is based on an assembly process within an in-time project delivery. Besides, the production of the elements takes place in a factory away from weather detriments while parallel work on-site is allowed. Hence, strategies focused on industrializing and professionalizing the sector, based on prefabricated elements, are needed to be investigated in order to take the lead in the market of urban multi-storey buildings, taking into account that already from the design phase, different procedures as in traditional planning are needed in order to achieve an Integrated Planning (IP) with a high definition grade, buildable and divided into aligned work packages.

With the purpose to explore the weaknesses and potential improvements of the timber industry towards industrialization, expert surveys and extended literature review was conducted, where two main topics were explored: the constraints and possibilities of implementing timber or timber-based materials in multi-story buildings and the potential benefits of using some Lean Construction principles and methods throughout the entire process from design to execution. Through a crossed information exchange and case studies, a holistic approach about how to efficiently behave when planning and constructing multi-storey buildings with timber or timber-based materials is proposed. As an ongoing project, the conclusions drawn served as basis to develop running systematic semi-structured interviews with selected experts on both themes with the purpose to deep into the underperformance of timber in multi-story buildings.

3.1. Expert surveys and literature review on multi-storey timber buildings

In the field of this research, a round of workshops under the umbrella of the project Holz.System.Bau were conducted and organized by MAGK-Architektur together with Eco.Plus (Bau.Energie.Umwelt Cluster Niederösterreich) and accounting 41 professionals taking part. Within two months different stakeholders from the timber industry actively highlighted weaknesses, potential improvements and possible strategies to investigate aiming to implement the use of timber as main material for multi-storey buildings. Planners, researchers, contractors, constructors, timber specialists and timber engineers, among others, in a brainstorming oriented round table, discussed an amount of decisive factors regarding to use resources more efficiently along the whole process from design to erection.

The first workshop was focused on highlighting the main goals and the boundary conditions of the approach, and the second was established as a follow up to deep into the proposed strategies and precisely establish work packages for a tentative project. A third workshop is expected to be arranged in upcoming months. The results of the sessions are organized in the following table (s. Table 2) with the purpose of simplifying the objectives, goals and strategies discussed.

Table 2. Summary of the main topics discussed within the workshops series

<table>
<tr><th></th><th>Urgent value-adding goals</th><th>Strategies</th></tr>
<tr><td>Design</td><td>- Extended knowledge in architectural design
- Know-how exchange platform
- Specific academic training
- Energy and material efficient concepts
- Less constructive elements, joints and details</td><td rowspan="5">- Define a reactive and adaptive modular system with standard assemblies from already existing components
- Develop an integral catalog with all load-bearing and not load-bearing modular system elements
- Spread the solutions through a BIM library as an open source
- Advance a collective value-adding actions catalog throughout the whole process
- Implement a crossed specific training
- Improve efficiency through Lean Management
- Promote reliable cost and time plans by implementing Lean Construction</td></tr>
<tr><td>Production</td><td>- Optimized logistic and coordination
- Competent handcraft
- Shorter production time in factory</td></tr>
<tr><td>Erection</td><td>- Faster assembly through higher prefabrication grade (plug-and-play)
- Use rainproof constructive elements
- Optimized logistic and coordination
- Null-error performance</td></tr>
<tr><td>Cost-time</td><td>- Refinement of planning costs
- Reliable cost and time plans
- Faster offers and lighter comparability</td></tr>
<tr><td>End-product</td><td>- Cradle-to-cradle
- Improved end-product quality</td></tr>
</table>

Planning a contemporary timber building implies more expertise, since factors such as support structure, fire resistance, sound isolation, energy concepts and prefabrication need to be taken into account in an early stage of the project. Hence, important decisions must be taken sooner than in conventional constructions such as element size, joints, timber system and degree of prefabrication. Also technical building equipment must be integrated and their interfaces identified and defined [7]. According to the specialists, around 80% of the projects are already defined when the decision to build it with timber comes, implying a re-design process wasting time, effort and resources. If the decision of building with timber were earlier taken and therefore, specific know-how from timber specialists or timber engineers were implemented in an early stage of the project, a significant amount of unneeded rework could be avoided. This lack of explicit knowledge in the design phase was highlighted by the specialists as one of the main factors constraining a fluent workflow. A collaborative design approach is needed to be implemented within an IP where all disciplines and aspects above mentioned are coordinated avoiding collisions, misunderstandings and errors among others. Some strategies regarding this procedure and cooperation models for planning and execution were proposed at the Technical University of Munich through the research project LeanWOOD showing how far is this ideal picture of a fluent workflow to reality [8].

Beside the lack of expertise in early stages, the overwhelming variety of materials and elements available on the market was also underlined as constraint, since the wide range of construction options eased often varies between construction companies. To simplify planning and construction, a standardization of available timber solutions should be implemented and construction sets should be implemented, which allows not only flexible solutions with fixed price, but technical details, work packages and coordinated production and erection. Within the research project Bauen mit WEITBLICK, a system building set was proposed based on parametric building blocks and a building assembly systematic to enable industrialized social housing in a high quality. All elements were digital defined in a BIM model including every relevant data to produce the building assemblies and the production planning. This optimization in planning and production shown a significant saving potential within a number of process analysis and optimization cycles [9].

According to the experts, an optimized construction management based on industrialized building methods using system components is still missing in the sector and should be implemented, for timber to take the lead as main material on multi-storey buildings. Main topics to be considered to reach such a goal are modularity and high prefabrication grade with standards elements and joints, and implementing reliable and transparent planning including work scheduling, tasks, logistics and construction techniques, what implies close collaboration within regular meetings, and fluent communication between architects, structural engineer and construction companies to coordinate the assembly sequence and connections. As a promising suitable work methodology, Lean Construction was proposed since the implementation of Lean Management in other industries such as automobile and manufacturing has brought relevant benefits in terms of productivity and resource and flow efficiency.

3.2. Literature review on Lean construction

Lean Construction (LC) is an adaptation of the Toyota Production System (TPS) applied to construction sector. The so-called Lean Management is a work philosophy whereas waste and errors (called *muda* in Japanese) are seen as opportunities to improvement, as quoted by his initiator Taiichi Ohno, “having no problems is the biggest problem of all” [10]. Its goal is to track and eliminate every task with no value to the end product. One of its main basis is the pull planning, instead of push planning, common on mass production like in the Ford Production System, where a large quantity of similar products are pushed forward along the production line. Contrary, pull planning delivers only the specific products and components asked, wherein a tight involvement and trust-based relationship between producers and sub-producers are needed. Throughout a Just in Time (JIT) delivery is allowed, coming the elements and products directly on site with no unnecessary stock space, no waiting time nor movements, also considered as *muda*. Another key concept related to lean is the so-called *Kaizen* or continuous improvement, where workers at every stage are able to stop the production process if a mistake is detected, being involved more actively in the process, assuming more responsibilities and avoiding unnecessary hierarchal climbing. Their implication is decisive since they know exactly how the tasks should be done. Such a statement was sentenced by Taiichi Ohno saying: “Standards should not be forced down from above but rather set by the production workers themselves” [10]. The source of the problem is then tracked and removed, becoming the process more efficient.

The term Lean Construction was first formulated by L. Koskela in 1992 [11] who highlighted the main and chronic problems of construction sector and suggested to learn from another industries which have managed to increase their productivity while in construction sector has stood still [12]. LC was then defined as a production system to minimize material use, time, and effort in order to generate the highest value possible, as it is made in a factory. Its principles follow transparence, quality and stability based on collaborative and reliable plans, with no constraints nor deviations. Such an approach is under the umbrella of LC within three main methods that trigger a cooperative and efficient way of construction management. These methods are Integrated Planning (IP), following the line of Last Planner System® (LPS), and the Takt Time Planning (TTP).

LPS is a pull planning system developed by Glenn Ballard, whereas regular meetings are handled between workers*, last planners*, aligning the tasks of every trade in a trust-based collaboration achieving a reliable planning and a continuous workflow [13]. It consists on defining which tasks *can* be done, which *should* be done and which *will* be done in different periods of time, providing besides the order and the requirements and preconditions for the tasks to be performed. This work methodology can be applied during the design phase by integrating the different departments and stakeholders in one planning process, and throughout achieve an IP [14].

TTP is another significant strategy inherent from LC, which aims to increase productivity by fitting and optimizing work packages and workers to suit a balanced and desired frequency of production, so-called *takt*, where non value-adding time is reduced and a continuous flow of production at a steady rate is achieved [15]. TTP was developed by Porsche Consulting and its suitability to improve project-based production systems has been highlighted since a better use of available resources is achieved. Although theories have explained how to apply TTP and its potential benefits, there is a lack of documentation about practical approaches and analyzed empirical data [16].

3.3. Case Studies: Timber goes Lean

Both the utilization of timber on multi-storey buildings, and the application of lean construction strategies have been barely implemented together in the sector, even though it is expected to bring a lot of positive aspects. Through this paper two case studies were selected whereas IP, LPS and TTP were implemented in high-rise timber buildings and analyzed through extended literature review, being suitable examples of the implementation of some principles described within this paper.

3.3.1.Moholt 50|50

A complex system was developed specifically to build the five passive house tower blocks made from timber elements which comprehend the Moholt 50|50 in Trondheim. At the time of construction, the project designed by Masu planning and MDH Arkitekter SA, was the largest massive timber building in Norway, with 632 student apartments [17]. The erection of this nein stories high student housing was based on prefabricated Cross Laminated Timber (CLT) elements industrially produced coming on site JIT and scheduled through TTP and an adaptation of LPS and IP to “Nordic Model of Work”, named “Involved Planning”, what was especially developed for this project by the construction company Vaidekke AS and the researcher Lars Andersen [18].

Builders were strongly involved throughout the whole process within the Involved Planning holding multiple roles and employing actively their skills in planning and problem solving. Because of their implication in early stages, the project was buildable and the technical plans detailed with a description of the building process. Planning meetings were regularly conducted, where builders, leaders and engineers planed work packages in terms of “look ahead”, as in LPS, for different periods of time, two months, two weeks or one week. Thus, the information was always up to date and the tasks for next week accurately updated, adapted and planned. Consequently, a smooth building process with few errors was achieved. The work on site involved an intense participation through daily planning meetings between on-site crew leaders and office foremen about what was done and how, being the Key Performance Indicators of the running status of on-site work. Works on-site started in February 2016 and in November 2016 the first three towers were completely finished and students moved into, while the last two were under final inspection [19].

The interior building process was structured under the TTP principle, since the deadline was extremely close and no delay was possible. The TTP was developed and managed by the site manager from the main contractor, who had been trained in Porsche *Takt*. The right method to correctly define a TTP according to his experience, consists on identifying trade order while minimizing the times each trade enters the same zone and reducing the time wasted on non-productive work [20]. It was the third project of the company and site manager where TTP was implemented. Within the first project was not able to maintain the path, and the second, though becoming better results and being smoother, could have been further optimized [21]. However and based on *kaizen*, the workers got more experience and achieved for this project a harmonized workflow. Despite the high reliability of the schedule planned, unpredictable errors and unforeseen issues occurred during the building process but were flexibly handled and adjusted by the builders since there was a shared holistic understanding of how the system works and a mutual interdependency [19]. However, there were suppliers who depended on third parties which resulted to be the most common source of problems since were not correctly involved in the shared agreement.

There were totally 23 assembly lines with two to four workers, called wagons, who moved along work stations of the tower blocks executing specific operations. The speed of construction was one floor per week and per wagon, moving the first wagon after finishing the first floor to the second floor and coming the second wagon inside the first floor. Following this path and once the first wagon finished the last floor of the first tower, moved to the first floor of the second tower to keep on working. Hence, the 23 wagons-train moved through the entire complex in 23 weeks [20]. Along this period, with a fixed train speed, builders became more efficient and the productivity increased, being the wagons occupancy reduced, while other tasks were parallel performed by builders within weekly meetings.

Based on this collaborative working model, builders were able to finish Moholt on time, below budget and without serious errors nor injuries. Furthermore, leaders stated they would continue to perform down this path [19]. However, an important factor to be mentioned is that the project was selected through an architectural competition, wherein its construction was planned within a conventional steel and concrete structure. It was after winning when the decision to build it with CLT came in order to meet better energy and climate standards [22]. Consequently, the whole process could have been optimized, as highlighted also within the expert survey, if the decision of using timber as main material would have been earlier taken, and thereafter specific know-how sooner implemented.

3.3.2. Suurstoffi 22, Baufeld A + Arbo, Baufeld 1 – Areal in Risch Rotkreuz

The first high-rise timber building in Switzerland, designed by Burkard Meyer Architekten, is a pioneer project where BIM and Lean Construction Management (LCM) were together successfully implemented. The ten stories high office building located in “Baufeld A”, in Risch Rotkreuz is part of a renowned innovative project with nine areal in Luzern promoted by Zug Estates Holding AG. The whole project, which has been widely praised because of its innovation and sustainability, was defined through a BIM model as a digital twin within all processes were defined and optimized through LCM in an iterative way linked to the architectural model. The 36 meters high building received the silver price from Prix Lignum, where the best accomplishment of timber use in Switzerland is recognized in an every three years event. The final CAM (Computer Aided Manufacturing) plans needed for the industrialized prefabrication of the timber elements within CNC (Computer Numeric Control) machines succeeded directly from the architectural BIM model by the company Erne AG Holzbau. The BIM model was based on a catalogue from the construction company where all building elements were defined and identified. Hence, a JIT delivery was allowed from ordering along production and delivery to on-site execution. LPS and TTP were implemented within the project, where one day was defined as the *Takt* Time and one floor was finished in ten days [23].

Following the discourse by S22, another 60 meters high timber building with 15 stories was designed by Manetsch Meyer Architekten and Büro Konstrukt AG in “Baufeld 1”. This new high timber-based building named Arbo (Tree in Latin) will host the Hochschule Luzern (HSLU) and is, since December 2018 [24], erected and therefore the highest timber-based building in Switzerland. Besides, two more buildings conform the area, whereas one is also a wood-based construction. The first phase is expected to be completely finished by August 2019 with two institutes from HSLU moving inside, and the second one by spring 2020 [25].

Drees&Sommer (DS Consulting Process & Organization GmbH), together with Schockguyan, are the responsible of the LCM of the project in “Baufeld 1”, which was praised with the Arc-Award BIM 2018 in the category “Innovation”. Besides, Kaulquappe AG and Archobau AG as BIM and LC

Managers, made possible the coordination of the information exchange between all stakeholder through an Open-BIM system, and the digital management of on-site performances through a permanent monitoring linked to the BIM model. For the development of the required IP, an Open-BIM system served for the coordination of around 260 stakeholders from 40 different companies using each office different software for their specific purpose. J. Amann from Kaulquappe AG assumed the role of BIM Manager together with M. Giera, and assisted, together with A. Eisenhardt, as BIM Support within architecture, engineer, building equipment and construction site management. Besides, there were BIM Coordinators also taking part from different offices [25].

Like in S22, the IP was conformed of construction elements from a catalogue what allowed a high definition and, as above exposed, the possibility of getting the CAM plans directly from the BIM model. Each activity was linked to its element on the model with an ID and subdivided into daily tasks [26].

The alignment of those tasks started with an overall process analysis with the definition of work areas and process steps enhancing transparency and identifying problems. Then the *Takt* and *Takt* zones were defined with the amount of work per area, size of crews and duration with the purpose to uncover optimization potentials. After that the TTP is leveled and visually draw with the identification of trades and workflows optimizing its duration and identifying parallel processes. Throughout, an overall schedule was planned with the milestones and checked upfront processes making sure all requirements are available and preconditions are solved, following the philosophy of LPS. At the end, a detailed planning board was developed with specific information for daily activities, where was possible to identify obstacles, increase the stability and reliability and consequently optimize the *Takt* [26]. Within the on-site daily meetings, the BIM model served as a basis to define the tasks to be done with information about work steps, resources needed and their ID's. Those tasks, were printed on so-called *Kanban* cards, like in manufacturing, and posted on the planning wall on-site. At the end of the day, for the controlling, the cards whose tasks were accomplished were turned green and scanned through a bare code and updated into the BIM model [25].

Consequently within the digital twin it was possible to know what had been done, how, when and with which amount of resources in a short period of time. Thanks to the Open BIM approach, a steady up-to-date Single Source of Truth (SSOT) was achieved, and throughout the loss of information and possible misunderstandings were minimized, while the transparence increased. According to Brigitta Schock, from Schockguyan, the application of lean construction principles came after the development of the BIM Execution Plan (BEP), what brought re-adjustments and changes. Consequently the whole process could have been further optimized if those principles would had been earlier implemented [27].

4. The holistic approach: potential of industrialized timber construction.

A systematic approach, where a project is subdivided in similar elements being produced in a factory, brings several positive aspects like higher productivity, speed of execution, fewer errors, higher quality and reliable cost and time plans. Since it is based on standardized elements and details, the planning and production of fewer elements is eased, while the errors are minimized. Timber appears to be predestined to success with such a systematic approach since solid timber products have been for decades made in industries and customized for specific projects, firstly being represented within 3D software with a high grade of detail and information, through CAM files, and then sent to CNC machines. Besides, collaboration and an engaged commitment with material use and resources are main pillars of the work systematic of the timber industry, what have been found as synergies between BIM and Lean philosophy.

Based on the research conducted throughout this paper, a holistic approach is proposed, where the whole process, from design to construction, is optimized and automated based on standardize products and processes with the purpose to highlight the potential of timber towards industrialization applied on multi-storey urban buildings.

Considering that on-site changes are not an adequate procedure when building with timber, the collaboration between all disciplines in the design phase is crucial. Technology, especially BIM, enables a continuous know-how exchange and a permanent up-to-date information access, and through the integration of detailed components, elements and systems in a BIM model, an IP is achieved, being fundamental for an off-site construction implementation. Based on the IP and within the Pull Planning, the off-site production is allowed, being the elements produced after being called, in the right amount, in the right sequence and delivered to the right place in the right time. Thanks to this JIT delivery, no stock space is needed, nor waiting time, minimizing the time spent on-site and consequently costs, accidents, noise and dust, and achieving a pulled smooth production line from factory to field.

Within regular collaborative meetings under the framework of LPS and its backwards working philosophy, the milestones and "look ahead" plans are visually settled down, where work packages, areas and steps are defined and aligned, identifying restrictions and unlocking constraints. Combined with TTP [15], the amount of work is leveled, synchronized, stabilized and sensible to be optimized through the definition and analysis of daily activities. Although it has been proven that TTP can be applied in non-repetitive projects [28], its application in projects sensible to be divided into zones with similar work packages appears to be the most suitable scenario [29]. Consequently it can be stated that a systematic approach, such as the one proposed within this paper, seems to be the most suitable procedure for an efficient TTP. Through the construction phase and thanks to these detailed tasks planning and based on regular collaborative meetings, an earlier detection of deviations and constraints is allowed, providing a proactive approach which brings the possibility to modify and adapt the procedure and stay in plan, while potential improvements are uncovered and sensible to be implemented.

Supported with specific software, the daily planned activities, are digital defined and shared with all participants. Within an ID, those defined activities are linked to the particular construction elements in the BIM model, including valuable data such as location, work stage, resources needed and trades among others. Printing those activities on so-called *Kanbas* cards, the daily tasks and their accomplishment are permanently monitored on-site and through the scan of their bare code, the real state of the construction site is up-to-date in its digital twin serving as a real SSOT.

5. Conclusions

BIM is the tool that allows a lean management along the whole process, from design along production to execution [30], starting with a Lean Design based on IP, following with a Lean Production on a factory within JIT and getting to LCM through LPS and TTP. All in a backwards planned smooth process which implements not only the resource efficiency, but the flow efficiency. Although their application is not specific for timber constructions and can and should be implemented also in massive construction, timber seems to be predestinated to optimally perform under such an approach, considering that the industry has been working since decades within 3D models with lots of information, off-site construction within a responsible material use and close collaboration. Nevertheless, there is a need of empirical applications regarding the use of lean principles linked to a BIM model in timber sector, in order to state and document some proven principles, strategies or methodologies and quantify benefits, deficits and potential improvements.

While traditional construction culture is strong based on the so-called "golden triangle" of "quality + schedule + budget", both BIM as a supporting tool and Lean as a work methodology are strongly based on collaboration and communication seeking for efficiency, higher productivity and continuous improvement, so is the timber industry, being those more focused on "people + process + technology". All in all, several synergies and enormous potential exist between Lean, BIM and timber, aiming to be explored and exploded, being the timber industry in an optimal position to take the lead in the multi-storey urban buildings market.

Acknowledgments

The authors want to express their gratitude to all contributors taking part on the expert survey, especially to MAGK-Architektur and Eco.Plus (Bau.Energie.Umwelt Cluster Niederösterreich) for their significant encouragement in seeking for sustainable, low-tech and resource-saving architecture.

Abstract. This work aims to investigate the environmental friendliness of building materials, and in particular the benefit of using biogenic products as replacement of conventional materials. The sustainability of wood as a construction material is a complex issue since the environmental impacts are strongly related to forest management, service life and, finally, to end-of-life scenarios and waste treatment processes. In this study, a Life Cycle Assessment (LCA) comparison was carried out between a semi-detached house out of cross-laminated timber (CLT) and a conventional building with similar geometric characteristics and equal thermal performance (U-value), out of light-clay bricks with a reinforced concrete structure. Particularly, the environmental impacts from raw materials supply, transportation and product processing (cradle to gate) were investigated and the Recipe mid-point method was adopted for the impact assessment to compare the environmental burdens of the two equivalent buildings. The positive environmental values resulted in the massive timber building are mainly connected to the replacement of the reinforced concrete mass used in the structure. The outcome, in terms of global warming potential, show that the use of wood as a building material instead of conventional materials results in a reduction of greenhouse gas emissions of roughly 25%. This material replacement, if extended on a large scale, could give a valid contribution on achieving the community goals of reducing emissions from the construction sector.

1. Introduction

The construction sector plays a decisive role in the achievement of the European targets for the reduction of energy consumption and carbon emissions. With this aim, European and, consequently, Italian standards mainly addressed the decrease of the environmental impact during the use phase through reducing the demand for operating energy [1]. As a consequence, the energy performance of buildings has been improved, mitigating the environmental impact of the operation phase. However, the importance of the other life cycle stages has increased due to higher material inputs [2]. As a matter of fact, the (fossil) carbon emitted when manufacturing the materials and during the construction stage might significantly affect the carbon savings from operational energy [3]. Building materials selection strongly affects the overall environmental impact of a building; in particular, the choice of the materials for the structural frame and the building envelope (foundation, exterior wall and roof) has a major influence [4].

This work presents the results of a study conducted with the aim of assessing the benefits, in terms of environmental impact, deriving from the use of construction technologies based on wood instead of traditional materials for the construction of residential buildings. Specifically, a Life Cycle Assessment (LCA) comparison was carried out between a semi-detached residential building with a load bearing structure made of Cross Laminated Timber (CLT) panels and a building of the same size and similar architectural and performance characteristics composed of a reinforced concrete load bearing structure and light-clay bricks. More precisely, the environmental impact deriving from the production cycle of the materials and products used for the construction of the two buildings has been assessed.

2. Methodology

The assessment of the environmental impacts of the two buildings was carried out according to the European standard EN 15978:2011 [5], which divides the life cycle of a building into different stages: the product phase (A1-A3), the construction process phase (A4-A5), the use phase (B1-B7), and the end of life phase (C1-C4).

The LCA analysis presented in this study was limited to the product phase (A1-A3) and it is used, specifically, to assess the environmental impact of materials and products used for the construction of the body of the two buildings. This phase includes the following activities: extraction of raw materials (A1), transport of the materials to the production company (A2), and production of the finished packed product up to the factory gates (A3).

For the comparative study of the two buildings, the construction technologies described in the technical documentation provided by the construction company were analyzed. Specifically, a list of all the materials necessary for the construction of the main structural and envelope elements was drawn up and the environmental impacts of these materials were calculated using the datasets available in the Ecoinvent 3 database [6]. Finally, the results for the two buildings were compared.

The methodology of LCA analysis is uniquely defined by the international standards ISO 14040:2006 and ISO 14044:2006 [7]. These standards provide the general principles, requirements and guidelines to properly conduct the analysis and define a scientific framework to assess the environmental load of products and processes allowing a comparison between them.

3. Case study analysis

The two case studies considered in the analysis are two residential buildings built in the same year in the same area in northern Italy with similar features and dimensions, but built with different construction technologies. The first, Building A, was built using a structural system of load-bearing walls made of cross laminated timber, while the second, Building B, was built using traditional construction technologies (i.e. a load-bearing frame of reinforced concrete and walls made of light clay bricks).

The objective of the analysis was to compare the environmental impacts of the two buildings, broken down with respect to the materials and components used for the construction of the two buildings.

Figure 1. Building A, built with a load-bearing structural system of cross laminated timber.

Figure 2. Building B, built with a reinforced concrete load-bearing frame and brick walls.

Table 1. Dimensional characteristics of the two buildings

	Year of construction	Gross floor area *(m²)*	Number of floors	Number of apartments
Building A	2016	820	3	8
Building B	2016	814	3	8

3.1 Preliminary assumptions and limitations of the analysis

The Functional Unit (FU) used for the comparison of the two buildings is 1 m^2 of heated floor area. An LCA analysis of materials was carried out from a "cradle-to-gate" perspective (i.e. from the extraction of the raw materials to the factory gate).

The following assumptions were made for the analysis:

- Only elements of the buildings that differ between the two scenarios were included in the analysis. For above ground elements, vertical and horizontal external structures and closures were considered, while installations, finishes (coatings, paints) and fixtures, which are assumed to be the same for both buildings, were excluded. For the same reason, all underground structures were excluded, including the lower horizontal closure (ground floor);
- Non-load-bearing internal partitions (partitions and doors) inside the apartments were excluded since they may vary according to the needs of space distribution;
- 10 kg/m^3 of steelwork and hardware were considered for the wooden building;
- 150 kg of steel bars were assumed to be used per cubic meter of reinforced concrete.

For each building an inventory of all the materials and components was compiled according to the documentation provided by the contractor, which included graphs of the executive project, technical reports, and tender specifications.

3.2 Inventory analysis and impact assessment

Secondary data from the Ecoinvent database were used for the inventory analysis. On the other hand, the characterization factors and the impact categories considered by the ReCiPe Midpoint method were considered to assess the potential environmental impacts of the two buildings [8]. Finally, the SimaPro software (www.simapro.com) was used for the analysis. In the results, only the most meaningful impact categories for the present case study are presented.

4. Results

4.1 Impact assessment of the whole buildings

'Figure 3' compares the potential environmental impacts of the two building scenarios assessed with the ReCiPe method. Figures are expressed in percentage terms, where the worst case for each impact category is set to 100% in order to simplify the comparison.

The wooden building proves to have a lower potential impact for many environmental categories, while it results comparable to a building with a reinforced concrete frame and masonry infill panels in the others. Only in one environmental impact category (i.e. marine eutrophication), the wooden house shows larger potential impacts.

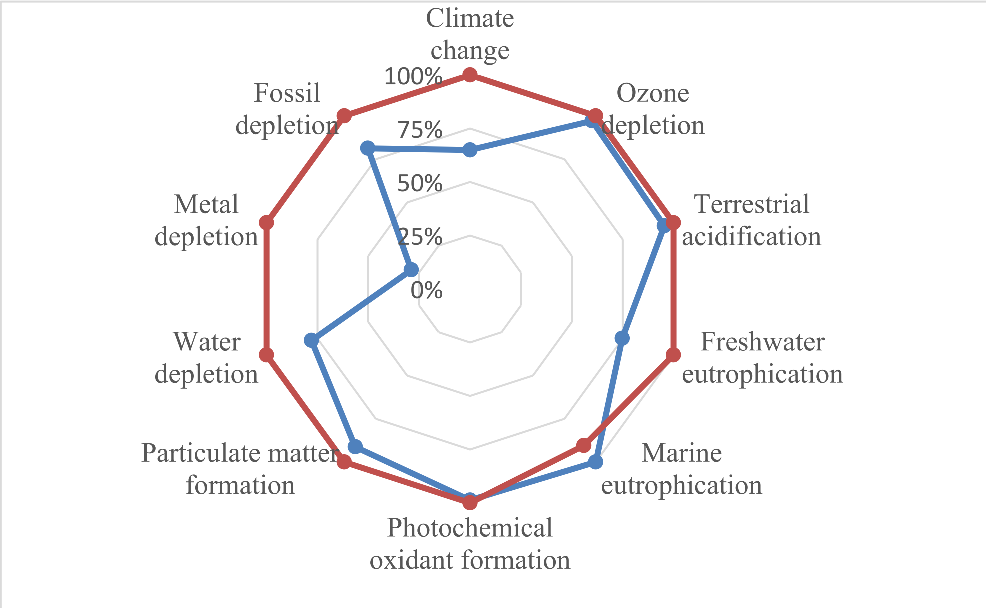

Figure 3. Comparison of results calculated using the ReCiPe method and the ecoinvent database. Blu line states for Building A (CLT), red line states for Building B (reinforced concrete).

Climate change results to be one of the categories where the timber building shows the highest impact reductions. In fact, more than 25% of the greenhouse gas emissions could be spared if timber was used instead of reinforced concrete and masonry. This difference could be even higher if the additional benefits related to the storage of biogenic CO_2 in construction products was included. In fact, wood can absorb carbon dioxide from the atmosphere and store it in the construction products. If the forest is properly managed, the carbon cycle can be defined as "neutral" since the biogenic CO_2 withdrawn is totally reabsorbed by the regrowth of the forest during the useful life of the building (i.e. 90 to 100 years). Nevertheless, these emissions were not included in the assessment since they are outside the scope of the study, given that they belong to the use phase of the life cycle of a building (i.e. B1-B7 modules in the EN 15978:2011 standard).

Moreover, the wooden building ensures a significant reduction in the consumption of non-renewable natural resources such as water, metals and fossils. Although it uses hardware to connect the various pre-shaped parts, the wooden building requires much less metal elements than the reinforced concrete counterpart, which uses large quantities of metal for the reinforcing structural elements. This results in a significant reduction in the impacts associated to energy usage as well, considering the high energy-intensity of metals production processes.

The use of wood, on the other hand, shows higher marine eutrophication impacts. The higher impacts are related to the management of the forest and the emissions of nitrates from fertilization.

For the remaining environmental impact categories, the two buildings do not exhibit significant differences.

4.2 Impact assessment of the buildings per FU

According to the design documentation, Building A (timber structure) has a gross floor area of 820 m^2, while Building B (reinforced concrete structure) 814 m^2. Total impacts were divided by the respective gross surfaces of heated floor to obtain the environmental impacts per functional unit. As the two overall surfaces are almost identical, results do not significantly differ from the results shown for the entire buildings. Results per FU are reported in 'table 2'.

Table 2. Results calculated using the ReCiPe method and the Ecoinvent database per functional unit (i.e. 1 m^2 of heated floor area).

	Climate change *(kg CO_2eq)*	Ozone depletion *(kg CFC-11eq)*	Terrestrial acidification *(kg SO_2 eq)*	Freshwater eutrophication *(kg Peq)*	Marine eutrophication *(kg N eq)*
Building A	2,24E+02	2,29E-05	1,29E+00	7,98E-02	7,01E-02
Building B	3,46E+02	2,35E-05	1,35E+00	1,07E-01	6,35E-02

	Photochemical oxidant formation *(kg NMVOC)*	Particulate matter formation *(kg PM_{10} eq)*	Water depletion *(m^3)*	Metal depletion *(kg Fe eq)*	Fossil depletion *(kg oil eq)*
Building A	1,39E+00	7,78E-01	2,65E+00	2,86E+01	6,80E+01
Building B	1,40E+00	8,53E-01	3,40E+00	9,91E+01	8,36E+01

4.3 Environmental impacts of each technical building component

In this section, the environmental impacts were divided into classes of technical elements (walls, roof, structure) and the results are presented in 'fig 4, 5'. For both buildings, "walls" and "roof" include all the materials and components that are part of the vertical and horizontal envelope that do not have a load-bearing function. On the other hand, the "structure" category include all the structural components with load-bearing functions. For Building A, all the materials used for the structure were considered: the internal load-bearing walls in XLAM, the beams and the joists, the slabs, the OSB panels in the internal floors, the stairs, the EPDM gaskets, and the metal joints. Conversely, for Building B, the "structure" includes the columns, the beams, the slabs and the stairs.

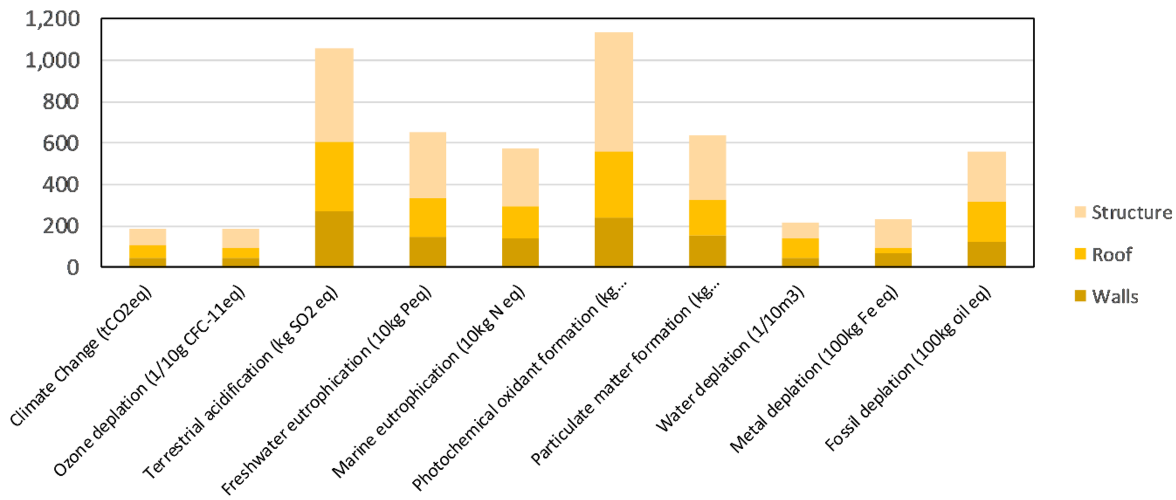

Figure 4. Results calculated using the ReCiPe method and the Ecoinvent database – Building A (timber structure)

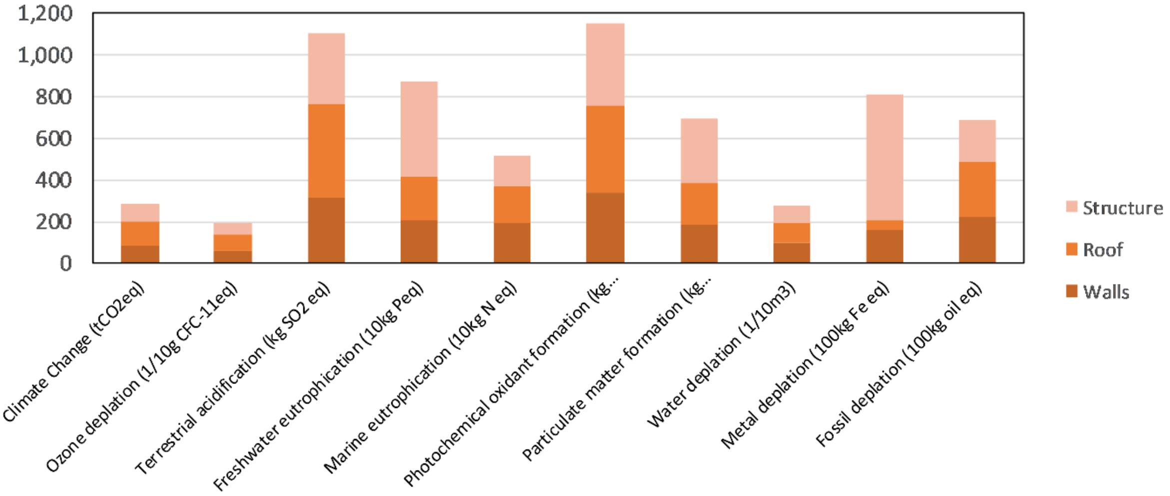

Figure 5. Results calculated using the ReCiPe method and the Ecoinvent database – Building B (reinforced concrete structure)

5. Discussion

The present analyses allowed to characterize the environmental impacts of the two houses both at the materials and the building level. As highlighted in other studies, the significant contribution of the structural elements to the total impacts was confirmed for both buildings, with a contribution of more than 50% compared to all the other technical elements for all the categories considered. Wooden building requires a lower amount of metal elements, and this results in a significant reduction of the potential impacts associated with the use of metals, which are particularly severe due to energy-intensive processes and typically long transports. The nearly total elimination of cement, used in the wooden building exclusively for the subfloors, also ensures a net reduction in the impacts. The production of cement, in fact, is one of the most impactful activities in the building industry, accounting alone in Europe for 55% of the CO_2 emissions of the entire construction industry. These impacts are particularly severe due to the clinker production process, which requires particularly high temperatures (around 1450 °C). In addition, large amounts of CO_2 are released as a result of the calcination reaction during the lime production process, which is also used in the preparation mixture of substrates and mortars. Nevertheless, it should be noted that part of the carbon dioxide emissions released during the production process can be reabsorbed during the useful life and end of life of the building due to the carbonation of the lime-based products. This process, however, is outside the boundaries of the analyzed system and it is not included in the assessment.

The use of wood is particularly beneficial for the Climate Change impact category compared to the use of reinforced concrete and masonry, thanks to the lower energy consumption during the extraction and production phases.

Moreover, the variation in insulation thickness can guarantee energy savings during the use phase of the building, but it is not so decisive in generating a significant environmental weight when compared to the contribution generated by the elements characterizing the entire building. This is partly due to the relatively modest masses of the insulating elements, which are typically rather light, and to the production impacts, which are not particularly heavy. Significant differences could be found in the use of alternative insulation materials, since moving from plant-mineral to synthetic materials can amplify the impact of some key indicators, such as Climate Change and Fossil Depletion.

6. Conclusions

Although life cycle assessment is becoming increasingly popular at the design level of buildings, there are still some methodological gaps due to the variability of the transformations involved in the building process. One of the main problems encountered is linked to the numerous uncertainties, at various levels, that characterise the several processes necessary for the production and assembly of the various building materials used in a building.

The sustainability of wood as a building material is a complex issue because from the point of view of the life cycle, the environmental impact is strongly linked to the management of the forest where the wood is sourced, to the durability of the building material, and, above all, to the end-of-life scenario. This study uses a standardised calculation methodology, based on EN-15978:2011, which allows comparison of the results of other works achieved with the same assumptions.

During the study it was necessary to establish some hypotheses and assumptions in order to clearly define the limits of validity of the results on the basis of the data currently available and provided by the contractor. In this context, the quantified contributions with purely economic values, the energy needed for the construction of the machinery, the energy provided by the workers and the energy spent on their transport to the workplace were neglected.

The positive environmental value measured in the wooden building is mainly linked to the replacement of the reinforced concrete masses used in the load-bearing structures. For instance, the use of wood as a building material instead of traditional materials leads to a reduction in greenhouse gas emissions of about 25%. The mere replacement of reinforced concrete and brick walls and floors with wooden panels guarantees a significant reduction in greenhouse gas emissions into the atmosphere, which, if extended on a large scale, could contribute on its own to the achievement of the EU Community objectives of reducing emissions from the construction sector.

alexander.roy.eliassen@gmail.com

Abstract. In this paper an LCA is carried out on a concrete and steel apartment building and a cross laminated timber apartment building to compare the greenhouse gas (GHG) emissions from the two buildings. The buildings are built by Veidekke Entreprenør AS and they are almost identical except for the structural system and the number of floors. They are connected by an underground car park of reinforced concrete. The product stage (A1-A3), transport to the building site (A4) and operational energy use (B6) is examined. Results show that the cross laminated timber building has 25% lower GHG emission compared to the concrete and steel building when looking at the production stage, and 13% lower emissions when looking at all stages. The results also show that the material that contributes to the most GHG emissions is reinforced concrete, and that the underground car park has a high GHG emission because it consists of a lot of concrete. What is new in this paper is that there are two real buildings close together that can be compared to find out which has the lowest environmental impact. The paper is valuable for people designing environmentally friendly buildings with a low carbon footprint.

1. Introduction

Climate change is an enormous problem for the world today, and if global warming is not limited it will have huge negative consequences. Therefore, it is urgent to reduce the greenhouse gas emissions to reach the 1,5° C goal stated in the Paris agreement [1]. The building sector is responsible for a large share of the world's total greenhouse gas emissions. In 2010, buildings stood for 32% of the total global energy use, and 19% of energy related greenhouse gas emissions [2]. Therefore, reducing the greenhouse gas emissions from the building sector can be an important measure to reach the goals of reducing global warming as much as possible.

Concrete is one of the most widely used construction materials in the world today, but one problem with using concrete as a building material is that it contributes to a huge amount of greenhouse gas emissions globally. It is especially cement, which is an important ingredient in concrete, that contributes to a large amount of greenhouse gas emissions. In 2017 cement clinker production stood for around 4% of the global CO_2-emissions [3].

One way to reduce the greenhouse gas emissions from buildings can be to use cross laminated timber-elements (CLT) as a construction material instead of concrete. More and more large buildings are constructed with CLT-elements today instead of more traditional materials like concrete and steel.

Mjøstårnet in Brummunddal is an 85,4 m tall apartment- and hotel building which was completed in March 2019, and is an example of a new building that uses CLT and glulam for the structure [4].

In this paper it will be investigated whether or not it is possible to save greenhouse gas emissions by using CLT elements to construct apartment buildings instead of concrete. The case which will be examined is Maskinparken 2 and TRE, which are two new apartment buildings constructed by Veidekke AS in Trondheim, Norway. Maskinparken 2 is a five-story apartment building which is constructed in concrete and steel, while Maskinparken TRE is an eight-story apartment building constructed using CLT-elements. What makes the two buildings comparable is that they are constructed side by side and they are almost identical except for the number of floors and the structural system. An LCA of the two buildings looking at the impact category climate change will be carried out to compare the greenhouse gas emissions from the buildings.

1.1. Previous research on greenhouse gas emissions of concrete and wood buildings

Skullestad et al. [5] investigated the climate change impact of reinforced concrete structures and timber structures in buildings with heights between 3 and 21 storeys. The study only examined materials in the load bearing structures and foundations. When attributional LCA was applied, the timber structures caused a climate change impact that was 34-84% lower than the reinforced concrete structures. The results of the study showed that the timber structures had a lower climate change impact than the reinforced concrete structures for all scenarios. Kaspersen et al. [6] looked at greenhouse gas emissions from technical systems for buildings of different heights. The scope of the study was cradle-to-gate. The results showed that the change in GHG emissions from the technical systems for increased building height was small.

Dodoo et al. [7] looked at carbon emissions from the entire life cycle of three different building systems in wood. The building systems that were investigated were CLT elements, beam and column system and prefabricated modules. They looked at both conventional and low-energy versions of the building. The results from the study showed that the low-energy version of the CLT building had the lowest carbon emissions, while the conventional version of the beam-and-column building gave the highest emission. The reason for this was because the beam-and-column system used more concrete and steel in the foundations and elevator shaft compared to the CLT building.

Dodoo et al. [8] also examined the effects of management of materials after use on the life cycle carbon balance of buildings. They found that carbonation of crushed concrete gave a significant uptake of CO_2, but that the emissions of CO_2 from fossil fuels that are used to crush the concrete reduced the CO_2 benefit of the carbonation. They also found that recycling of rebar and energy recovery of wood was more important and gave larger CO_2 benefit compared to the carbonation of concrete.

In a Swedish report from 2018 [9] an LCA of five different construction systems (cast-in-place concrete frame, cast-in-place concrete frame with light wooden and steel walls, prefabricated concrete frame, volume elements of wood and CLT frame) was carried out. The reference building is a 6-story apartment building in Stockholm which was completed in 2010. In this study the CLT frame building had a 40% lower greenhouse gas emission compared to the concrete frame building in the product stage. The CLT frame building had a higher emission in transport than the concrete frame building.

1.2. LCA of buildings

Life Cycle Assessment (LCA) is a method to assess the environmental effects of a product through the whole life cycle of the product, from extraction of resources to disposal. LCA is used to evaluate all types of products and product systems. NS-EN-ISO 14040 is a standard that describes principles and framework of an LCA, while NS-EN-ISO 14044 gives detailed requirements for the implementation of an LCA [10, 11].

NS-EN 15978 gives calculation principles to assess the environmental performance of new and existing buildings [12]. In this standard, system boundaries are defined for LCA of buildings. The system boundaries defined in NS-EN 15978 are A1-A3 (product stage), A4-A5 (construction process stage), B1-B7 (use stage), C1-C4 (end of life stage) and D (benefits and loads beyond the system boundary).

Environmental product declarations (EPDs) are built on an LCA of a product, and gives verifiable, accurate, non-misleading environmental information for products. NS-EN 15804 gives core product category rules for all construction products and services [13].

2. Method

2.1. System boundaries and functional unit

The goal of this study is to compare greenhouse gas emissions from a concrete and steel apartment building and a CLT apartment building. Therefore, the impact category which is investigated is climate change.

In this study the product stage (A1-A3), transportation to the building site (A4) and the operational energy use (B6) is examined. It is chosen to look at these stages because it is assumed that these are the stages with the highest greenhouse gas emissions [9], and because there is a lack of data on the other stages. The end of life phase (C1-C4) is not included in this study because there is a lack of data in many EPDs when it comes to end of life. There is also a large amount of uncertainty with respect to how the materials will be treated when the building is demolished in 60-100 years.

The functional unit that is used is kg CO_2-eq per m^2 gross internal area. The lifetime of the building is set to 60 years in this study. All the materials that are in the actual buildings, and that are assumed to contribute to the greenhouse gas emissions, are included in the calculations. The materials that are not included are assumed to be less than 1% of the total mass as stated in NS-EN 15804 [13]. Any materials used outside the buildings or foundation are not included in the calculation.

A detailed calculation of the technical systems has not been done in this study, because the main goal of the study is not to look at the technical systems, but rather to compare the two building structures. The technical systems are assumed to be very similar in the two buildings, and therefore it will not have any effect on the results that the technical systems are omitted from this study. [6] showed that there was not a large increase in GHG emissions from technical systems for increased building height.

Biogenic carbon is not included in the greenhouse gas emission calculations because the end of life phase is not included. The approach within the ZEB Research Centre is to exclude biogenic carbon if the end of life phase is not included [14]. This is because the biogenic carbon that is absorbed in the trees in the product phase will be released in the end of life phase when the wood is burned, or it decomposes.

2.2. Calculation of quantities

The quantities of the building materials are extracted from the BIM-models of Maskinparken 2 and TRE. The program Solibri model checker v9.8 is used to extract the quantities, and the quantities are afterwards exported to Excel where they are organized. Drawings of the buildings have also been used to get information about quantities and to understand the structure of the building.

2.3. Calculation of emissions

Environmental product declarations (EPDs) for the different building materials have been used in this paper to calculate the emissions of greenhouse gases. For most products EPDs for the actual product used in the buildings are used, but for the products without EPD available, EPDs for similar products that could have been used in the building were used. The EPDs are obtained from the Norwegian EPD Foundation [15], the German Ökobaudat [16], the International EPD system [17], IBU [18] and manufacturers' websites.

Energy calculations performed by Ramboll [19, 20] are used in this study. The dynamic calculation program Simien 6.007 is used to calculate the energy use of the buildings.

The emission factor for district heating is 51,1 g CO_2-eq/kWh taken from Statkraft [21] which is based on data for Trondheim. For electricity an emission factor of 132 g CO_2-eq/kWh is used. This is the CO_2-factor used in the ZEB Research Centre, and it is the simulated average carbon intensity of the European electricity grid for the next 60 years [22].

The bathrooms used in the project are prefabricated bathroom cabins which are fabricated in Finland and transported to the building site. No EPD was available for the bathroom cabins, and to calculate the GHG emissions, the bathroom cabins are assumed to be made of concrete, reinforcement, steel and ceramic tiles. This is based on drawings of the bathroom cabins and the SINTEF certification [23]. EPDs of the different products have been used to calculate the GHG emissions of the bathroom cabins.

The GHG emissions from the concrete underground car park are allocated between the buildings by using the gross internal area of the buildings as a factor.

2.4. Calculation of emissions from transport

The emissions from the transportation to the building site (A4) is taken from the information in the EPDs for the different products. This means that the greenhouse gas emissions from transport is not accurate for this construction site, but it gives an indication of how large the greenhouse gas emissions from the transportation of materials could be for a typical building site.

For the materials that did not have any transport information (A4) in the EPD, a transport calculator developed by Østfoldforskning has been used [24]. This transport calculator is based on data from Ecoinvent version 3.1. In the calculator information about the weight of the material, distance and the means of transport is entered. Both direct and indirect environmental impacts are included in the total environmental impacts from the calculator.

3. Case buildings

Maskinparken 2 and TRE are two apartment buildings in an area called Lilleby in Trondheim, Norway. Maskinparken 2 was completed in August 2018 and Maskinparken TRE was completed in December 2018. The buildings are connected by an underground carpark made of reinforced concrete.

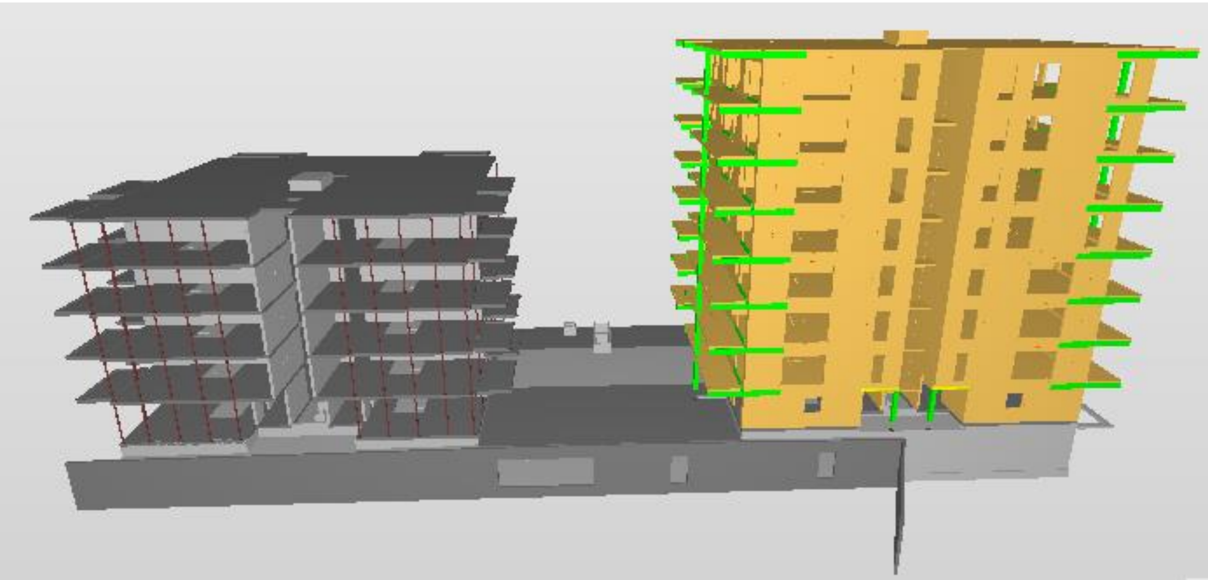

Figure 1. Maskinparken TRE to the right and Maskinparken 2 to the left with the concrete underground car park underneath. The picture is taken from the Solibri model of the buildings.

3.1. Maskinparken 2

Maskinparken 2 is a 5-story concrete and steel building with 31 apartments. It is built according to the Norwegian TEK10 standard energy demands. Slabs and walls in the building are made of reinforced concrete, with steel columns around the edges of the slabs. The slabs are reinforced with prestressing steel. The main staircase in the building is made of prefabricated concrete elements, and the elevator shaft is cast-in-place concrete. There is a technical room on the roof of the building. The outer walls are built as isolated timber frames with outer wind barrier and inner vapour barrier with gypsum board, and the façade of Maskinparken 2 is an aired plaster system. The concrete quality used in the slabs and walls of Maskinparken 2 and the underground car park is C35.

3.2. Maskinparken TRE

Maskinparken TRE is an 8-story wooden apartment building with a total of 47 apartments. The building is built to meet the passive house standard NS 3700 [25]. The walls, slabs, main staircase and the elevator shaft are made of CLT-elements. Outer and inner load bearing walls and the ceilings are lined and covered with gypsum board. The façade cladding is wooden panels. Maskinparken TRE has a technical room underneath the building in the underground car park.

Table 1: Differences between the two buildings

	Maskinparken 2	Maskinparken TRE
Gross internal area	2376,1 m^2	3784,8 m^2
Number of stories	5	8
Number of apartments	31	47
Construction system	Reinforced concrete and steel	CLT
Foundation	Concrete underground car park	Concrete underground car park
Façade	Aired plaster	Wood panelling
Balconies	Prefabricated concrete	CLT
Outer walls	Insulated stud work	Lined CLT walls

Table 2: Delivered energy

	Maskinparken 2 [kWh/m^2]	Maskinparken TRE [kWh/m^2]
Direct electricity	34,0	36,4
District heating	63,9	49,9

Table 3: Material quantities of the two buildings

	Maskinparken 2 [ton]	[%]	Maskinparken TRE [ton]	[%]
Cast-in-place concrete	3874	82,8	3185	65,6
Prefabricated concrete	227	4,9	66	1,4
Steel	20	0,4	23	0,5
Screed	196	4,2	417	8,6
Reinforcement	151	3,2	125	2,6
Cross laminated timber	4	0,1	540	11,1
Wood	34	0,7	51	1,1

Doors	11	0,2	16	0,3
Glass railing	0	0,0	17	0,3
Other materials	10	0,2	10	0,2

4. Results

The results from the LCA are shown in figure 2 below. The total GHG emissions for the production stage (A1-A3), transport (A4) and operational energy use (B6) is 801,5 kg CO_2-eq/m^2 for Maskinparken 2 and 696,6 kg CO_2-eq/m^2 for Maskinparken TRE for a building lifetime of 60 years. When looking at the production stage alone, Maskinparken 2 has a greenhouse gas emission of 312,9 kg CO_2-eq/m^2, while Maskinparken TRE has an emission of 233,9 kg CO_2-eq/m^2.

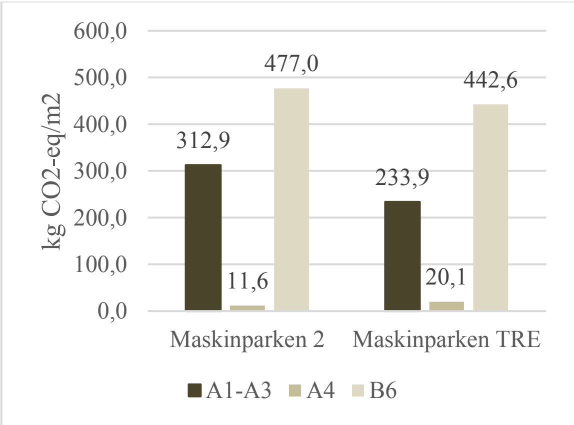

Figure 2: GHG emissions from Maskinparken 2 and TRE for the production stage (A1-A3), transport (A4) and operational energy use (B6).

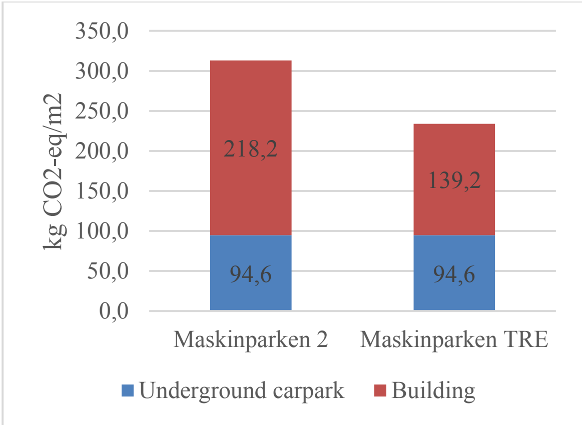

Figure 3: GHG emissions from the underground car park and the building (A1-A3).

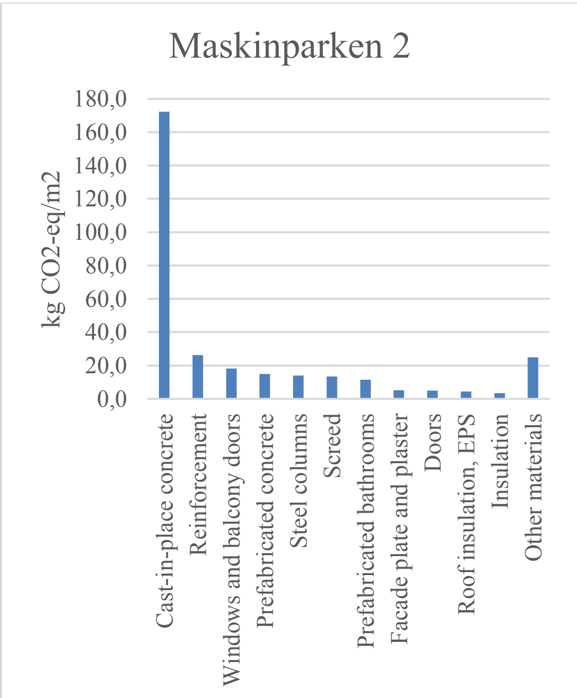

Figure 4: GHG emissions from the materials that emit the most greenhouse gases in Maskinparken 2 for the production stage (A1-A3).

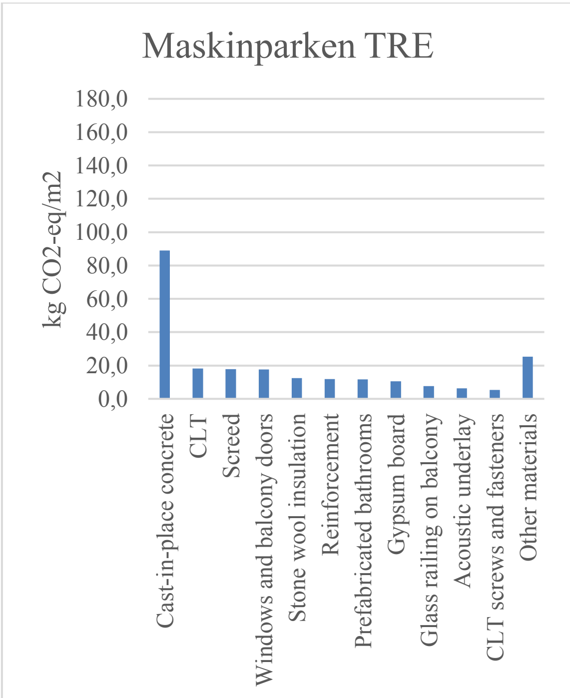

Figure 5: GHG emissions from the materials that emit the most greenhouse gases in Maskinparken TRE for the production stage (A1-A3).

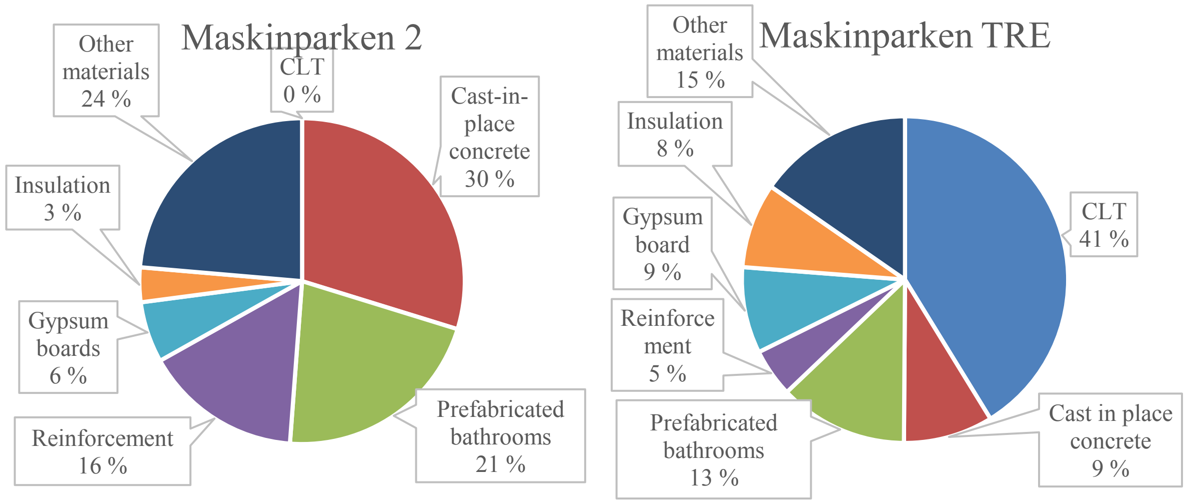

Figure 6: Greenhouse gas emissions from transport in percentage of the total emissions from transport for the products used in Maskinparken 2 and TRE.

5. Discussion and conclusion

The results in figure 2 show that in both the production phase and operational energy use, Maskinparken TRE has a lower emission of greenhouse gases than Maskinparken 2. The emissions per gross internal area (GIA) for the product phase are 25% lower for Maskinparken TRE compared to Maskinparken 2. The greenhouse gas emissions from operational energy use are 7% lower for Maskinparken TRE compared to Maskinparken 2. This was as expected, since Maskinparken TRE is built to the passive house standard NS 3700 and Maskinparken 2 is built to the Norwegian TEK10 standard, which is less strict when it comes to energy use than NS 3700. The results also show that for a 60-year lifetime of the buildings, the operational energy use is the phase that emits the most greenhouse gases. This would change if another lifetime than 60 years was chosen.

Figure 4 shows that for Maskinparken 2, cast-in-place concrete is the material that contributes with the most greenhouse gases, followed by the reinforcement used in the concrete. Cast-in-place concrete is also the material that emits the most greenhouse gases for Maskinparken TRE, see figure 5. This is because of the large amount of concrete in the underground car park. The third most emitting material for Maskinparken TRE is screed, which is used over the acoustic underlay. This means that choosing a material with low greenhouse gas emissions for screed can be important to lower the greenhouse gas emissions from CLT buildings.

As can be seen in Figure 3, the underground car park contributes significantly to greenhouse gas emissions. The underground car park contains a large amount of concrete and steel reinforcement, and this means that if the buildings were built without the underground car park, this would reduce the GHG of the two buildings greatly. Where it is possible to have parking above ground, a concrete underground car park should therefore be avoided to reduce the GHG emissions.

It can be seen in Figure 2 that greenhouse gas emissions from the transport phase are small compared to the product stage and the operational energy use. Maskinparken TRE has a higher GHG emission from transport compared to Maskinparken 2. The products that contribute the most to emissions from transport are shown in Figure 6. The main reason Maskinparken TRE has a higher emission from transport is because of the CLT-elements which are transported from Ybbs in Austria to Trondheim. This means that the greenhouse gas emissions from transport could have been lowered if the CLT was produced in a factory nearer Trondheim. It is important to note that a detailed calculation of the GHG emissions from transport has not been carried out, and values from EPDs have been used for most products. This means that there is a large amount of uncertainty in the results with respect to transport.

Operational energy use (B6) is the phase that contributes the most to the greenhouse gas emissions for both buildings for a lifetime of 60 years. The results for the emissions from operational energy use are uncertain, because they are highly dependent on the emission factors for electricity and district heating. In this paper constant energy use and emission factors are assumed. There is a high level of uncertainty in the building's future energy use and the future emission factors, and therefore this phase should be examined further to gain more knowledge of the emissions in the operational phase.

There are some differences in the two buildings other than the structural system that makes comparison of the buildings more difficult. The most important differences are that the buildings are of different heights, have different cladding, and that they are built to different energy standards. A version of Maskinparken 2 with 8 stories has been made to compare the difference in GHG emissions in buildings of 5 and 8 stories. The results show that the version with 8 stories has 3-4% lower GHG emissions per square meter in the production phase compared to the version with 5 stories when the parking cellar is not included. The cladding on Maskinparken 2, aired plaster, has a higher GHG emission than the wood paneling used on Maskinparken TRE. Because the façade and other materials are different, maintenance during the lifetime could be different on the two buildings.

Maskinparken 2 is built to the TEK10 standard, and Maskinparken TRE built to the passive house standard, and this means energy use in Maskinparken 2 is expected to be higher than in Maskinparken TRE. Material use is expected to be higher in Maskinparken TRE compared to Maskinparken 2 because of the different energy standards. For example, more insulation will be used in Maskinparken TRE to get lower u-value on the outer walls. Even though material use should be higher in Maskinparken TRE than in Maskinparken 2, embodied emissions was found to be lower for Maskinparken TRE compared to Maskinparken 2. This confirms that CLT buildings have lower embodied emissions than comparable buildings in concrete and steel. However, maintenance emissions over the lifetime of the building needs to be confirmed.

Acknowledgements
The authors would like to thank Vidar Amundal for information about the buildings, and Liv Høijord Svare for help with the energy calculations.

Potential of contemporary earth architecture for low impact building in Belgium

Van der Linden J[1], Janssens B[1], Knapen E[1]

[1] Faculty of Architecture and Arts, Hasselt university, Belgium

jasper.vanderlinden@uhasselt.be

Abstract. Earth architecture during the 21st century has resurfaced worldwide as a sustainable, low environmental impact material with expressive aesthetics and textures. Contemporary projects attempt to modernize the traditional techniques of building with earth in order to adapt them to today's projecting needs. Examples of such techniques are unfired earth bricks and rammed earth. In order to disclosure and highlight future possibilities of earth construction, advantages and limitations of earth construction in a contemporary Western-European context are reviewed, based on a literature study. Because it is hard to generalise due to the case-specific context and constraints, a case study analysis of earth utilization in two contemporary architectural projects is presented. To assess if these contemporary projects meet the environmental benefits associated with traditional earth construction, several environmental aspects are taken into account, such as material sourcing proximity, production process, reuse potential, etc. Based on the literature study, case study analysis and current evolutions in neighbouring countries, promising applications for future development of earth construction for low impact building in Belgium are highlighted.

1. Introduction (context)

Earth has been used as a building material for millennia. Architecture in the ancient cultures of Egypt, the Middle East, China, Central Asia, and Latin America was closely tied to this material. In Central Europe, there is archaeological evidence of the use of earth as a building material for thousands of years [1-3]. In Belgium, after the industrial revolution, the development of brick factories contributed to the gradual replacement of the earth building construction. Nowadays, earth construction is still used significantly in developing countries. Roughly one-third of the world's population lives in buildings made from unfired earth [3-5]. Lack of advanced technology and often the availability of labour and local materials encourages the use of simple earth building techniques [6].

But also in the developed world of the 21st century, there is an interest in building with earth. Earth architecture has resurfaced worldwide as a sustainable, low environmental impact material with expressive aesthetics and textures [7, 8]. Contemporary projects attempt to modernize the traditional techniques of building with earth in order to adapt them to today's projecting needs.

Such projects have appeared also in Western-Europe countries; Germany, France and Austria (among others). In Belgium, contemporary projects have been built with earth, but in limited numbers. Despite the potential of contemporary earth architecture in the achievement of environmental sustainability, there is no widespread use of earth in Belgium. Based on a literature study and a case study analysis, in this paper, the advantages and limitations of earth construction in Belgium are studied and the potential of using the material for low impact building is discussed.

2. State of affairs: literature

2.1. Earth construction techniques

Earth suitable for building is generally a well-graded subsoil with a good distribution of clay, silt, sand and aggregate. It should be noted that the clay component is essential for providing cohesion and plasticity during construction, and strength during service [9]. The inevitable variation in subsoils, including the moisture content, has resulted in a number of manufacturing and construction techniques. According to Reeves et al. [9], it is this versatility of techniques that makes it possible to build with earth in cold wet climates such as Britain and hot dry climates such as Morocco. Among the different construction techniques are e.g. wattle and daub, adobe, cob and rammed earth [6, 8, 10]. In this paper, a project with rammed earth (RE) and one with compressed earth bricks (CEB) are studied. Rammed earth is the product of compacting (ramming) consecutive soil layers in a formwork by using a manual or pneumatic rammer [8]. The unshaped earth mixture is slightly moist [10]. A variation of the rammed earth technique consists in the fabrication of compressed earth bricks, also using the technique of compacting a slightly moist earth mixture. But as opposed to rammed earth, bricks are produced which are subsequently assembled to form masonry structures. Other construction elements are also gaining popularity including extruded raw earth bricks (mixture in plastic state put into shape by extrusion [11]) and prefabricated rammed earth panels [8].

2.2. Advantages and limitations of earth architecture

Egenti & Khatib [12] did a literature review towards the advantages and limitations of earth construction (table 1). They give a comprehensible overview of advantages and limitations commonly associated with earth construction. Although this review was done rather recent (2016), some elements need further research. Firstly, this review seems to be done without keeping a particular context in mind and is based on research in contexts varying from Europe (e.g. UK, Germany, France) to Africa (e.g. Sudan, Southern Africa, Nigeria) to Asia (India) to Oceania (Australia, New Zealand). Secondly, it is hard to generalize such aspects since each project is different, each earth construction type differs. So, some of the listed aspects depend on the contextual reality (e.g. economic, social, climatological,…conditions). In this paper, some of the listed advantages and limitations will be evaluated for contemporary Western European applications, based on an analysis of two recent projects in Belgium.

Table 1. advantages and limitations of earth construction
as listed in sustainability of construction materials, chapter 13 by Egenti & Khatib [12]

Advantages	**Publications**
Low cost	Guillaud et al. (1985), Lal (1995), Easton (1998), Minke (2006), Morton (2007), Walker et al. (2005), Zami and Lee (2007)
Encourages self-help with less skilled labour	Adam and Agib (2001), Minke (2006), Maini (2005), Hadjri et al. (2007)
Good sound insulation	Morton (2007) and Hadjri et al. (2007)
Good heat insulation and fire resistance	Binici et al. (2007), Taylor et al. (2008), Hadjri et al. (2007), Adam and Agib (2001), Walker et al. (2005)
Capable of providing strong and secured structure	Lal (1995), Rigassi (1985), Walker et al. (2005)
Promotes culture, natural material	Frescura (1981)
Improves indoor air quality	Minke (2006), Hadjri et al. (2007), Lal (1995), Walker et al. (2005)
Low impact	
Reusable	Minke (2006)
Low embodied energy	Keefe (2005), Venkatarama Reddy and Jagadish (2003)
Saves energy and no emission of CO2	Minke (2006), Glavind (2009)
Sufficiently available	Easton (1998), Adam and Agib (2001), Hadjri et al. (2007), Lal (1995)

Limitations	**Publications**
Non-standardised material	Head (1980), Minke (2006)
Non-resistant to water and less resilient	Minke (2006), Lal (1995), Walker et al. (2005)
Needs high maintenance	Hadjri et al. (2007)

Structurally limited	Hadjri et al. (2007), Maini (2005), Adam and Agib (2001)
Suitable only for in situ construction	Walker et al. (2005)
Special skills (required for plastering)	Hadjri et al. (2007)

3. Materials and methods

In the introduction of this paper (section 2), an overview of contemporary earth construction techniques was presented, together with commonly associated advantages and limitations of earth construction, based on a literature review by Egenti & Khatib [12]. In Section 4, two projects using unfired earth, will be presented (table 2). These selected projects were recently built in Belgium and contain main walls of unfired earth. Meanwhile, they reflect an image of contemporary material use. Both are public tenders, therefore needing to fulfil common standards for Belgian construction.

A semi-structured interview was done with the architects of both projects to identify important financial, technical and environmental aspects of building with earth in Belgium. A preparatory and subsequent analysis was done based on the architectural plans and technical reports and through site visit(s) of the projects.

Table 2. project case studies and interviewed architects

# Project type (earth construction technique)	Interviewed architect (affiliation)	reference
I Watchtower (rammed earth)	Jan Thys (de gouden liniaal architecten)	JT2019
II Bioclass (compressed earth bricks)	Nicolas Coeckelberghs (BC architects&studies)	NC2019

In the next chapter (section 5), the validity of the commonly mentioned advantages and limitations, as extracted from literature (table 1), will be discussed, based on the case studies. Complimentary, literature is used to compare with current insights in neighbouring countries within a similar context. The application potential of unfired earth in a contemporary Belgian context will be discussed as three reflections, i.e. on the financial cost of earth construction, its technical aspects, and the environmental impact (including energy use and transportation). In the last chapter (section 6), the reflections are combined, highlighting the importance of balance between ecological, technical, practical and economic aspects.

4. Case study projects

4.1. Case study I: watchtower, rammed earth

The first case study is a rammed earth watchtower in Negenoord, on a former gravel extraction area. The watchtower is designed as a concrete core with external rammed earth walls, with in between concrete prefab spiralling stairs resting onto the stabilized rammed earth walls of 80 cm thick and 12 m high (figure 1). The surface area of the rammed earth external walls will slowly erode, so the gravel will become visible after a while [13].

Building	watchtower
Location	Negenoord, Limburg
Year of construction	2016
Earth construction technique	Rammed earth
Architect	De gouden liniaal architecten
Earth consultant	BC studies, Craterre, Vessiere&Cie
Available documentation	interview with architect, plans, technical report
Site visit(s)	25th of August 2015

The tower is one of the first contemporary public earthen building in the Benelux region. At the moment of writing, there are no standards for earth construction technique, which makes it difficult to describe rammed earth for use in a public project.

To guarantee the quality of the earth construction, the design and construction team was supported by an international team of experts in rammed earth. These consultants defined a material mix (20% gravel, 40% sand, and 40% loess, stabilized with 6% hydraulic lime), using materials from nearby excavation sites (Section 5.3). Also, they advised on how to organize the construction site for in-situ earth mixing and rammed earth construction. Despite the consultancy, training of the contractor and follow-up, some issues arose during construction. This resulted in the use of cement instead of lime as stabilizer. The rammed earth works took 7 weeks, carried out by a professional contractor.

4.2. Casestudy II: bioclass, compressed earth bricks

The bioclass, a class for nature education built in an existing warehouse (figure 2, right), was constructed with compressed earth bricks (CEB). These bricks, masoned into one floor high walls, are the loadbearing construction of the building. Towards the inside, the bricks are left apparent without extra finishing (figure 2, left). An insulating exterior façade and roof of hempcrete is left apparent as exterior finishing (figure 2, right).

Building	bioclass
Location	Edegem, Antwerp
Year of construction	2017
Earth construction technique	compressed earth brick (CEB)
Architect	BC architects
Structural engineer	Util
Available documentation	interview with architect, plans, technical material report
Site visit(s)	15th of December 2017, construction site visit 10th of July 2018, tour by architect

The bricks are made in-situ using clay from a nearby quarry (Section 5.3), mixed with sand (Benor, 0/8) and without addition of a chemical stabiliser such as lime or cement. During a 3 week workshop with volunteers, 19000 bricks were produced [14] using a hydraulic CEB machine [15].

The bioclass demonstrates that it is possible to construct with unstabilised CEB in a loadbearing way if construction conditions are dry. The design and detailing takes into account the nature of the material by using its compressive strength (3,3MPa) through arches and by avoiding contact with water. This was done by offsetting the brick from the floor (figure 2, left) and not using it near the bathroom.

5. Reflections on the application of earth in Belgium

5.1. Reflection on the financial cost

Whereas Eghenti & Khatib [12] present the use of earth in construction as an economic advantage, in an industrialized country with high labour costs, such as Belgium, low-quantity, non-industrial production for on-demand projects results in a significantly higher cost. In both case studies, earth was mixed on-site and processed in small amounts for the specific projects. When preparing construction materials on-site, the organization of the construction site becomes more complex and costly. Such on-demand material processing in small quantities is very different from the large-scale industrial production of conventional building materials.

Depending on the size, a non-industrial CEB would be around 30-40% more expensive than a conventional industrially produced fired brick (NC 2019). However, with greater demand the unit cost of production would reduce [16] and through industrial mass production it might be possible to make unfired bricks which are cheaper than the fired brick (NC 2019). A rammed earth construction, rammed on site, would be around 60% more expensive then exposed concrete [17].

Self-help can potentially lower the cost, but it is not always evident to do so. In the case of the watchtower, the involvement of unskilled labour in the construction process was impossible because the public client did not allow it. For the bioclass, workshop sessions with unskilled labour lowered the price of on-site brick production. During the workshops, the participants were offered practical experience and knowledge sharing. However, the cost to organize such workshop on a high level, as including the training of the participants and preparation, should be taken into account.

Although self-help is mentioned as an advantage, Schroeder warns that people should only execute the construction work under professional guidance. Earth as a building material can only be accepted by society if it is seen as a "normal" building material [1]. This requires the existence and application of current building regulations. At the moment, earth is not a conventional building material in Belgium and advice and study work of experts is needed when designing and constructing with earth. Especially when dealing with a public construction, as is the case of the two studied projects, a professional expertise is necessary to fulfil building regulations, deliver a high quality construction and provide the technical certainties necessary for a public tender. This expertise also leads to an additional cost.

5.2. Reflection on the technical aspects

Interviews with the architects of both projects did not indicate any technical reasons for not using earth construction in Belgium. But, where and how the material is applied should correspond to the potential and limitations of the applied earth construction technique. This means that in the design and detailing, the material properties should be taken into account, such as the low water resistance and low strength when compared to more conventional building materials [1, 18]. Some examples:

Water resistance:

- (case I+II) Use of a concrete plinth to prevent capillary water rise
- (case I) Specific attention to water drainage on the inside of the tower to avoid excessive contact with rainwater, special attention went to the detailing of drainage along the concrete stairs
- (case II) Earth for interior use only
- (case II) Glazed bricks instead of CEB in the bathroom area

Strength:

- (case II) Arches, loading the bricks with only compressive stresses
- (case II) The limited height of one level avoids high loads
- (case I) Wall thickness of 80cm to carry the 12meter high massive walls
- (case I) Concrete plinth to prevent that the cows grazing around the tower scrape the RE wall

Meanwhile, the limited amount of regulation, standardization and experienced craftsman might form a barrier for implementation [19]. In both projects, it was emphasised that the need of an expert in earth construction is essential. Since standards and norms are currently lacking, each project should be followed up by an expert to avoid mistakes by stakeholders that are less familiar with the material. One architect mentioned the need for a building team, with the architect, constructor, client that includes an earth consultant to follow up the project from the very start till the process of maintenance. This makes it possible to avoid mistakes in a building environment where earth construction is not common knowledge and which is not guided (yet) by standards and regulations. Among other standardization initiatives, the RILEM Technical Committee 274-TCE is critically examining current experimental procedures to propose appropriate testing methods that could be adopted as standards.

5.3. Reflection on the environmental impact

In the literature review (table 2), it was mentioned that earth construction has 'low embodied energy' and 'no emission of CO_2'. Such claims have been nuanced for contemporary earth construction by Schroeder [1]. He mentions that "the traditional manual processing of suitable excavation material into earth building materials and structures on the building site was and still is the ideal situation as far as the embodied energy is concerned". He continues with the analysis that "contemporary earth building is largely mechanized and characterized by the physical separation of building material production and product use on the building site. This automatically leads to energy consumption and transportation."

This is also the case for the studied projects. The material on the site of the watchtower was a priori not suitable for construction. The former gravel extraction area where the tower is situated has been refilled and the earth was therefore inconsistent (JT 2019). Also for the bioclass, no earth from the site has been used for the same reason. Additionally, it was practically difficult to specify a local earth mix already during the public tender phase since it would need an allocated budget for local soil investigation and specification of a reformulated earth mix (NC 2019).

However, in both projects, special attention went to the transportation distance between the excavation site of the earth materials and the construction site. The architect of the watchtower project mentioned that pre-mixed earth with specified material characteristics can be bought (e.g. from a producer in Germany), but they preferred a mix of locally sourced materials. Testing was done with different mixtures of material in the region resulting in an earth mix with material taken from within a range of 25km (figure 3). For the bioclass, clay was bought from a nearby quarry, sand was bought at a local distributor. As the exact sand source is unknown, the distance on figure 3 represents the distributor.

Figure 3 distance from site to material source

Both projects used material from quarries; such choice is made because it is practical, the continuous availability is assured and the quality guaranteed. Sand, clay and gravel are indeed sufficiently available (in those regions) but are originating from finite resources. An alternative for this would be the industrial processing of suitable 'excavation soil'—into earth building. This could result in a lower demand for landfill space and lower transportation impacts, both for excavation soil and for construction materials, which could be major environmental benefits for contemporary earth building ([1], NC2019).

In both projects, parts of the production and construction process have been mechanized. In the case of CEB, Schroeder [1] reports a duplication of the CO_2 emission as well as a tripling of the energy demand when mechanically instead of manually producing CEB's. However; it is clear that this are still very low amounts compared to fired bricks or concrete. Schroeder [1] claimed a CO_2 emission that is 63% lower for a mechanically produced and stabilised CEB compared to a fired brick.

For the rammed earth watchtower, 6% of cement has been added. Despite the absence of cement in the proposed mix of the earth consultants, cement was added. This to avoid any risk after a series of irregularities took place at the start of construction. The used mixture was differing from the prescribed mixture, either by being more wet or not respecting the prescribed particle size distribution. Although the amount of added cement is less than a common concrete construction, the 12m high walls of 80cm thick contain a not negligible amount of cement. This is negatively impacting the CO_2 emissions during production.

A last topic concerns the possible future reuse and recyclability of the material. For the bioclass, a simple wooden structure and hempcrete is mounted on the CEB. This should make it easy to take apart the pure earth material, which can then be recycled or reused. If unstabilized, reversible clay binding allows a complete and low-energy reuse of earth at end of life [18, 20]. Therefore, the lack of cement or lime as a stabiliser in the mixture is of significant importance. In the bioclass, a small amount of lime was added to the mixture, it has not been studied if this would negatively affect the recycling options. For the watchtower on the other hand, cement is contaminating the earth mixture, which eliminates the reversible binding process. Although the architect aimed to make a solid structure that will survive for a long-time, in the worst case needing some retouches (JT2019), the end of life should be taken into account. In that context not stabilizing earth to improve recyclability is an important consideration, that could be of particular value for applications which are typically changed in a shorter time span, such as indoor walls.

6. Conclusion and discussion

In the context of a renewed interest in building with earth, resurfacing worldwide as a sustainable, low environmental impact material, the potential of contemporary earth architecture in Belgium is investigated by means of a literature study and a case study analysis of two projects using unfired earth, recently built in Belgium.. The architects of both projects were interviewed to investigate the economic, technical and environmental aspects of building contemporary projects with earth. By confronting the commonly mentioned advantages and limitations in literature (table 1) with the results of the case study analysis, a reflection on the application of earth in Belgium is presented from an economic, technical and environmental perspective. Some inspiring potential suggestions for a more successful future development of earth architecture in Belgium are derived.

Firstly, the two studied projects made it clear that earth construction is not necessarily cheaper than conventional construction, even on the contrary. One way of lowering the costs would be to scale-up the production of earth material products, doing this in a more industrialized and standardized way. Another way of dealing with it could be to accept the additional price and approach earth as a unique building product, which reflects certain values such as locality and craftsmanship.

Secondly, it was clearly mentioned that earth expertise is essential in all phases of the project. Material knowledge is essential in any architectural project, but in the case of earth, it is especially important since norms and standards are lacking, and since the limits and possibilities of the material are not common knowledge. A project using earth should be designed with intelligent details and appropriately combined with other materials. This should avoid excessive contact with water, and take into account the compressive strength and its vulnerability to abrasion or erosion. Also during the phase of construction and maintenance, it is important to have access to specific technical knowledge of the material. Therefore, a good knowledge transfer and the building up of expertise, norms and standards is important.

Thirdly, earth does offer potential to construct with low environmental impact. Although zero transportation through the use of on-site excavated material was not achieved in the studied projects, clearly an effort has been done to keep the sourcing within the region. Although part of the process is mechanized and in the watchtower project some cement stabilization was used, primary energy use and CO_2 emission still is rather low compared to fired bricks or concrete. For the further development of earth as a sustainable construction material, smart sourcing and processing seems a key-point to avoid finite material excavation. Gathering suitable excavation soil and processing it to earth building products or mixtures, in a semi-centralized way, might be a useful next step in the field of earth construction.

To conclude, the findings of this study, and even more the discussed projects themselves, show that there is potential for contemporary earth architecture in Belgium. Using earth can be a low impact building solution, but this should not be taken for granted. It is the role of the architect, material producers and constructors to balance between ecological, technical, cultural, practical and economic aspects. For example, processing material on-site might lead to less transport but turns out to be rather expensive and complex in construction site organization. This could be a trigger to look more into prefabrication of earth building elements. Improving the compressive strength and water resistance by adding chemical stabilisers should be done with care as it negatively impacts the environmental impact and recyclability. Designing smartly with the right material where necessary and possible should be a priority when using earth. This preferably with a team that includes the different project stakeholders and earth construction experts, collaborating from concept phase till maintenance.

leanWOOD – towards resilient design and building processes

Geier S

Lucerne University of Applied Sciences and Arts, Competence Center Typology & Planning in Architecture (CCTP), CH-6048 Horw

sonja.geier@hslu.ch

Abstract. With the introduction of the concept of resilience in the discourse of building design, design and building processes have to react to complex challenges presented by the extension of the perspective from physical building structure to living space. Instead of conserving effort, resilience demands integrated and argumentative processes and interdisciplinary cooperation. Forerunners in industrialized timber construction have long-standing experience and are starting points for new advanced design processes. The international leanWOOD project (2014-2017) aimed at outlining the requirements for future timber building planning processes to put them on a broader base and thus contribute to advanced processes in the future. To achieve resilience in building design, rigid and sequential process-chains must turn into flexible, argumentative process approaches. The paper illustrates the key elements for resilience-oriented design processes, discusses procurement and cooperation models, identifies pitfalls in current development and outlines the impact on resilient buildings. Finally, the outlook shows the potential of the implementation of BIM to this change towards resilient design and building processes.

1. Introduction

Building stock and cities are increasingly challenged by the consequences of climate change, such as dwindling resources, demographic trends and migration flow, and must be able to react to diverse changes. Utilising scarce resources efficiently, creating favorably priced residential space whilst simultaneously doing justice to our affluent society's demands for sustainability, barrier-free design and increasing expectations regarding land usage, all present planners with complex challenges. The dynamics of change on the timescale of a building's life-cycle cannot be predicted and present those acting according to a rational planning model with tasks that are neither clear nor readily soluble. Models with a functional/technical focus deal with symptoms (like energy consumption for example), but are unable to accommodate societal, ecological or economic changes. This is exacerbated by short-term investment perspectives and how they are reflected in current procurement practice applied to planning and construction services. Planning models able to react to this must adopt an extended perspective: from the physical building to built environment. Consideration of life-cycle during planning would constitute a necessary first step towards long-term planning horizons, whilst a systemic planning approach must then follow.

2. State-of-the-Art

2.1. Systemic planning models

It was in the 1950s that Burckhardt L was already criticising predominantly *"military-polytechnical"* planning approaches. Instead, his theories of planning react to the *"dynamics of urban realities"*. His demand was to *"accept the complexity and processual nature of the environment"* [1]. Like him, Rittel H also sees problematic scenarios holistically and the consequences of the planning process as not being clearly predictable. On the basis of this logic, Rittel speaks of *"argumentative processes"* in planning. Questions must be raised, diverse positions and points of view must be taken into account and arguments must be formulated. Here mere *"objective, scholarly"* action is not productive. He sees the solution on a *«political»* level. His planning theories are *"conspiratorial"* in the sense of sharing between all the actors involved and the cooperative manner of proceeding [2]. Habraken J also says that changing variations must be possible because of the unpredictable future within the planning horizon. He compares the rational planning models to military parades, where the greatest threat is presented by unanticipated disturbances. In contrast with this he describes a football game, which follows rules but does not obey a strict sequence: the unexpected can happen and takes place in a *"dynamic reality"*. [3]

2.2. Resilience as planning approach

As solutions were being sought, the term resilience entered the vocabulary of planning theory. The term resilience was coined and defined in psychology as *"a system's capacity and ability [...] to respond to crises and disruptions"* [1] and the ability to recover from stresses. Resilience indicates sustainability and also implies the maintenance of identity and structure [5] though it is not a conserving factor but rather leads to self-renewal and opens up creative possibilities [1]. Within the discourse on planning, resilience belongs to the third generation of planning theories and, with a systemic orientation, interconnects planning processes with political, economic and social causal networks [6].

Consideration of this systemic planning model shows that resilience-oriented planning depends on the diversity of position and arguments from the point of view of the various actors, and on the possibility of discussing variations and flexibility in the running process permitting reaction to the unexpected. In contrast, inflexible, hierarchical and rationally-based procedural models are susceptible to disturbance and cannot deal either with complex problem scenarios or with the unexpected.

3. Outstanding issues

Thus resilience-oriented planning means integrative and discourse-oriented processes that offer scope for the debate of involved actors and a buffer for unplanned happenings. This results in the demand for more cooperation between disciplines. This is not new, at least in theory. Currently resilience is indeed in demand as a buzzword in urban and building planning (e.g. Brenet Status-Seminar, ETH Zurich, 6-7/9/18), albeit insufficiently represented in current planning practice. Either it is shifted into the area of soft skills and/or falls victim to rationalization in the course of raising process efficiency.
It is therefore desirable to put forward approaches for how this can also be effectively implemented in the planning process in future.

4. Proposition

In seeking solutions, the forerunners in prefabricated timber construction come to one`s mind. The timely integration of knowledge of construction and manufacturing processes is a prerequisite for any prefabricated timber construction. The actors in prefabricated timber construction are more or less forced into early interdisciplinary cooperation by the logic underlying timber construction design. Their experience and findings point out ways of implementing resilience-oriented design and building processes in the practice of future planning.

5. leanWOOD (WoodWisdomNet 2014-2017)

Forming the basis of this paper is the work done in leanWOOD, a project which was carried out from 2014 till 2017 [7] on the WoodWisdomNet platform.

The methodological approach of the leanWOOD project was based on detailed analyses of case studies realised in industrialised timber construction with high levels of prefabrication. The bottom-up-oriented approach taken in the project was based on intensive dialogues between theory and practice -

between research and business partners as well as a broad variety of stakeholders in the sector. The objective of the leanWOOD project was to establish a new understanding regarding prefabricated construction with timber and the foundations for process innovations still required. The central fields of work were the development of planning processes aligned with timber construction and the analysis of procurement and cooperation models in relation to their strengths and weaknesses regarding prefabricated construction with wood.

6. The timber-construction-aligned planning process

6.1. Results

However, analyses in practice forming part of the leanWOOD-project showed that exploitation of the technical as well as economical potential of prefabricated timber construction is limited because of inflexible, sequential, hierarchically organised planning processes and traditional procurement practices and cooperation models [8].

On the basis of these analyses, the leanWOOD-project team put together the «ideal» timber-construction-aligned planning process (as shown in Figure 1).

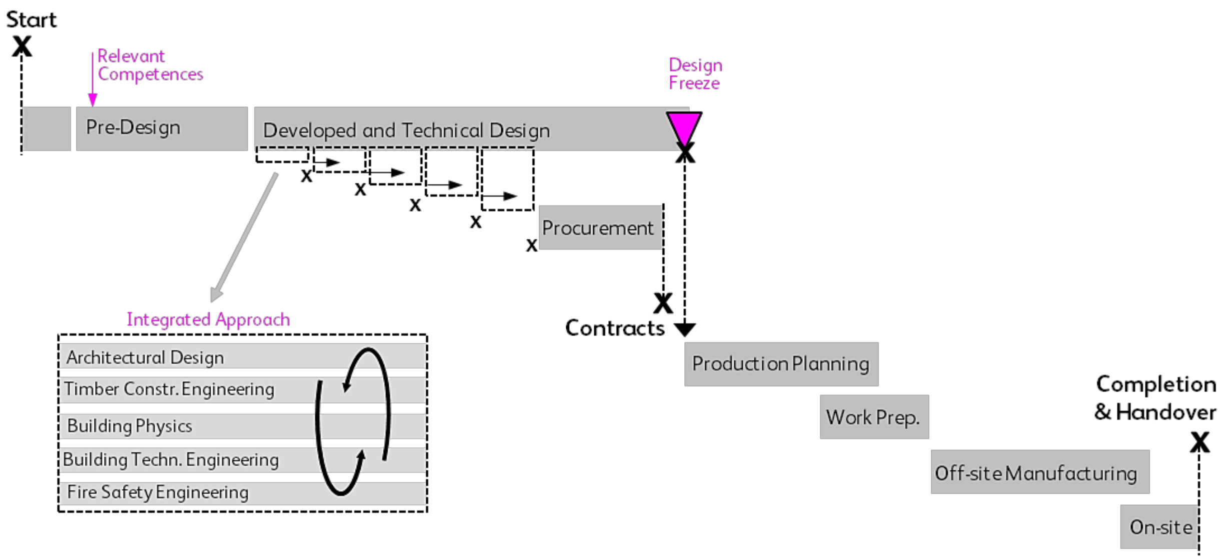

Figure 1. The elements of an "ideal" planning process aligned with timber construction

This ideal process offers many advantages with regard not only to confidence in compliance with timing and cost targets but also the far more extensive scope for decision-making for building contractors in comparison with "rolling" planning. This advantage is explained in the 2018 Brenet Status-Seminar contribution of Geier S and Zöllig S [9].

For it to be possible to profit from the advantages too, it is necessary to understand the logic underlying timber construction and to lay out the process accordingly: In timber construction, insulation, fire and noise protection are provided collectively by the primary and secondary structure, so all structural components and layers must be given collective consideration at early phases of design [10]. Thus the increasingly overly-differentiated range of products in timber construction, in combination with diverse construction options, which offer distinct solutions that are production and thus company-specific, demand a great deal of detailed knowledge which has to be integrated in these early phases. The process of technical and economical optimisation must begin at the same time as architectural design. Basically, recognising this is nothing new (cf. the McLeamy curve), the early design phases has the biggest influence on costs [11]. This integrative approach during design must be continued in a synchronised manner as the project progresses. It is necessary to open and close decision gates at appropriate times [12]. Here, each stage has a zoom factor (one might speak of a more finely resolved

"Level of Detail LOD"), which has to be reconciled within the individual disciplines. At each stage, decisions have to be arrived at through argument and finalised before the next stage. The "Design Freeze" constitutes an important milestone before the start of production planning, assuming a concluded and complete implementation planning process.

Decisive in this integrative approach is the discourse-based development of arguments. As mentioned earlier, fire protection and sound insulation can be achieved in a variety of ways. As to which solution can best be realised with reference to the tasks at hand, whilst being fault-tolerant in its execution and economical, this has to be determined within the field of activity covering architectural layout, design and structure, construction with reference to building physics, fire protection concept as well as the routing of building services. This covers not just fire protection and sound insulation, but given that humidity protection, ventilation concepts, installed components like solar protection and integrated ventilation components must be also designed and planned integratively. In these early stages, approaches that are isolated according to discipline can later result in far-reaching plan revisions or sub-optimal solutions.

6.2. Conclusion

One can say that the "ideal" planning process in prefabricated timber construction illustrates by example how disciplines must cooperate in an integrated manner, as distinct from *"poly-technical planning"*. The diversity of potential solutions demands an *"argumentative process"* that brings together all relevant competences in early design phases, preferably including the timber construction company too. Thus, forerunners in prefabricated timber construction are role models for integrative, discourse-oriented and systemic planning approaches paving the way to resilient design and building processes. Nevertheless, the question of whether this bringing together can, in organisational terms, also be realised in practice is discussed below.

7. Procurement and cooperation models aligned with timber construction

7.1. Selection of suitable procurement and cooperation models

Project team collaboration in the planning process is organised and regulated by procurement and cooperation models. During the leanWOOD-project detailed analyses were carried out regarding procurement and cooperation models aligned with timber construction [13].

It is evident that the decision regarding selection of the actual procurement and cooperation models (in the analysed projects) was reached essentially by the building owner/prinicipal according to their own profile and/or corporate mission statements. The criteria for the decision were founded on confidence in cost and timescale planning, questions of liability, administrative outlay for contract and payment management, albeit also the possibility to take part in or withdraw from the design and building process themselves.

The criteria for selecting a suitable model, from the point of view of a planning process aligned with timber construction, differ from the above mentioned ones. Playing an important role here are the potential for early, integrative planning, i.e. cooperation between disciplines during early stages, ideally including a timber construction company, along with coordination of execution tailored to timber construction.

Thus, the selection of procurement and cooperation models is not straightforward, instead requiring recognition of the strengths and weaknesses for individual cases and selecting the best models with respect to building owner/principal and timber construction.

7.2. Classical procurement and cooperation models [13]

Figure 2 shows a comparison between differing procurement and cooperation models. The horizontal bars depict the course of the design and building process from project start to completion. A precise designation of individual project stages has been omitted, given that various models throughout D-A-CH-territory were analysed and discussed. The individual stages differ according to country, so the diagram only delineates the overall structure, without further resolution: preliminary design («pre-design»), developed and technical design, construction. The message of the diagram focuses on the comparable approximate moment at which it is possible to cooperate with the executing companies according to model.

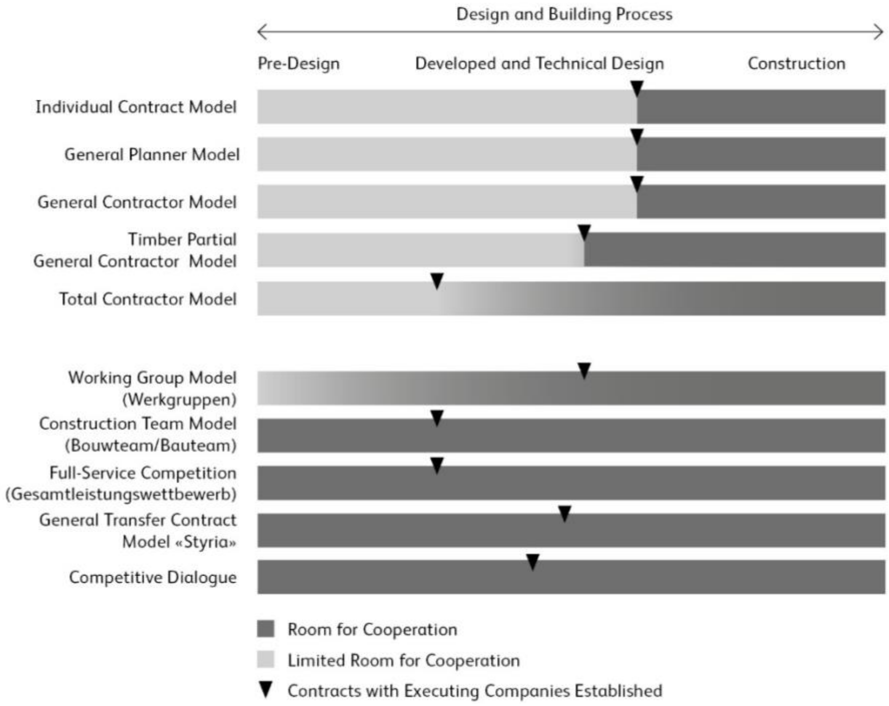

Figure 2. Overview of cooperation potential for businesses responsible for planning and execution in selected procurement and cooperation models. [14]

The upper group in Figure 2 depicts the primarily “classical” models. These are still highly respected, not only by building owners/principals but also by businesses. The Individual Contract Model, as well as the General Planner Model, offer good comparability of offers from the building owner`s/principal`s point of view, and a precise definition of work in relation to quality and quantity. In these models, businesses value the small effort required for calculation that results from the detailed performance descriptions. In both models, the choice of specialist planners is decisive. If choices are solely based on the lowest fee or the building owner`s/principal`s preferences, there is a great risk that the planning team will not be optimally aligned. The General Contractor Model is also very popular and often proves to be practicable, because one business coordinates the interfaces between the firms executing the work. This has led to the establishment of the Timber Partial General Contractor, because in this model the timber construction company can control execution of the work in a manner attuned to timber construction. The timber construction company takes on only the specialist work directly connected with timber construction (mostly being the “airtight building shell”) and not the entire construction (which is also advantageous regarding liability law). In both models, Partial and General Contractor Model, cooperation between the businesses depends on the General Contractor’s policy. Again, if price is the controlling factor here, the quality of cooperation also suffers.

The black triangles in Figure 2 mark the dates of the conclusion of contract with the businesses executing the work and indicate the split between the planning and implementation teams. Before that date, the inclusion of the timber construction company is not permissible (at least in public sector procurement). These models, which do not enable inclusion of the timber construction company before procurement, reach their limits when the necessary competences regarding product selection, manufacturing and assembly technique or logistics are not present (as a specialist planner or expert) in the project.

With the Total Contractor Model, these limits are removed. They bring together several disciplines and specialist planning departments within their corporate structure under one roof. Most often these are the market`s big players. Opinions of the Total Contractor Model diverge: whilst it constitutes a “black box” for some building owners/principals, for others it is an opportunity to be relieved of contract and payment management as well as the coordination of all interfaces.

Yet, the analyses carried out in the leanWOOD-project showed that there are still few big players in the timber construction sector who could deliver total contractor services. However, the structure in the sector, as well as in the domain of architectural and specialist planning within D-A-CH-territory, is more often small-scale and also characterised by changing teams. Even though industrialisation in the timber construction sector demands structural change through capital-intensive production lines, one must ask oneself whether it is desirable for the characteristic elements of the culture of construction in D-A-CH-territory to be lost.

7.3. Alternative procurement and cooperation models [13][15]

In the lower group in Figure 2, alternative models for procurement and cooperation are shown. They offer more scope for cooperation with executing (timber construction) companies. However, the desire and search for alternative models is nothing new. For example, the idea of Working Group Models originated in Switzerland in the 1990s and, among other things, focused on better cooperation between those planning and those executing. In the Netherlands, the Construction Team Model (“Bouwteam”) was established and also developed further. Here the intention is for the team of those planning and executing to develop commercially and technically optimised solutions. This model is less successful in D-A-CH-territory, the disadvantage being the lack of clarity in terms of responsibility for coordination within the team and also liability. Depending on the configuration, there is a risk that the architect may be confronted with joint and several liability. A solution for this was created in the form of the Full Service Competition in Switzerland, which is regulated in SIA 142:2009. The General Transfer Contract Model of the Styrian housing subsidy organisation also works on a very similar basis. Whilst the Full Service Competition directly addresses a consortium of architects, specialist planners and businesses, in the Styrian model it is only the architect and one timber construction company. Both need a very clear description of the tasks to be accomplished from the building owner/principal, neither is decided upon on the basis of a competition over simply price or design, but rather a jury evaluates the solution and awards on the basis of the fixed price. The great advantage of both models is that instead of the big players it is rather the large variety of businesses on the market, ranging from small to medium-sized, can become part of a team on the basis of trust and good experience in preceding joint projects. In both cases, the final contracting of planning and construction services is handled by the business charged with execution by means of a kind of total contractor service contract, which includes all the others via subcontracts. To avoid a mess with the reimbursement of fees, along with architectural aspects, good preliminary agreements are necessary. With the Competitive Dialogue of 2004, the EU created an instrument that does justice to the complex tasks at hand. The Dialogue includes the project team and the building owner/principal, with procurement taking place based on a solution and award criteria defined at the start. In Germany and Austria, the Competitive Dialogue can be used whilst, in Switzerland, currently only the federal government has this option. According to expert opinion, this model only makes sense for large (infrastructural) construction projects. However, there is some indication as to why models like Full Service Competition have spread even less: the effort that the building contractor must put into clear formulation of the task to be accomplished and the jury process is not insubstantial.

7.4. Pitfalls in current practice

The investigations conducted during the leanWOOD project highlighted the reality that current procurement practice mostly takes place according to the classical models, which offer limited scope for legitimate cooperation between planning offices and executing companies. What is altogether possible in these models is integrative collaboration between specialist planners. Yet here too, many building owners/principals hesitate to integrate the necessary specialist planners to a sufficient extent (with corresponding payment) in the planning team before the official building permission is issued. The much more frequent practice is to include timber construction companies by means of informal (and hence cost-neutral) consultancy. Many architects and building contractors are too little aware of how they are thus operating in a grey area and risking procedural delays or stoppages.

Here a distinction is to be drawn between procurement practice and the possibilities afforded by EU directives and national legislation. It was already in 2014 that EU directive 2014/24/EU rang in a change of culture. The changes in the area of award criteria actually form the basis for the integration of sustainability aspects and requirement-oriented service procurement, and thus constitute a step towards quality-based competition [16]. These are thus anchored in Germany and Austria. In Switzerland too, currently with the revision of procurement law, not only price but also quality and sustainability have become decisive in procurement.

8. Conclusions

Implementing a resilience-oriented design and building process means having to worry about not only the process, its progress and the potential for raising efficiency in the process. In particular it means carrying over the process model via the organisational form, legal circumstances and also the actors' personal skills into the implementation. Timber construction with high levels of prefabrication has the potential to be a role model for resilient design and building processes. However, implementation in practice is largely hindered by traditionally rooted actors and organisational issues.

Hence, the task in future is to enable these in practice through legally secure procurement and cooperation models. The analyses in the leanWOOD project showed that models already exist, which make this possible. But in order to achieve the step to widespread implementation, there is still a need for efforts towards simplification of the outlay in these models and cultural change among the actors.

9. Discussion and Outlook

An aspect of the current roll over of Building Information Modelling BIM in the building sector is the change towards resilient design building processes. Similarly to prefabricated timber construction, BIM is committed to change in planning culture: methods, processes, and strategies must change with its implementation. Prefabricated timber construction is already very well positioned in the adoption of BIM. With BIM, integrative planning is also supported at early stages and technical/economical optimisation can be combined with architectural layout from the early design phases. If, as a result, one creates space for argumentative processes and thinking in terms of variations, one then enables flexibility in the process and a buffer for the unexpected. If, through visualisation, one also improves communication between experts and laypersons and thus enables the competent integration of building owners and users in the process, then prefabricated timber construction can make a great contribution to resilience in buildings and in cities.

If one closes the loop to those attributes of resilience-oriented design and building processes mentioned earlier, it is also necessary to cast a critical eye over the objectives of BIM implementation. If the focus of BIM implementation is directed towards further efficiency improvement in the process to reduce planning time, misusing BIM solely for economical optimisation, then planning is reduced to a polytechnical collaboration in planning models, which cannot coincide with the process of transformation to a resilient building stock.

Acknowledgements

The research in the leanWOOD-project leading to these results has received funding from the WoodWisdom-Net Research Programme which is a transnational R&D programme jointly funded by national funding organisations within the framework of the ERA-NET WoodWisdom-Net. The Swiss involvement was financed by Innosuisse Swiss Innovation Agency and Swiss business partners.

ingrid.bertin@setec.com

Abstract. The research work presented aims at setting up an infinite cycle of use of materials by their reuse and answering in particular to the problems of circular economy. Structural work and foundations represent the majority of the embodied energy of a building. The research effort is therefore focused on the structural elements. Reuse is here defined as the reuse of an element without transformation, unlike recycling which induces a new industrial cycle. It is therefore about reducing the consumption of materials and lowering GHG emissions. Today, it is impossible in France to reuse structures because of responsibilities, insurance and lack of traceability. How to make possible the reuse of structural components in order to reach a low carbon building? The challenge of this work is to find the best structural configuration making the components reuse easier at the EOL. The methodology we are implementing aims to design the structural elements by increasing the BIM parameters (6D, LCA), to attach the mechanical information, material durability, ageing to each object of the digital mock-up. A digital and physical traceability makes it possible to follow the evolution of the element over the years and to feed a database. At the end of its life the database is accessible and searchable for the design of a future building. A development of tools and gateways will then allow from a model of calculation to go to query the database to find an element resulting from the deconstruction that can be reused in the future structure.

1. The need for solutions to environmental issues

The environmental findings require rethinking our construction methods to fight against the depletion of natural resources and greenhouse gases (GHGs) emissions.

1.1. The environmental impacts of construction

The construction and building industry is the principal emitter of GHGs [1] with 116 million tonnes of CO_2 equivalent (according to the Global Warming Potential, EN 15804), i.e. 33% of total GHGs, and the biggest consumer of material with, for example, in the USA in 2017, the total value of industrial minerals production which was $48.9 billion, a 3% increase from that of 2016. Of this total, $23 billion was aggregates production (construction sand and gravel and crushed stone), that is to say around half dedicated to concrete. [2].

These emissions have two distinct causes: energy consumption or functional energy (electricity, heating, ventilation, etc.) and energy used during its construction, known as embodied energy (production of materials, transport, site, etc.). Buildings are now capable of producing their own functional energy and providing the required level of user comfort. Environmental impact assessments show that for recent buildings, the majority of total GHG is due to this embodied energy [3]. In his study [4], Peuportier shows that for a RT 2005-compliant building (RT 2005 for the French thermal regulation for buildings), approximately 12% of total contribution is due to embodied energy but this figure rises to 29% for a passive building, as confirmed by [5]. Research work must now focus on reducing embodied energy due to construction activities.

In terms of where a building's embodied energy is used, structural works is found to be the main culprit. To this effect, Hoxha, in his doctoral thesis defended in 2015, analysed 16 collective buildings and concluded that concrete was preponderant for impact indicators: waste, renewable energy, and climate change [6]. Accordingly, elements of superstructure linked to elements of infrastructure and foundations make up more than half of a building's embodied energy with 58% of the LCA Global Warming Potential impact of a building's component products and systems [7]. This makes civil engineering a key focus to reduce environmental impacts over the coming years according to Figure 1.

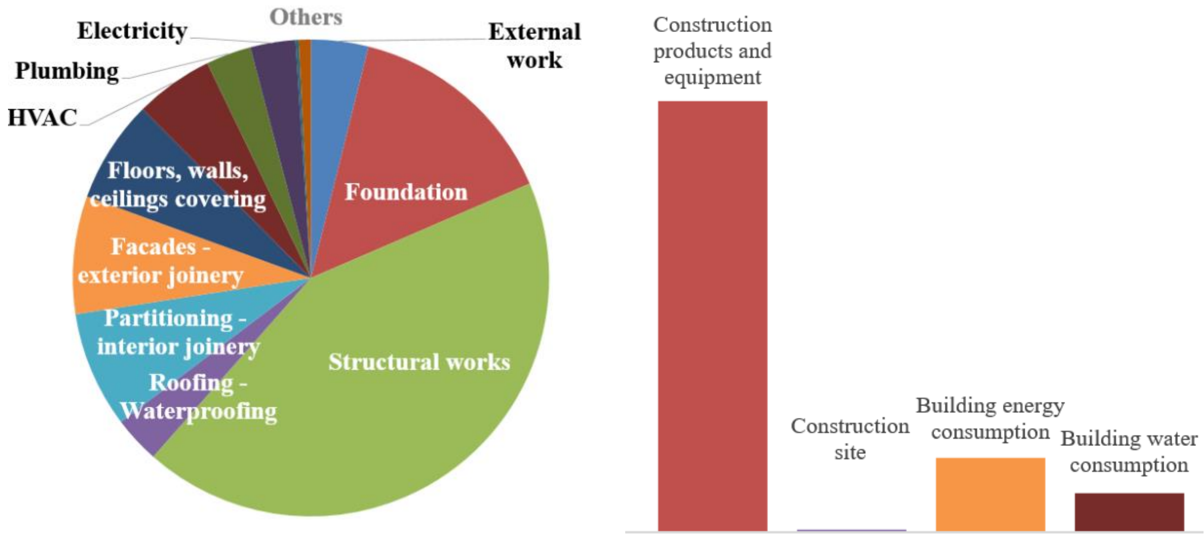

Figure 1. (a), (b), Distribution of impacts over 50 years for climate change in kg of CO_2 equivalent and breakdown for products and systems (unit-less) [7].

1.2. The circular economy (CE) applied to structural works

The research presented suggests solutions to the issues of the CE. The ultimate objective of the CE is to break the pattern of economic growth depleting natural resources. The idea is to extend the useful life of material (reuse, recycling) and products (eco-design) over the product's entire lifespan. This model is based on creating positive feedback loops for each use or reuse of the material or product before its final destruction. The material is passed on indefinitely from stakeholder to stakeholder until a new use process is found. The research is focused on structural elements, which have a greater impact in terms of GHG as the Global Warming Potential according to EN 15804 reveals, and establishing the conditions for their reuse, which is more sustainable before recycling and then energy recovery. In France, legal definition for reuse is: particular preventive action designating any operation by which substances, materials or products that are not waste are reused for a use identical to that for which they had been designed. To this effect, in April 2018 the French government presented its roadmap to develop a 100% CE. It wants to "turn existing buildings into a bank of future construction materials".[1]

1.3. Reuse of structural elements

Reuse induces additional operations for its establishment as dismantling, transport, storage, reprocessing and reconstruct. Brière, in his doctoral thesis defended in 2016, has established five parameters to evaluate the environmental impact of re-use: I_c (collection impact); I_s (storage impact); I_t (transport impact); I_r (reprocessing impact) and I_e (avoided impacts) [8]. Brière proposed re-employment specific impacts that were not included in the current standardization. With these parameters he studied three scenarios for a reinforced concrete beam in an existing housing building: its reuse, recycling and landfilling. He showed that the reuse scenario was for many indicators the most relevant solution in the case where 10 beams from the recovery would replace 7 new beams. Now if we consider a structure designed to be disassembled, impacts I_c and I_r will be substantially reduced. Better traceability will allow keeping the same number of reused beams as the number of new beams. The present study of ten tall buildings structural configurations for easy reuse leads to the best 86% of reusable hinged posts (for the posts parameter), so that is 18% of the climate change impact of the structure. The database presented here may also decrease I_s.

So the idea is to reduce consumption of materials and cut GHG emissions. Eventually, anticipated design in terms of end-of-life (EOL) reuse will prevent any waste being produced. The primary energy will also necessarily be reduced if we avoid the manufacture of new elements thanks to the reuse of the elements manufactured in the past. However, materials already used in the structures of the buildings surrounding us, known as "stockpiles", will be difficult or even impossible to reuse. Technically, there are no major obstacles but as far as liability and consequences in terms of insurance and above all due to the cost involved, reuse of current structures is not worth a client considering. However, methods and processes are progressively being consolidated, as explained in the "Repar 2" paper [9], which looks at the loadbearing wall deconstruction and reuse methodology. However, today re-use implies the downgrading of the structural elements. To achieve the minimum environmental impact, the structural function should be maintained at the same level.

The lack of traceability of material characteristics and the loss or inexistence of documents such as as-built records faced by prime contractors working on existing real-estate, often prevents them from making any attempt to reuse materials. The residual performance characterisation and assessment process can become an obstacle to decision-making.

To enable this reuse of structural elements, it is essential that it be anticipated in current designs of structures that will be built tomorrow.

2. The need for data traceability from the design

In the same way that information on the existing structure is to be found in the case of rehabilitation, reuse induces an anticipation of the necessary information in 30, 50 years or more for future engineers.

2.1. Liability data

By being properly insured in France, the engineer can cover their mandatory ten-year liability. From an insurance point of view, evidence of use of a standard technique must be provided to be insured without having to pay any additional premiums. However, reuse is neither covered by standardised technical documents. So for the moment reuse cannot be recognised as a standard technique.

To this end, all structural data essential for the engineer recovering the element in 30 or 100 years' time will need to be linked during the design phase. On a structural level, knowledge of at least the physical and mechanical properties of the materials is expected. The list must be drawn up based on the structural function: column, beam, loadbearing wall, crosswall, slab, but also the type of material:

[1] https://www.lemoniteur.fr/article/economie-circulaire-les-5-mesures-qui-impacteront-le-btp.1966709

concrete, steel, wood, etc. Additional studies by structural engineers may be required based on the degree of complexity of the dismantled structure and the project featuring the reused elements. Traceability must be made reliable using digital tools to guarantee the data linked to the structural elements.

2.2. 6D BIM : sustainable development data

A study shows that existing DfD practices and tools are not BIM compliant [10]. Tools are developing to optimize deconstruction and EOL but have not been thought for reuse and DfReu (Design for Reuse) practices. The described methodology here aims to design structural elements by increasing the BIM 6D[2] and life cycle assessment (LCA) parameters. 6D is the "dimension" covering environmental data[3] relating to sustainable development. The BIM tool then helps the designer and client to assess the environmental impact of decisions taken throughout the project until its EOL. Engineers can react to this carbon footprint and propose the most environmentally-friendly construction systems.

2.3. Structural calculation data: BIM to reuse structure

For essential reasons of liability, a structural engineer who decides to reuse an element previously used in another building must make sure he is fully aware of the characteristics of this element and possibly the conditions of life of the entire structure of which it was a component. The principal structural data for high-rise buildings can be divided into four categories:

- the properties of the element (static): geometry, composition, resistance class, relevant standard, etc.;
- the behaviour of the element (mechanical): position, type of loads, stress applied, connection conditions, creep, ageing characteristics, etc.;
- the overall behaviour of the structure (mechanical): exposure class, differential shortening, soil compaction, top displacement, top acceleration, differential displacements between floors, scaling criterion, useful life of structure, etc.;
- information for the reuse process: checks required, residual performance tests, deconstruction phasing, etc.

3. Types of traceability

As previously seen, many pieces of information needed for the reuse of structural components have to be obtained through specific traceability.

3.1. Digital traceability: BIM model

Each stakeholder tends to take ownership of a model by modifying part of the initial data for their own use. At the end of the chain, some data is definitively lost as a result. For reuse, digital building models and as-built records are particularly crucial. A system of filters to manage access to certain data based on stakeholders concerned must be set up to prevent deletion of data not used at this stage of the project but also guarantee a level of confidentiality.

3.2. Passive physical traceability: RFID chips

Passive physical traceability refers to systems that can be integrated into materials for a very long time (life of the element) and that will be self-sufficient over this time. So most will not have a built-in power supply but rather the reader, e.g. "Near Field Communication" (NFC) system, will supply the power needed to read the data built into the material. The most fully-developed technology is currently the "radio frequency identification" (RFID) chip. Start-ups plan to incorporate RFID chips into concrete before or during its implementation. RFID chip are self-sufficient and could potentially last forever.

[2] *6D*: Covers all issues concerning a building's sustainable development, e.g. energy assessments and estimated carbon footprint for each phase.

[3] http://www.mediaconstruct.fr/ba-ba-bim/fondamentaux-bim

Today the RFID chips used are designed to withstand attacks (especially in concrete). Once trapped in the material, nothing can come to damage the chip as the structural element is not damaged either. However, this contemporary technology has a very short experience feedback (2013 for the first chips in concrete in France). But current designers point to a potentially infinite lifespan inside the elements. The information is hosted digitally and remotely. Potentially, this information could be corrupted (malicious modifications, deletions). RFID chips can also internally store an unmodifiable text file but it must be extremely limited in size. Today, there are three types of RFID chips [11]: passive, semi-passive, and active. Active chips have a power source. This means they have a significant read-write range (5 to 30m), further than passive chips (approx. 2m or under). But this makes these active chips more expensive than passive labels. Passive chips, however, are very cheap and very resistant to harsh environments, which means they can be submerged in concrete when its pouring.

The problem with these contemporary technologies is their immaturity. There's still only very limited user feedback, well the reuse process covers periods of 20, 50, 100 years, or even more. Passive traceability is better suited to recording the properties of the element (static).

3.3. *Active physical traceability: sensors, IoT*

Though active RFID chips are available, it's preferable to use sensors to benefit from full-building instrumentation. Using sensors linked to the Internet of Things (IoT), changes to the element can be monitored over time and data progressively added to the database. The IoT's potential was initially identified for the operation and maintenance of smart buildings. It is also very useful for reuse, offering comprehensive monitoring of a structure's functional behaviour.

To reuse structural elements, their full history, particularly in terms of specific stresses and strains to which they have been subjected, needs to be known. Today, it can help to improve knowledge of the structure, for example including: monitoring of the structure's overall behaviour, direct marking of materials for geolocation purposes, real-time strain alerts. So instrumentation monitoring can be easily adapted for reuse purposes. Structural health monitoring (SHM) methodologies provide information on the ageing of elements and data for updating and checking calculation models.

Finally, it should be noted that active traceability is better suited to the needs of monitoring the structure's overall behaviour (mechanical).

4. Design to reach total reuse

As previously discussed, reuse of existing building is not optimal. However today it is necessary to build differently to systematize the reuse of the elements implemented in new buildings.

4.1. *Bank of available materials*

The reuse process is anticipated in the very long term. The objective is of course to integrate the principles of this methodology into contemporary design. The actual lifespan of buildings varies according to criteria that cannot always be predicted when they are built (real-estate market trends, changing development project needs, etc.). Current trends show a sometimes very short lifespan of around twenty years (mainly for offices) and the history of architecture is littered with buildings that practically last forever. The reuse process is based on a certain level of renewal of existing real-estate, which is estimated to have a lifespan of between 20 and 100 years.

So a materials bank created today, from the structures we are currently building, must be designed to remain effective over the next 100 years or at least to enable its upgrading to ensure compatibility with future technologies. The materials bank can be designed for a multi-owner client who wants to become self-sufficient in raw materials and who would use his material resources to supply materials for the entire renewal of his existing real-estate, just-in-time. It can also be designed at a national level on a very large scale based on the trend set by the French government with the objective of achieving a

100% CE. If data on all new-builds is added to this database, there will be sufficient choice to integrate a large number of reuse elements into new structures.

4.2. New paradigm of design

High-rise buildings have potential for reuse due to the repetitiveness of its structural elements. For this exercise, structural elements subjected to simple stresses (compression) are preferable and overly complex elements are to be avoided (combined bending and axial load). In fact, the more an element is subjected to a simple stress, the less specific it will be, which will increase its chances and fields of subsequent reuse. For a complex element, it will be even more difficult to find a use configuration similar to its initial use.

The connections between these elements play a decisive role in determining whether the structure can be deconstructed [12]. Use of reversible connections [13], which do not damage the materials or its characteristics, must be anticipated during the design phase. This means that their impact on the overall model must be assessed. An in-depth structural analysis is then required to determine the points that should be hinged and the ones that need to be fixed. The choice of the structural typology is also essential [14] and must be analyzed for its reuse potential. Accordingly, a study conducted at **setec** tpi (the French engineering and civil engineering company that finances this PhD research) analysed 10 models (based on four different concrete load-bearing systems rated M1 to M4 in Table 1) of a high-rise office 41-storey building, attempting to hinge as many elements as possible and comparing their carbon impact. The variants of a single load-bearing system are rated A to D (none / façade / interior / façade + interior) with a varying number of hinged elements illustrated in Figure 2. For M2C (Model with "Outriggers + cross bracing" and 540 hinged posts) to M2D (Model with "Outriggers + cross bracing" and 1452 hinged posts), an increase in the number of articulated poles of 269% causes an increase in the climate change indicator of only 0.56% in 1st cycle. This study promises also an 18% decrease for this impact in 2^{nd} life cycle, if the posts are reused. It is particularly important for there to be a balance between types of connections, deconstructability, quantity of material used and safe disassembly.

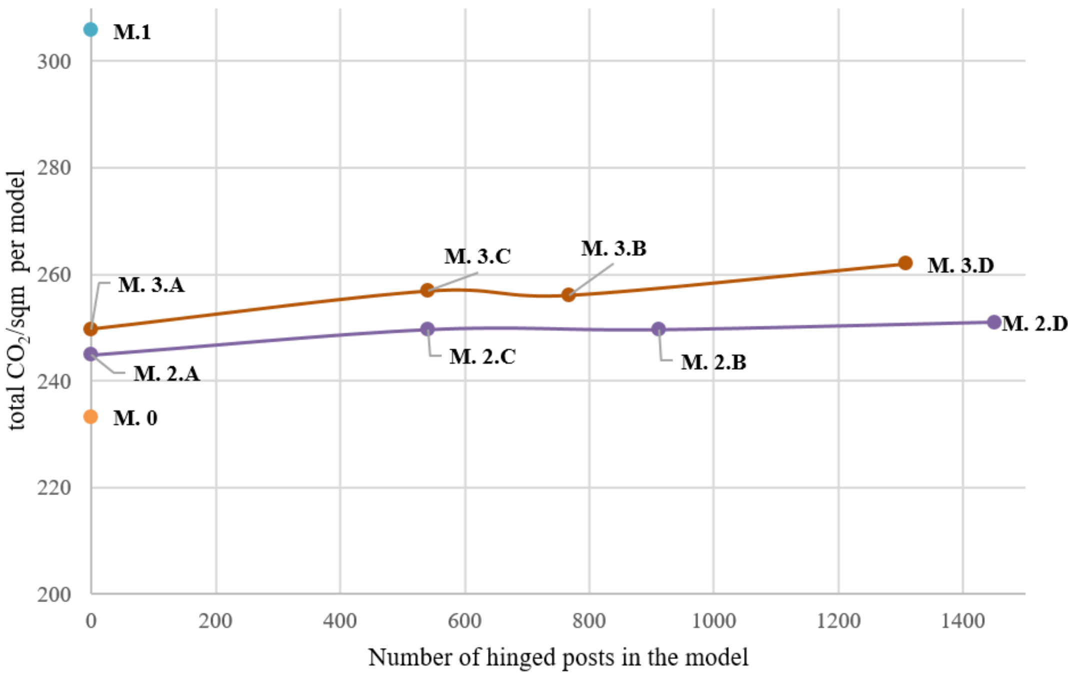

Figure 2. Study of structural variants of an office tower with the aim of hinging as many columns as possible.

Table 1. Relationship between increasing articulated posts and increasing the climate change impact of the structure.

	Number of hinged posts (maximal increase)	Total CO_2/sqm (maximal increase)
M0 "Concrete tube"	-	-
M1 "Tubed mega frame + outriggers"	-	-
M2 "Outriggers + cross bracing"	268,89%	0,56%
M3 "Crosswall + cross bracing"	242,22%	1,99%

5. End-Of-Life (EOL) reuse process to design a new building

Therefore, the first effort is to build reusable buildings today. But tomorrow, we must learn to build anew with these components from deconstructions.

5.1. Conceptual margins

Designing a new building using reused elements is different from the "traditional" design process that we use on a daily basis. Depending on what element are available in the database, the geometry of its structure will have to be more or less flexible. One of the challenges is setting acceptable margins for the choice of elements. For the span of a beam, for example, a range will have to be determined such as plus or minus 50cm for the span of a batch of beams, according to the materials available in the database. The new geometry of the building must then be adapted according to the batch of available beams. These margins inevitably have an impact on the overall design. However, it is expected that most reused elements will be available in batches and it will be easy to find several identical elements, which will mean only one criterion will have to be adjusted. If the span of the beam is adapted by increasing it by +50cm, this will be the case for all the beams. The more beams on the database, the easier it will be to find the right span, without margins.

The same applies for ceiling height, which is today calculated for maximum gain with a view to building the maximum number of floors for operational profitability. With reuse, increased structural height can be expected, but also a considerable economic gain on the cost of the reused materials. For safety reasons, an additional margin in the safety coefficients is to be expected. Even if in the very long term, design needs to be adapted to reuse as many reused elements as possible, the transition will be progressive, with first, integration of vertical elements, which are more structurally suited to recovery.

5.2. Compiling this information: the database

This database is a bank of materials for future buildings. When the existing building, of which the elements feature in this database, is set to be deconstructed, the elements become available for a new structural project. When the structural engineer designs their new project, they create a calculation model. Based on this calculation model, queries are sent to the database to identify a structural element that could fulfil a new function over its second life cycle. This process is illustrated in Figure 3.

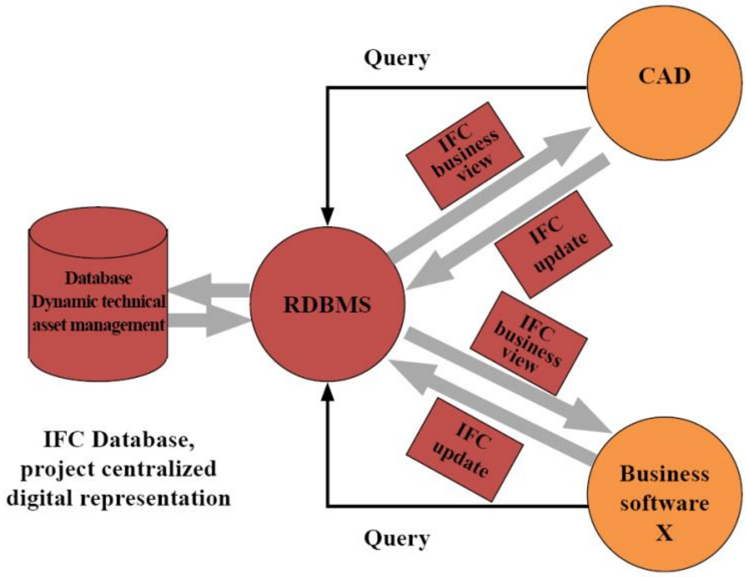

Figure 3. Dynamically shareable database [15].

This database system, to which data is added whenever a new building is constructed, makes it possible to work on a just-in-time basis with these structural elements and avoid storage issues, particularly in areas with little space available such as metropolises. However, the amount of data must be limited and optimised. Reducing the amount of data will, *inter alia*, make it possible to save both calculation and database search time, plus energy on the servers that are used.

For this research, the parameters were listed by materials and by phase according to the different stages of the project and entered in the BIM model. The information is attached to the objects in the BIM model. The methodology proposes to export, at each end of phase, these parameters on the database (ultimate normal effort, etc.). A gateway between the BIM model and the database and then the software for calculating reused structures has been developed.

5.3. Database queries

Depending on the stage of the project, queries will be more or less complex. For a column, for example, the initial issue may be to find a column in the database with an allowable stress enabling it to bear the load determined in the calculation model following analysis of the distribution of loads in the building. Next, the compatibility of the existing reinforcement drawing with the new use must be thoroughly checked.

This database query process will be an iterative process as a series of hypothetical uncertainties will have to be examined. Clearly, if the modelling of the new structure requires the use of a 50x50cm section beam and, in the database, the beam best meeting the stresses of the model has a section of 60x60cm, the structure's overall weight will be modified. As a result, a certain number of iterations are to be expected.

6. Concluding remarks and work to be continued

The contribution of the article concerns the reflection on the properties that must be known for reuse and the best tall building structural typology to achieve this. The environmental assessment of this unusual design questions impact allocations, especially for future reuse benefits. This research work has so far focused on the design of high-rise buildings to make their structure removable. Decommissioning scenarios must now be clarified and optimized to reach zero carbon. Data from traditional demolition sector must be refined for deconstruction. Then the data from deconstruction, transport, storage and reconstruction will make it possible to specify life cycle assessments with all the environmental impact indicators.

julien.cravero@enpc.fr

Abstract. City revegetation strategies seem appealing to mitigate urban heat island effects through shading and transpirational cooling. Moreover, other potential benefits that may derive, e.g. biodiversity enhancement, the reduction in buildings energy consumption, stormwater management, acoustic insulation or air purification, earned them the designation 'no-regrets approaches' for adapting to climate change. However, the lack of understanding and quantification of green infrastructures' environmental impacts prevents urban planning policies to be consistent and to turn attractive initiatives to effective implementations. The monitoring of existing green infrastructures is required to evaluate their cooling effect. For this purpose, an elastic gridshell in composite materials has been designed as a support for climbing plants at *Ecole des Ponts ParisTech* (Champs-sur-Marne, France). The life cycle assessment of the vegetated structure is performed in order to develop sustainable design strategies. Based on an energy balance approach, the collected thermo-hydric data can be used to determine which mechanisms are the most suitable for urban vegetation to enhance outdoor thermal comfort.

1. Introduction

City revegetation strategies seem appealing to contribute to urban heat island mitigation in a sustainable manner. However, current technical solutions employed to green dense urban areas are rarely adaptable to existing buildings and need major works to be carried out, as in the case of extensive green roofs. Supports of vegetation that are lightweight, cost-effective and compatible to various urban configurations are lacking. Moreover, the cooling effects provided by different types of urban vegetation are not yet properly understood and quantified, which prevents an effective implementation of green infrastructures in the townscape.

2. Vegetated structures

2.1. Elastic gridshells with composite materials

Given the constraints specific to dense cities, vegetated elastic gridshells (see figure 1) may represent an interesting type of green structure or furniture for enhancing thermal comfort on public spaces. Elastic gridshells aim at simplifying the construction of freeform structures and reducing the amount of material needed to cover large spans. Frequently, the fabrication process consists of assembling straight and slender beams into a flat regular grid. During the erection process, the elements are elastically bent so that the grid becomes doubly-curved. Once the desired geometry is obtained, it is braced to keep this final shape. Large-scale elastic gridshells that contributed to the reputation of active-bending structures were mainly manufactured out of timber, like the Mannheim Multihalle in 1975, the Weald and Downland Museum in 2002 and the Savill Garden in 2005. During the past, elastic gridshells used steel, aluminum, bamboo, cardboard and more recently carbon fiber reinforced polymers (CFRPs) and glass fiber reinforced polymers (GFRPs) [1].

Based on Ashby charts [2], Douthe [3, 4] showed that technical composites were perfect candidates for gridshell applications. In particular, pultruded pipes in composite materials display better results than timber laths when their respective mechanic properties (i.e., deformability, stiffness, toughness) are compared and GFRPs stand out from CFRPs when cost and embodied energy are considered. However, the environmental impacts due to materials and fabrication processes are expected to be greater for GFRP elements than for timber ones. As GFRPs exhibit a good resistance to many kinds of chemical attacks, the relevance of GFRP gridshells is thus amplified by the harshness of the environment. For example, GFRP gridshells are well-suited to any long-term outdoor exposition whereas timber gridshells would need regular maintenance operations under continental climatic conditions, hence increasing (environmental) costs. As the energetic content index in Ashby's method only reflects partly the environmental footprint of a material, life cycle assessments (LCAs) of the whole system are preferred to have a comprehensive mapping of its environmental impacts. More details on the LCA of GFRP rods are given in section 3.

Figure 1. Vegetated "tree-shaped" gridshells. [credits: Théo Mondot]

2.2. Climbing plants

The choice of the plant species depends on biological criteria (hardiness with respect to the climate, soil, growth rate, competition between species), esthetical criteria (shape, flowering, fructification, integration in the surrounding landscape), technical criteria (maintenance, stresses exerted on the structure), etc. According to gardeners working for the City of Paris, a mix comprising about two-thirds of deciduous trees and one-third of perennial ones is adopted in the parks and streets of the city to ensure shade in summer without blocking the incoming sunlight in winter. As the pots depicted in figure 1 contain one cubic metre of substrate, it has been decided to plant three climbers per pot in the same proportions. Possible candidates for the climbers in the Paris region are vines (e.g., *Vitis coignetiae, Parthenocissus quinquefolia, Parthenocissus tricuspidata*), clematis (e.g., *Clematis armandii, Clematis montana, Clematis 'Jackmanii')*, honeysuckles (e.g., *Lonicera japonica, Lonicera caprifolium*), hops (e.g., *Humulus lupulus 'Aureus'*), passifloras (e.g., *Passiflora caerulea*), jasmine (*Jasminum officinale*) or false jasmine (*Trachelospermum jasminoides*). Some of these climbing plants have been studied recently for green facades in Reading [5] and in Berlin [6] and demonstrated cooling potential through transpiration and shading.

2.3. Prototype

An experimental vegetated gridshell has been designed (see figure 2(a)) and will be built at Ecole des Ponts ParisTech in Champs-sur-Marne to assess the cooling effect provided by such structures. The grid comprises 32 pultruded composite rods made from vinylester resin and glass fiber, each rod having a length of 6m and a diameter of 18mm. The rods are assembled every meter with polyamide connections (see figure 2(b)) that are designed to let the rods rotate freely along their longitudinal axis. As the rods are initially straight and have equal principal moments of inertia, this free-rotation condition at the nodes and the supports ensures that the rods are not subjected to torsional stresses [3]. The stress level in the rods is capped at 25% of their limit stress to minimize creep and comply with recommendations for long-term mechanical performance of GFRP rods in actively-bent structures [7]. The gridshell is braced by 3mm-diameter steel cables at the top and the middle and by a steel sheet at the bottom. This metal cylinder envelops a pot containing three climbing plants, the substrate, pozzolan for drainage and a water reserve.

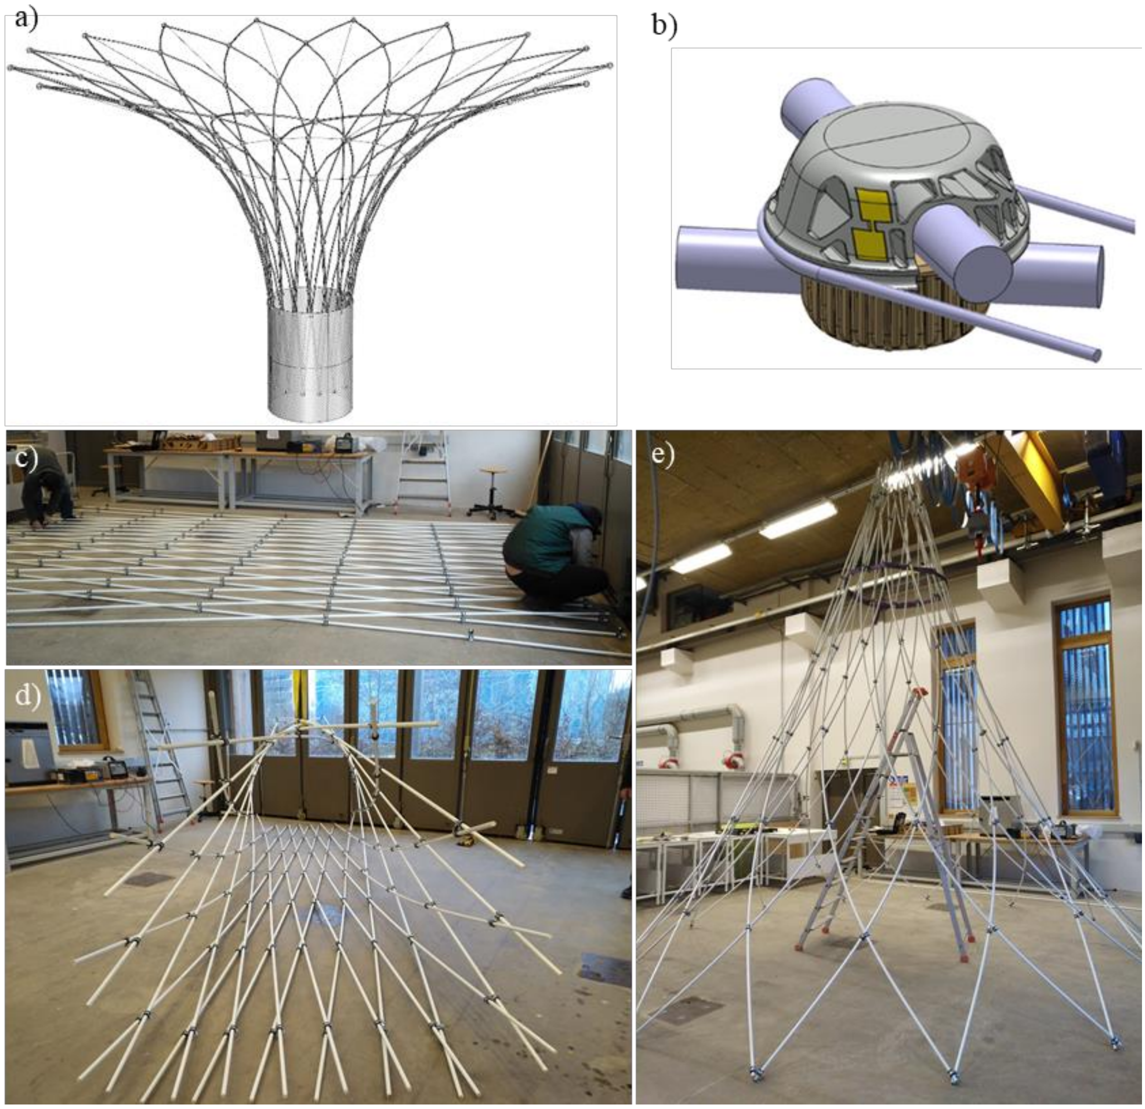

Figure 2. (a) Perspective view of the experimental prototype; (b) connection between two rods; (c) assembling of the rods into a flat grid; (d) closing of the grid into a cylinder; and (e) bending of the rods before bracing the grid.

The structure is 4.5m high, 1m wide at the base and 7m wide at the top, hence covering a projected area of circa 40m². The mass of the gridshell alone is 100kg. The whole vegetated structure weighs approximately 500kg when the water reserve is empty. A few pictures illustrating the main construction steps are shown in figure 2.

3. Life-cycle assessment

3.1. Description of the system

Processes are modelled with OpenLCA v.1.7.4. Ecoinvent 3.2 database is used for the life cycle inventory (LCI). The life cycle impact assessment (LCIA) method is based on NF EN 15804 [8] and NF EN 15804/CN [9] standards that apply to construction products. French national complement NF EN 15804/CN is employed to characterize air and water pollution. The nine impact categories proposed by NF EN 15804/CN are considered: acidification of soils and water (kg SO_2 eq.), ozone depletion (kg CFC-11 eq.), eutrophication (kg PO_4^{3-} eq.), photochemical ozone formation (kg ethylene eq.), air pollution (m^3), water pollution (m^3), global warming (kg CO_2 eq.), mineral and fossil resource depletion (MJ), and non-fossil resource depletion (kg Sb eq.). The model graph of the processes considered in the analysis is shown in figure 3. Each process is detailed below.

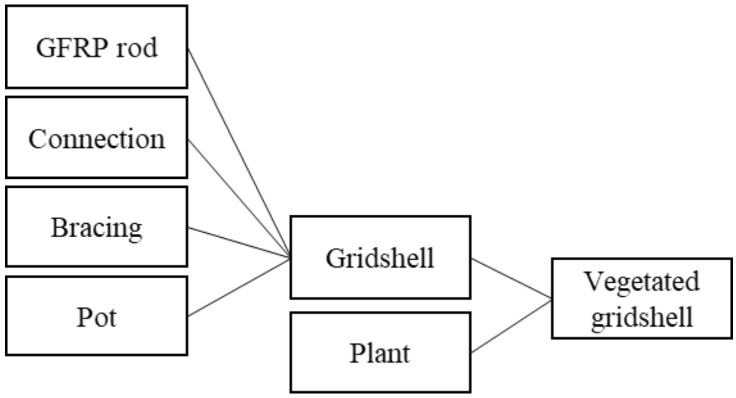

Figure 3. Flowchart of the system.

The LCI for similar glass fibre reinforced polyester resin composite elements has been performed previously [10]. It accounts for energy consumption, material consumption, types of packaging and transport, wastes related to production (such as raw material wastes) and the treatment of the latter. It does not consider the end of life of the end product. As vinylester resin is not yet available in ecoinvent 3.2 database, the process *polyester resin, unsaturated | polyester resin production, unsaturated – RER* used in [10] is kept to model the LCI of GFRP rods.

Gridshell connections are made in glass fibre reinforced polyamide and weigh 90g each. The process *injection moulding | injection moulding – RER* is employed. The mould is modelled as a 100kg-low-alloy-steel element with average metal working (*metal working, average for steel product manufacturing | metal working, average for steel product manufacturing*) and 800km aircraft transport pending further information from the manufacturer. According to the manufacturer, one million connections can be fabricated with this mould. Hence, an amortization of the mould is considered.

The braces (3mm-diameter steel cables with cable clamps) and the 40kg pot are modelled as low-alloy steel elements with average metal working.

The gridshell fabrication needs the production of 96kg of GFRP rods, 112 connections, 35m of braces and one pot. Transport from the production sites is not yet taken into account because of a lack of information.

In a first approach, waiting experimental results, the water consumption (i.e., irrigation) is estimated to 200L per plant per year. Based on [11], the potential productivity per plant is estimated to 4kg of dry matter per year. Assuming a carbon content of 50%, each plant stores 2kg of carbon per year, which corresponds to 7.3kg of carbon dioxide used for photosynthesis. Thus, each plant is modelled in OpenLCA by a single process that uses 200L *tap water | market for tap water* for irrigation as an input and avoids 7.3kg of carbon dioxide yearly. These figures consist in rough approximations and will be refined later experimentally (see sub-section 4.2). Processes used for the production and transport of the soil, sand and pozzolan are not considered at this time. The data will be collected and analyzed when the prototype is built.

Finally, a vegetated gridshell comprises the production of one gridshell and three plants as modelled above. The lifetime of the plants is estimated to 30 years but the service life of the structure is expected to be larger based on durability studies carried out on GFRP rods [7]; the treatment or reuse of the structural elements is beyond the scope of this study.

3.2. Results

The potential impacts due to the gridshell production alone and to the vegetated gridshell after 30 years are given in table 1. As the plants only need tap water for irrigation in this model, the differences in the impacts of the gridshell and the vegetated gridshell are very limited, except for the global warming potential. This is due to the amount of carbon dioxide removed by the plants in their surroundings because of their growth. However, this carbon is stored temporarily and will be released sooner or later depending on the end of life of the plants: they may be burnt at the recycling centre to serve as fuel for heating the district, shredded to be used as mulch, decomposed by composting, etc. These scenarios will be considered in future works.

Table 1. Impacts of the gridshell production and of the vegetated gridshell (the results are shown for a lifetime of 30 years).

Impact category	Gridshell	Vegetated gridshell
Acidification of soils and water (kg SO_2 eq.)	2.9	3.0
Ozone depletion (kg CFC-11 eq.)	$6.3\cdot10^{-5}$	$6.3\cdot10^{-5}$
Eutrophication (kg PO_4^{3-} eq.)	0.46	0.47
Photochemical ozone formation (kg ethylene eq.)	0.17	0.17
Air pollution (m^3)	1700	1700
Water pollution (m^3)	$4.8\cdot10^{5}$	$4.9\cdot10^{5}$
Global warming (kg CO_2 eq.)	690	40
Mineral and fossil resource depletion (MJ)	$1.0\cdot10^{4}$	$1.0\cdot10^{4}$
Non-fossil resource depletion (kg Sb eq.)	$1.4\cdot10^{-8}$	$1.4\cdot10^{-8}$

Figure 4 shows how the GFRP rods, the connections, the pot and the braces contribute to the environmental impacts caused by the gridshell production. The graph indicates that in this case, the share among the four processes follows a similar pattern for all the impact categories. The impacts due to the production of the GFRP rods accounts for approximately two-thirds of the total, which suggests that future designs should aim at decreasing this material quantity. For the gridshell to keep a similar global structural behaviour, this could be achieved with a denser grid of rods of smaller diameter (at the cost of a greater number of connections) or with GFRP tubes (i.e., hollow instead of solid rods). Natural fibre reinforced polymers (NFRPs) could also be utilized to reduce the amount of glass fibre in the structure. However, this may lead to mechanical long-term issues [7] and one has to ensure that their industrial production does not require more polluting processes. This has still to be assessed.

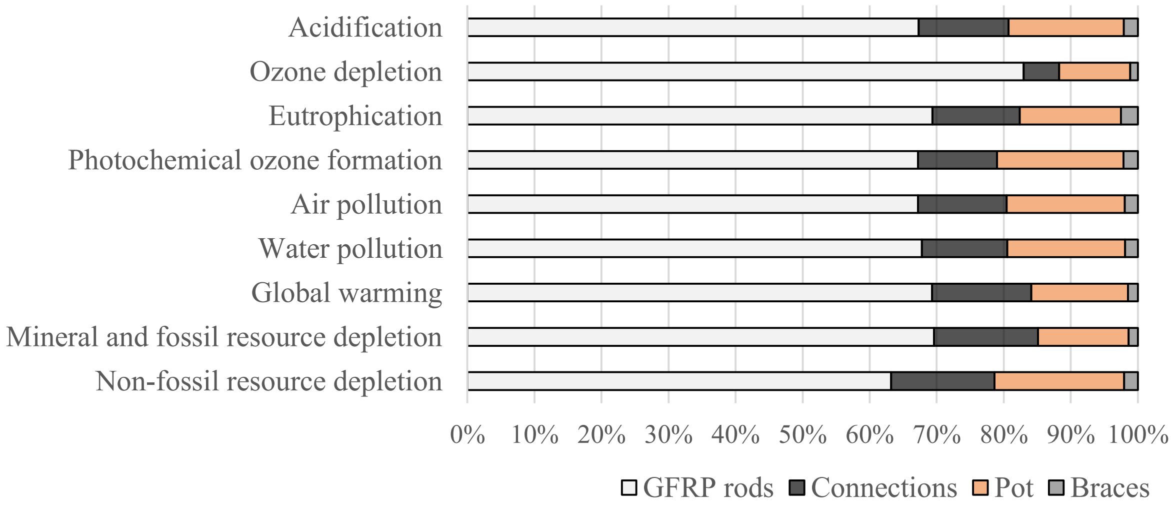

Figure 4. Relative contribution of each element production to the total environmental impacts of the gridshell production.

Table 1 shows the interest that urban vegetation could play in terms of climate change mitigation, as it temporarily stores carbon, but other potential benefits, such as cooling effects, are not reflected by the LCA. This is discussed in the following section.

4. Evaluation of the cooling effect at a local scale

4.1. Cooling mechanisms

Oke [12] proposed in 1982 a sound theoretical framework to advance knowledge in the field of urban meteorology and overcome the mere description of urban heat island effects. His approach popularized the use of surface energy balance models for predicting the thermal response of cities to various urban forms and environmental conditions. Since, numerous works have attempted to improve the modelling of energy, mass and momentum exchanges at stake in the energy balance. A general way to write the energy balance at the interface between the urban area and the atmosphere is given by Offerle [13]:

$$Q^* + Q_F = Q_H + Q_E + \Delta Q_S + \Delta Q_A + S \qquad (1)$$

in which Q^* is the net all-wave radiation, Q_F the anthropogenic heat flux, Q_H the sensible heat flux, Q_E the latent heat flux, ΔQ_S the heat storage, ΔQ_A the net advected flux and S all other heat sources or sinks. All these terms are homogeneous to heat flux densities and are expressed in W.m^{-2}. The rationale of this approach is detailed in many works, e.g. in [14]. Neglecting anthropogenic and advected fluxes, and in the absence of heat sources and sinks, equation (1) may be rewritten as per Masson [15] to highlight the dynamics of the energy exchanges:

$$eC\frac{\partial T_s}{\partial t} = Q^* - Q_H - Q_E - Q_G \qquad (2)$$

in which e is the layer thickness (in meters), C the heat capacity (in J.m^{-3}.K^{-1}), T_s the temperature of the surface and of the layer (in kelvins) and Q_G the conduction heat flux between the surface layer and the underlying layer (in W.m^{-2}). The terms used in equation (2) may be written as:

$$Q^* = (S_\downarrow - S_\uparrow) + (L_\downarrow - L_\uparrow) = (1-\alpha)S_\downarrow + L_\downarrow - \varepsilon\sigma T_s^4 \qquad (3)$$

$$Q_H = h_{ch}(T_s - T_{air}) \qquad (4)$$

$$Q_E = LE = Lh_{cm}(p_{sat}(T_s) - p_w) \qquad (5)$$

$$Q_G = -\lambda \left(\frac{\partial T_s}{\partial z} \right)_{z=e} \qquad (6)$$

where $S\downarrow$ and $S\uparrow$ are the downward and upward short-wave radiations (in W.m^{-2}), $L\downarrow$ and $L\uparrow$ the downward and upward long-wave radiations (in W.m^{-2}), α and ε the surface albedo and emissivity, σ the Stefan-Boltzmann constant (σ=5.67·10^{-8} W.m^{-2}. K^{-4}), h_{ch} the convective heat transfer coefficient (in W.m^{-2}. K^{-1}), T_{air} the air temperature (in kelvins), L the specific latent heat of vaporization of water (in J.kg^{-1}), E the evaporation rate (in kg.m^{-2}.s^{-1}), h_{cm} the convective mass transfer coefficient (in s.m^{-1}), p_{sat} the saturation vapour pressure (in pascals), p_w the partial pressure of water vapour in the air (in pascals) and λ the thermal conductivity of the layer material (in W.m^{-1}. K^{-1}). Equation (2) may be used to model the temperature evolution of the substrate, of the ground under the gridshell shade or of one leaf, irrespective of the surface area. However, the area of the surface under consideration may play an important role in terms of fluxes repartition, as smaller objects have greater heat transfer coefficients according to Sakai [16]. Note that "surface" often denotes a control volume with homogeneous properties that could represent a large urban area (e.g., [14]) or a crop canopy (e.g., [17]). The energy balance of a thin layer as described above is graphically summarized in figure 5.

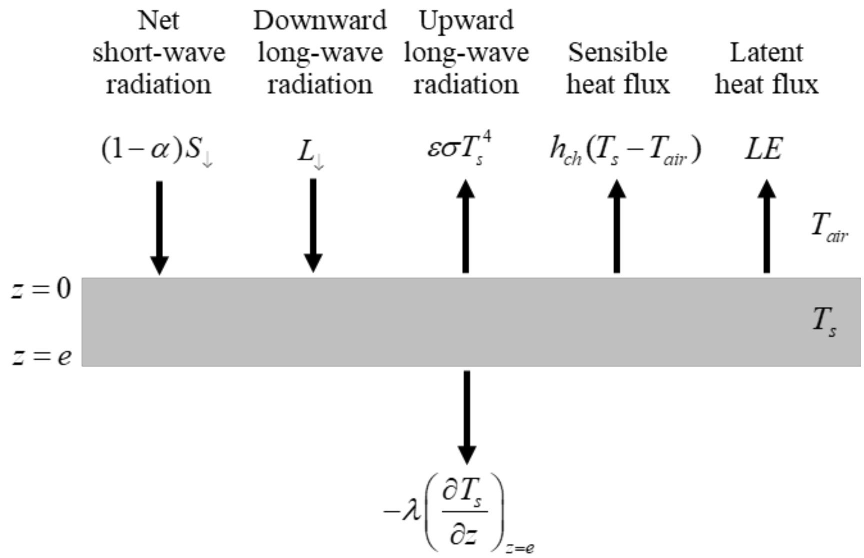

Figure 5. Energy balance for a thin layer of material.

The quantification of these energy exchanges enables to predict the urban surfaces temperature evolution and to better understand by which means heat island effects could be mitigated by vegetation. As trees transpire, they cool down their leaves, which then cool down the air by convection if their temperature is lower than that of the air (i.e., Q_H < 0). This is not always the case, as demonstrated by measurements of tree crown temperatures in Basel that were found to exceed air temperature by 5 K [18]. Recently, Manickathan [19] showed with computational fluid dynamics (CFD) simulations based on leaf energy balances that the top of a tree crown could warm the air (even if the transpiration is high) whereas cooling occurs at the bottom of the tree where the absorbed radiation is low. This small amount of direct cooling caused by trees agrees with previous CFD simulations [20, 21]. As the amount of air cooling seems to be limited based on a meta-analysis on the cooling effect provided by parks and green spaces [22], the main impact of urban trees upon thermal comfort is attributed to their shade as reported by Armson [23]. Based on equation (2), shading an artificial surface (i.e., lower $S\downarrow$) decreases its surface temperature, hence reducing the convection of heat to the air (i.e., lower Q_H) and the radiation towards pedestrians and other surfaces (i.e., lower $L\uparrow$). Decreasing absorbed radiation also reduces thermal storage in materials and release of the heat during the night [24]. Moreover, during summer trees may be able to keep a foliage temperature closer to the air temperature compared to surrounding artificial surfaces thanks to their numerous small leaves [16]. Hence, they would act as a radiative screen for pedestrians. This agrees with studies assessing the human comfort in outdoor environments based on the Universal Thermal Climate Index (UTCI) [19, 25].

4.2. Instrumentation

The gridshell prototype described in section 2 will be instrumented to assess the cooling effects due to air cooling and surface shading. Load cells will be placed under the pot to measure the evapotranspiration (i.e., the mass of evaporated water), as with a lysimeter. This data will also be used to measure the water needed for irrigation and refine the plant growth model. The radiation balance is measured with pyrgeometers and pyranometers. Temperature sensors are employed to get the temperature of the air, of the substrate and of the ground. Leaf temperature is obtained by a thermal imaging camera. These experimental results will permit to have a deeper understanding of the dynamics of heat exchanges around an isolated vegetated structure and to compare their cooling efficiency with other species of climbing plants [5, 6] and other types of landscape strategies (e.g., [26]).

5. Conclusions and perspectives

An innovative 40m²-gridshell in composite materials has been designed as a support for climbing plants in order to provide shade in urban areas. A life cycle assessment of this structure has been performed to evaluate the environmental impacts due to its construction. Modelling the end of life of both the materials and the plants is still needed to develop sustainable solutions that may contribute to heat island mitigation. Experimental results are also required to assess the cooling effects and the maintenance costs provided by this vegetated urban furniture and by urban vegetation in general. This will allow to derive indicators describing the cooling performance of various landscape strategies and to establish trade-offs between outdoor thermal comfort and resource use, e.g. materials utilized for the structure and water needed for irrigation.

Design concept for prefabricated elements from CDW timber for a circurlar building

Klinge A, Roswag-Klinge E, Paganoni S, Radeljic L, Lehmann M

ZRS Architekten Ingenieure, Schlesische Str. 26, 10997 Berlin

klinge@zrs.berlin

Abstract. The EU funded project RE[4] (REuse and REcycling of CDW materials and structures in energy efficient pREfabricated elements for building REfurbishment and construction) looks into opportunities for prefabricated, CDW timber elements (structural and non-structural) for circular buildings. Main goal is to minimise resource consumption for building construction but also waste generation related to building dismantling. An innovative design concept for a fully reversible, prefabricated, multi-story residential building from waste wood has been established that reflects robust but flexible and adaptable solutions to extend the buildings-life cycle. Reversible connections, reusable elements and recyclable materials shall minimise future waste generation, when such buildings reach their end of life. A prefabricated façade element manufactured for a two-story prototype shall deliver figures for easy installation, dismantling and future reuse. The study aims to show how current challenges can be overcome and design for disassembly can be promoted.

1. Introduction

In 2014 the building sector contributed with approx. 750 million tons of construction and demolition waste (CDW) significantly to the overall waste generation in Europe [1]. Recovery rates (50%) are relatively low, especially as recovered materials are mainly used for low-grade applications or diverted to energetic recovery [2]. Vast amounts are still directed to landfill, as existing buildings were not designed for disassembly. The dismantling of timber elements (columns, beams etc.) from existing buildings illustrates evidently the wasteful approach the industry is still pursuing. To avoid time consuming investigations related to the application of wood preservatives, timber elements are predominantly classified as Waste Wood Class AIV. This in turn implies thermal recovery as only exploitation method. As a result, high quality timber is lost for future applications. Furthermore, CO_2 stored in the element is released back into the atmosphere. In light of the forthcoming legal changes that stipulate the reduction of CDW by 70% in weight until 2020 (2008/98/EC), the industry needs urgently innovative concepts for circular construction that minimise the reliance on fossil resources and high-tech solutions in order to meet such ambitious goals set out by the European Union [3].

2. Requirements

2.1. Prerequisites

Although waste wood is one of the few materials that offer unique opportunities for direct reuse, this resource is mainly diverted to landfill or send to energetic recovery. Cheap access to fresh wood, low disposal cost and time-consuming detection methods for application of wood preservatives are currently the main barriers for circular timber construction. If waste wood shall be reused or recycled for construction purposes, the following prerequisites have to be addressed. Recovered sections must be free of:

- wood preservatives;
- other pollutants, resulting from previous uses that might have penetrated the wood;
- wood-destroying fungi and insects;
- any metal impurities that could damage machinery for reprocessing and
- demonstrate sufficiently strength, large cross-sections and lengths.

2.1.1. Harmful substances. The Waste Wood Ordinance regulates the handling of salvaged timber and implies that the absence of harmful substances must be proved in order to allow its reuse or recycling [4]. In the absence of any commercial rapid on-site test, material samples from retrieved elements (Figure *1*) have been examined in a certified lab. Instructions for removal of timber layers were given by the respective expert, in case of evidenced wood preservatives, which in turn permitted the utilization of salvaged sections instead of thermal recovery.

2.1.2. Pollutants from previous uses. In case harmful substances or pollutants were used or applied in a building identified for dismantling, suitable investigations must prove that timber identified for reuse or recycling is not affected. As such cases could be excluded for the salvaged waste wood within the RE^4 project, no special investigations in this field were carried out nor required.

2.1.3. Metal impurities. Metal fittings are one of the main barriers that prevent the reuse and recycling of waste wood, as such impurities can considerably damage wood working machinery, if they remain undetected. All timber sections have therefore been examined by means of simple metal detectors to identify any kind of metal impurity, which have then been removed by means of hand tools (Figure 2).

2.1.4. Strength grading. CDW timber has to be strength graded according to harmonised standards [5], [6], [7] and national grading rules. On-site inspections have been carried out by an expert to categorise the timber, measure available sections and identify the extend of decay, defects and damages. Based on these results, timber sections have been sorted and separated on site for further reprocessing and strength grading. All impurities (paints, coatings etc.) were removed to obtain clean raw material that was cut and planed into rectangular cross sections. As access to a drying chamber could not be established, timber was not technically dried so that the average moisture level of 20% required for strength grading was not always achieved.

Figure 1. Timber for recycling

Figure 2. Metal detection

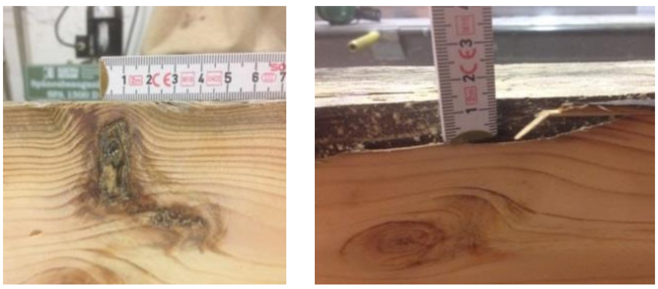

Figure 3. Strength grading: assessment of defects, decays, cracks and dimensions, location + orientation of branches

The actual strength grading process was carried out on cleaned timber sections, which were assessed with regards to dimensions and location of cracks, branches and slope of grain (Figure 3). Classification according to DIN 4074-1:2012 [8] into the relevant sorting classes led in turn to the respective strength class according to EN 338:2016 [9]. Additional requirements for lamellas, designated for glued laminated timber, regulated in superior standards were applied during production [7]. Lamellas were then used for the production of timber beams and columns as well as thresholds, plates and studs for non-load bearing façade elements.

3. Design concepts

3.1. Load bearing timber beams and columns

The general design for load bearing timber elements for the bearing structure of the building complies with EN 14080:2013 [7] and follows the principal of glulam timber, where single lamellas are joined together. Glueless connections of single lamellas have also been investigated but will not be elaborated in this study. The design concept pursues the idea of maximisation and optimization of usable sections from waste wood, which is illustrated in Figure 4.

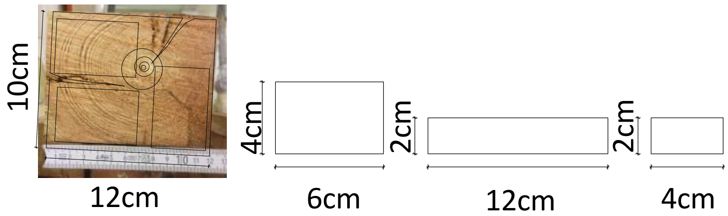

Figure 4. Possible division of salvaged timber sections

For the construction of the elements, cracks have been cut away from salvaged sections and obtained dimensions were assessed for suitable use in beams and columns. Initial trials have been undertaken and lamellas of 4/6/12 cm x 4 cm have been joined with glue in vertical and horizontal direction. (Figure 5 - Figure 7).

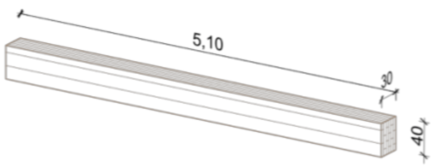

Figure 5. Design concept for glulam timber beam from CDW timber

Figure 6. Glulam beam

Figure 7. Glulam timber beam, with lamellas joined in vertical and horizontal direction

3.2. Non-load bearing, prefabricated timber façade elements

The design concept for a prefabricated, reversible, rear ventilated façade element made from CDW timber proposes a non-load bearing timber frame construction. A self-supporting stud system is covered either side with stiffening wood fibre boards. In certain load cases a wood fibre hardboard might structurally be required to replace the wood fibreboard on the inside. The panel is insulated with a blow in insulation, based on recycled timber flakes or fibres. The weatherboards are fixed with screws to a batten and counter batten system to enable future dismantling. An earthen plaster made from recycled aggregate is applied as final finish to the interior, to provide a healthy and comfortable interior climate. All connections are either screwed or plugged as carpenter connections. Figure 8 shows the general design concept for the prefabricated timber façade element and illustrates the single components.

Similar as for beams and columns, the general design aims to minimise material usage. In addition, the concept follows the approach of a cascading use and looks into opportunities for using cut offs from reprocessing and manufacturing for production of other components that are part of the element. Exemplary investigations regarding source material (Figure 9) and possible outcome (Figure 10) after cutting have been carried out on planks, which were the main source for the production of the façade element. At first, the plank was cleaned and planed. In a second step, required sections for structural members were cut to size. As a result, different usable sections, various cut offs, shaves and sawdust were obtained. Table 1 provides an overview about the different sections and provides details regarding dimensions and final amounts. Larger sections were used for the structural parts of the element (threshold, plate, stud), whereas smaller sections were applied as weatherboards. It is intended to use cut offs and sawdust for the production of stiffening boards (wood fibre hardboard) and wood chips or shavings as insulation material. Smaller cut offs shall be separated further for production of wood fibreboards. For the time being, commercial products have been used for such components.

Figure 8. Design concept for timber element, Model: 1:20

Figure 9. Source material (plank)

Figure 10. Outcome of usable material

Once the element has reached its end of life, single components can be reprocessed and recycled. Weatherboards can be dismantled, planed to remove decayed parts and further processed for the use of wood chips, suitable for the production of chip boards or wood fibre boards or insulation. All structural parts offer similar potential for a timber cascade.

Table 1. Outcome of usable material after cleaning and cutting

Piece	Length in dm	Width in dm	Height in dm	Vol. in dm^3	Vol. in %
Total	**32.9**	**2.35**	**0.558**	**43.14**	**100**

Sawdust	**25 liters / 1.74 kg**			**4.61**	**10**

For material efficient studs, different design concepts have been developed (Figure 12 - Figure 14). A supporting framework allows the optimised use of different timber sections obtained from processing CDW timber. Dimensions and layout of the single lamellas are set out according to static calculations but consider sizes of salvaged cross sections and possible divisions (Figure 11). For thresholds and plates massive sections were produced.

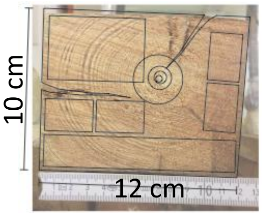

Figure 11. Salvaged cross section, division for material optimised studs

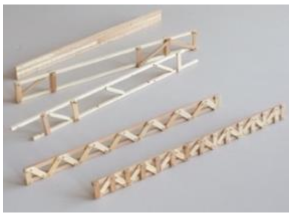

Figure 12. Models of material efficient studs

Figure 13. Framework studs, battens with different or same sizes, assembled eccentrically

Figure 14. Framework stud, different sized battens, assembled centrically

For the final production of the panel, the structural components (threshold, plate and studs) have been assembled to a frame, based on the standard grid for timber construction. The frame has then been covered with the wood fibre hardboard, to provide the required stiffness for the element. As a next step, wood fibreboards and blow in insulation have been applied in parallel (Figure 15 - Figure 16). Finally, weatherboards have been fixed to a support structure of battens and counter battens (Figure 17). The CDW earthen plaster will be applied on site. Reversible connections have been provided by means of screws and metal brackets. In a next step, it is intended to apply timber in timber connections where possible, to minimise metal fasteners.

Figure 15. Timber frame with studs, incorporation of blow in-insulation

Figure 17. Weather shell

3.3. Reversible connections

Reversible connections at component and element level but also within elements are key to enable the reuse and recycling of building parts. Investigations at component and element level have been carried out. Different timber in timber connections (carpenter connections) or metal ones have been tested. For corner connections of the frame (façade element), initial tests have been conducted (Figure 18 - Figure 19). For connection of structural components, commercial solutions have been taken into consideration, that offer viable options (Figure 20 - Figure 21).

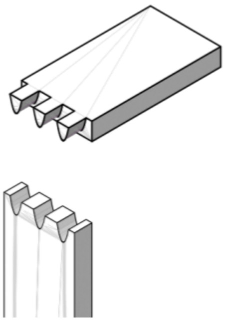

Figure 18. Carpenter connection (dovetail)

Figure 19. Screwed connection facade element

Figure 20. Bolted connection column - foundation

Figure 21. Reversible joist hanger (© Sherpa)

3.4. *Design concept for reversible buildings*

The design concept for a reversible building focuses on the lifespan of various building elements and enables meaningful divisions so that elements demonstrating a significantly shorter lifespan can relatively easy be maintained or exchanged. In addition, a high level of flexibility, decent ceiling heights and opportunities for adaptation shall generally increase the service life of a building (Figure 22). Although building elements are modular, they offer variation in size and shall be designed in such way that they can easily be dismantled and reused in future applications. In addition, they follow the concept of material purity or allow for easy dismantling so that different components can be separated and reused or recycled if necessary [10]. Additionally, the use of high quality materials shall further increase the durability as well as the lifespan of the component and therefor also the building.

The design proposal suggests a timber skeleton support structure with reversible connections in combination with a stiffening core and a wooden non-load bearing façade system (Figure 22). All elements and components are made out of CDW timber. The column system offers the highest level of flexibility when it comes to adaptation of floor layouts (Figure 23). The non-load bearing facade system allows for a complete exchange of the elements, once they have reached their end of life or in case of a use change of the building requires a different configuration. Reversible connections, still under investigation, are planned for all connections. It is anticipated that they can either be realised as carpenter connections or through reversible, metal fasteners or connections.

Figure 23. Skeleton system with stiffening core

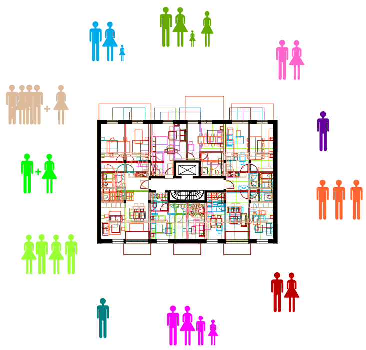

Figure 24. Adaptable floor layouts offer a high level of flexibility

4. Results and discussion

4.1. *Prerequisites*

On-site inspections have proved to be an appropriate strategy to identify whether existing timber structures might be suitable for a direct reuse or recycling. Although, strength grading according to standard has been carried out on cleaned timber sections, initial on-site assessments delivered reliable results regarding the general structural capacity of the installed timber components and elements.

Furthermore, it could be established through firm lab testing that not all constructions were treated with wood preservatives so that salvaged timber could be directly reused. On-site investigations were also suitable for the assessment of timber regarding insect and fungi infestation. Furthermore, it could be proved by means of simple metal detectors that all metal impurities were identified. The final strength class of the assessed timber achieved either C16 or C24, which is suitable for the development of structural timber elements.

4.2. Material and design concept for load bearing timber elements

The material and design concept for load bearing timber beams and columns could successfully be implemented. Material efficient construction could be achieved through application of standardised sizes for lamellas. Cracks and branches were cut off without major losses of material. Although not tested in the lab, industrial finger joints enable the incorporation of shorter sections. The use of glue for connection of single lamellas has proven to be very time and cost efficient and delivers frictional connections also for waste wood. As developed elements can be classified according to DIN 68800 as use class 0, the application of wood preservatives is not required [11].

4.3. Material and design concept for non-load bearing, prefabricated timber façade elements

The concept for a cascading use of timber for facade element seems very promising. The overall material that could be recycled from processed planks summed up to approx. 90 %. Nail plates would have to be removed to bring sections covered with metal back into the material cycle. Although only solid sections have been manufactured so far, the usage of cut offs for production of other components seems a viable solution. The industry is following this concept already, although with fresh wood. The concept for material efficient studs delivered also promising results. However, this approach was more time consuming in comparison to the production of solid ones. Encouragingly enough, the production of the final element was entirely carried out with hand machinery. Similar to beams and columns, the façade element can be classified according to DIN 68800 as use class 0, due to special constructive measures, set out in [11]. Therefore, the application of wood preservatives is not required. The environmental benefit regarding the reduction of environmental impact due to the reuse and recycling is currently under investigation.

4.4. Reversible connections

Initial studies were only carried out at lab scale. However, both concepts, timber in timber but also metal connections are suitable to enable reversible connections at component but also element level. Carpenter connections were more time consuming due to the lack of appropriate machinery. Additional studies and testing are required, to investigate and deliver solutions for the various different applications. However, results so far enabled the complete dismantling of elements and components.

4.5. Design concept for reversible buildings

Although the developed concept needs to be approved in real application, skeleton systems are well known for a greater level of flexibility. Also, the separation of elements according to their life spans seems to deliver viable and long-lasting buildings. The use of timber in construction offers generally much higher potential for reversible buildings in comparison to massive construction. The material is much lighter and enables dry connections. Furthermore, the concept of material purity is easier to achieve for structural elements as timber is able to take compressive, tensile and shear loads.

Regarding the service life of the single elements that have been developed, it is expected that the use of waste wood that grew under less harmful environmental impacts in comparison to today increases the lifespan of the single elements and therefore of the entire building. This however has to be verified through further investigations.

5. Conclusions and recommendations

5.1. Prerequisites

Investigating aged timber, different factors have to be taken into account. The state of conservation, dismantling damages, and previous load condition can have an influence on the load capacity of the timber. Since the 1950's different research projects established that the influence of aging can be neglected if the state of conservation and other impurities are surveyed carefully [12].

The use of standardized cross sections can help to avoid storage costs and increase the market acceptance for salvaged timber. Finger joints make the recycling of CDW timber very attractive as defects can be cut out and shorter pieces can be finger jointed into an endless lamella that in turn can be cut into the required length.

Today, visual strength grading can be assisted by machines, which can lead to a better yield in higher strength classes. Traditionally grading machines work by bending the timber and assessing the stiffness. Today machine grading also includes technologies as flexural resonant frequency, x-ray measurements and ultrasonic wave speed.

To address the issue of wood preservatives, a kind of rapid on-site test would be desirable, as sampling and lab analysis is costly and time intensive. The Fraunhofer Institute developed a prototype for an on-site measurement device, which could be an opportunity to upgrade the classification of wood from demolition sites [13].

5.2. Material and design concept for load bearing and non-load bearing timber elements

The high level of CDW timber that could be integrated into all components and elements demonstrates the enormous potential of this approach for minimisation of both, CDW generation but also resource consumption. However, unless holistic costs for construction and deconstruction are imposed or incentives for more sustainable solutions are granted, such solutions will experience difficulties to enter the highly economically driven market.

5.3. Reversible connections

Reversible connections based on metal fittings are not common in modern timber construction to date. Without modern industrial trimming machines, carpenter connections are economically not viable. However, if circular construction becomes mandatory, suitable solution shall be implemented relatively easy.

5.4. Design concept for reversible buildings

New material and construction concepts must be developed to enable the adaptation of buildings. In addition, today's planning process of new timber structures needs to take possible disassembly and reuse into account. Reversible connections, most often more expensive, are key for the success of such concepts. The growing digitalisation and increased use of Building Information Modelling (BIM) may support the implementation of circular construction. Especially in timber construction 3D modelling is a common approach. Engaged component producers and suppliers in the aftermarket of products offering e.g. take-back systems for construction left-overs and possibly end-of use products, upgrades and repairs services etc. could support the reuse of building elements. However, without governmental interventions, attempts for circular construction might remain at pilot level.

Abstract. The growing scarcity of resources calls for a paradigm shift from linear material consumption to circular economy – especially in the construction industry. This shift involves a complete rethinking of design principles, materials, construction technics and technologies, as well as the introduction of new business models evolving from these reconfigurations within the field. This paper will show on-going research on these themes with a focus on direct material re-use and recycling through the discussion of a prototypology – the recently concluded Mehr.WERT.Pavillon (MWP) at the BUGA 2019 in Heilbronn. The research specifically addresses a reversible, mono-material structure that is made from re-used structural steel and recycled glass. The concept of cycles therefor is significant: Utilized materials are not consumed and disposed of; instead, they are borrowed from their material cycle for a certain period of time and later returned there at equal value and utility. Sourced from recycled materials, the prototypology is a built example of urban mining; designed for disassembly at the end of its service time, it also represents a material banks for future projects – while proofing the claim, that it is possible already today to build within a circular system.

1. Introduction: towards a closed-loop building industry

A transition from the currently still dominantly linear economic system towards the Circular Economy (CE) is widely accepted as essential for the implementation of global commitments taken by the European Union (EU) and its Member States, notably the U.N. 2030 Agenda for Sustainable Development and the G7 Alliance on Resource Efficiency [1]. The most-widely accepted characterization of the concept has been framed in 2013 (and revised in 2015) by the Ellen MacArthur Foundation: "A circular economy is one that is restorative and regenerative by design and aims to keep products, components, and materials at their highest utility and value at all times, distinguishing between technical and biological cycles" [2]. On December 2nd, 2015, the EU adopted the Circular Economy Action Plan [3] aiming to develop and implement a regulatory framework for the shift towards the CE in its single markets, as well as send clear signals and provide concrete actions to be carried out before 2020. The plan addresses four phases (production, consumption, waste management and closing of loops) in several priority areas of high impact – one of them being Construction and Demolition. Within the union, the building sector represents one of the biggest consumers of raw materials and one of the biggest producers of waste and emissions: construction and use of buildings account for about half of all extracted materials and energy consumption as well as about a third of water consumption and waste production [4]. Article 11.2 of the Waste Framework Directive (WFD) stipulates that "Member States shall take the necessary measures designed to achieve that by 2020, the preparing for re-use, recycling and other material recovery (...) of non-hazardous construction and demolition waste excluding naturally occurring material (...) shall be increased to a minimum of 70 % by weight" [5].

This EU-wide mandatory target however includes (in the majority) down-cycling and backfilling operations using waste to substitute other materials – procedures that do not fulfil the requirements of the above-mentioned characterization of a CE, where materials or components circulate at their highest utility and value. Consequently, increased efforts have to be spent on direct and high-value re-use and recycling processes in the building industry in order to realize a true shift from linear to circular economy. The article at hand describes an exemplary case study building – a prototypology for the circular building industry (section 2) – and its re-use and recycling (section 3) related steps and decisions in regard to design, construction, structure and permit process for two selected material categories (section 4). A discussion on future work (section 5) and conclusions (section 6) are provided in the end.

2. Prototypology: *Mehr.WERT.Pavillon* at BUGA 2019

Joined from the terms *prototype* and *typology*, the prototypology represents a full-scale building, that is experiment and proof in itself to effectively and holistically discover connected aspects and unknowns of a specific question. Yet, at the same time, it is part of bigger, and systematic test series of different such types with similar characteristics, yet varying parameters [6].

The 2019 German Federal Garden Show (BUGA) in Heilbronn is both garden and city exhibition. The newly built city quarter *Neckarboden* is intended to be a test bed for new urban development scenarios concentrating on highest living standards and qualities for a socially diverse population group within a densely populated central urban setting [7]. Economic and ecologic aspects are foregrounded. Within this context, it was found necessary and relevant to implement a new thinking about resource application, leaving the present linear take-make-throw mentality behind [8].

Situated on a central lot of the BUGA terrain, the *Mehr.WERT.Garten* (translation: *Added.VALUE. Garden*) and its pavilion address the question how we can perform a paradigm shift in the way we use our resources towards a CE of closed and pure material cycles. The *Mehr.WERT.Pavillon* (MWP) is the shell, as well as main element of this exhibition on local and global resource use, alternative materials as well as their applications in circular design and construction. On the one hand, the pavilion makes use of the existing urban mine: all materials used in the project have already undergone at least one life cycle, either in the same or in a different physiognomy. On the other hand, it acts as a material depot, which will become available and productive again for future constructions at the end of the exhibition: Materials utilized in the construction of MWP are specified and employed in a way that allows their complete re-introduction into pure and type-sorted material cycles for re-use, recycling or bio-degradation after the decommissioning and deconstruction of the building. The pavilion's objective is to proof that it is possible already today to design, detail and construct according to the principles of the CE [9].

Figure 1. View of The Mehr.WERT.Pavillon

Figure 2. View of the façade from the inside

The pavilion's building materials are separated into four groups: (1) the load-bearing structure is largely made from re-used steel originating from a disused coal-fired power plant in north-western Germany. It consists of four inclined supports that fan out like tree branches and are connected to each other by a rigid steel frame structure. (2) The façades and roof are clad in panels manufactured from recycled bottles glass and industrial glass waste. (3) The furniture is built from recycled HDPE plastic waste, while the chairs are 3D printed from plastic household waste. (4) The floor of the pavilion as well as the landscape design of the garden forms an assemblage of various re-used and recycled materials and products made from mineral construction and demolition waste (Figures 1-2).

MWP serves as a laboratory and test run for future construction projects as well as building processes. The aim is to discuss important issues of construction and the associated use of resources with decision-makers from politics, construction planning and implementation and to develop new innovative concepts, applications and methods from these, both in practice and in teaching. Therefore, it is all the more important to note that the concept of MWP originated in a student design studio by the Professorship of Sustainable Construction at the Karlsruhe Institute of Technology [10].

3. Re-use and recycling in construction

The WFD defines waste quite broadly as 'any substance or object which the holder discards or intends or is required to discard' [5], whereby this action can be both intentional or unintentional / involuntary / accidental and neither commercial value nor storage location of the substance or object have an influence on the waste status. Article 4 of WFD introduced a legally binding 5-step hierarchy of waste management operations, which member states must apply in the following order: (1) prevention, (2) preparing for re-use, (3) recycling, (4) other recovery, and (5) disposal [5]. Technically, *prevention* is not a waste management operation, as both quantitative as well as qualitative waste prevention concern substances or objects before they become waste. Obligations under waste management legislation consequently do not apply. This important distinction also applies to *re-use*, defined as 'any operation by which products or components that are not waste are used again for the same purpose for which they were conceived'.

Steps 2-5 together comprise *waste treatment*. Steps 2-4 are defined as *recovery*, where 'the principal result of a recovery operation is waste serving a useful purpose by replacing other materials'. In contrast, step 5 is negatively defined as their opposite: *disposal* includes all operations that are not recovery. Recovery is divided into three sub-categories: preparing for re-use, recycling, and other recovery. *Preparing for re-use* includes all 'checking, cleaning or repairing recovery operations, by which waste, products or components of products (…) can be re-used without any other pre-processing'. *Recycling* on the other hand is defined as 'any recovery operation by which waste materials are reprocessed into products, materials or substances whether for the original or other purposes'. This includes any physical, chemical or biological treatment creating material, which no longer is considered as waste – as long as it closes the economic material circle. Consequently, operations that reprocess materials for fuels or backfilling activities are excluded from recycling and represent *other recovery* – as long as the primary purpose of the treatment still is the substitution of other materials rather than the elimination of waste [11].

Within the EU, construction and demolition waste (CDW) is the single biggest waste stream (by weight): In 2014, CDW accounted for 33.5% of EU waste or 871 million tonnes [12]. This total mass consists of several different material groups such as concrete, bricks, gypsum, wood, glass, metals, plastic, solvents and excavated soil - many of which have a (high) re-use or recycling potential [13]. In fact, most EU countries already today report a recovery rate of CDW above the mandatory 70% target, which applies to the above described steps 2-4 of the waste hierarchy, including material recovery however (contrary to the WFD definition) excluding energy recovery.

Unfortunately, the reported data is still based on varying waste and reporting definitions in separate Member States, which makes comparison and interpretation difficult. It is however very clear that the reported recovery rates always include a high percentage of operations that do not fulfil the criteria of closed material cycles in the CE, where materials, components and products should be kept at their highest utility and value at all times. In terms of the waste hierarchy, only step 2 at the moment satisfies these criteria, while step 3 would need to exclude any downcycling processes, which in a CE understanding belong to the category of other recovery. Steps 4 and 5 both represent economical, ecological and socio-cultural losses and are to be prevented, remaining within above described hierarchy of steps. A possible definition for recycling within the CE could be: any recovery operation by which waste materials are reprocessed into products, materials or substances *of equal or better purity in fractions* whether for the original or other purposes. Within waste treatment, preparing for re-use remains the favourable operation as it conserves embodied energy, water and knowledge while reducing the need for re-processing and associated emissions.

In all cases it is essential that a material, component or product achieves the end-of-waste (EoW) status after undergoing a recovery operation and thus falls outside the scope of waste legislation before beginning its next life cycle application. In regard to the aspired paradigm shift towards the CE, ideally however materials, components or products never fall into the scope of waste legislation in the first place. Various CE-concepts such as *Design for Disassembly* [9], *Product as Service* [14] or *Extended Producer Liability* [15] aim to prevent the intention, the need or the interest in discarding substances or objects by ensuring their utility and value of a closed-loop application at all times.

Annex I of EU Construction Product Regulation (CPR) summarizes a list of basic requirements for construction works, whereby paragraph 7 addresses issues of sustainable resource use. 'The construction works must be designed, built and demolished in such a way that the use of natural resources is sustainable and in particular ensure the following: (a) re-use and recyclability of the construction works, their materials and parts after demolition; (b) durability of the construction works; and (c) use of environmentally compatible raw and secondary materials in the construction works' [16]. Written in 2011, this document lays down important principles of the CE for construction as described above – unfortunately by now not a single Member State has transformed Annex I into national law, keeping CPR at the status of a non-binding recommendation.

3.1. *German legislation on re-use and recycling*

The case study MWP is located in Heilbronn, Germany. Additionally to EU regulations, it is thus necessary to consider German waste and construction legislation when re-using and recycling materials or products within this specific setting. The German definition of waste can be found in the 2012 Waste Management Act (Kreislaufwirtschaftsgesetz), which transposes WFD into national law. However, there are no national legislative instruments governing the requirements for the recycling of mineral waste or for the use of recycled building materials or spare building materials so far, as these are within the competence of federal state legislation [17].

Because of these legal differences, the Federal Ministry for the Environment, Nature Conservation, and Nuclear Safety (BMU) started working on an overarching national legal framework for ground water, substitute building materials, landfill and soil protection, the so called Mantelverordnung already in 2006. So far, unfortunately no approved version exists, but a 2017 version by the Federal Cabinet includes a new Substitute Building Materials Ordinance (Ersatzbaustoffverordnung), which aims to provide legal certainty with uniform national requirements that apply when discharging substances into groundwater, when constructing engineering structures with the use of mineral substitute building materials, and when backfilling with soil material [18].

One key element of the ordinance is its EoW definition (after extensive testing and documentation) of recovered wastes as a product with specific classes and specifications, e.g. RC-1 for recycling materials or BM-0 for soil materials, allowing their direct application in high value applications [19]. At the current state, application of recycling materials continues to be based on case-by-case approval, where materials certified and approved by an accredited laboratory in one state might not be applicable in the other 15 federal states. Section 4.2 explains the procedure based on a product from recycling glass for application in Baden-Württemberg.

In regard to re-use, legislation makes no distinction between use phases. Re-used products or materials need to be able to comply with the standards of DIN or EN norms in respect to e.g.

structural, fire, health or other specification. The problem here is that most of the times no producer or owner will certify these as the manufacturer of virgin products or materials does. Also, missing documentation on origin as well as treatment during use phases makes this step additionally difficult. As a result, often extensive testing is necessary to specify material or product properties before re-using them. Section 4.1 explains this procedure based on structural steel for Baden-Württemberg.

4. Structural application of re-used and recycled materials on the example of MWP

In general, materials used in construction are subject to numerous national standards and regulations. When used in load bearing elements, however, the demands are particularly high. The approval of a material for a structural application requires strict quality assurance during its production. In addition, it also requires a comprehensive investigation of its mechanical and physical properties as well as the knowledge of its behaviour in different load situations and climatic conditions. In Germany, structural applications must comply either with national building standards or a general technical approval (Allgemeine bauaufsichtliche Zulassung), which corresponds to a European technical approval for construction type and construction product. If there are no such corresponding approvals for the material, an exception can be obtained for the type of construction and construction product in the form of a so-called *approval in individual cases* (Zustimmung im Einzelfall - ZiE). This ZiE is approved by the building authority of the respective federal state. However, its validity is limited only to the specific construction project for which it was requested.

4.1. *Re-used structural steel*

Due to economic incentives, the recycling of steel scrap has been well established for a long time "without any need for stimulation or subsidy. The recycling rate is 88%" [20]. The direct re-use of structural steel, on the other hand, is currently practiced only to a minor extent with a re-use rate of 11%. In addition to a careful dismantling from the building stock here the knowledge of the material quality (classification) and the previous use is required. It must be determined what imperfections and damage to the disassembled element exist after its use. Furthermore, the nature and frequency of the previous stress situations may be relevant. The re-use of steel elements still has a high development potential, "the biggest challenge here is quality control" [20].

As mentioned, the steel structure of the MWP largely consists of steel tubes that were dismantled from a disused power plant. In addition to an exact visual inspection to determine any possible damage of the elements, the steel was examined for various properties. Tests on tensile strength, elasticity, notched impact strength (Table 1) and chemical composition (Table 2) made it possible to draw the necessary conclusions regarding the material quality. The steel quality proofed to be equal to that of standard structural steel (S235JR or S235J2), which allowed the direct re-use of the elements in a new structure.

Table 1. Test results of notched bar impact tests according to DIN EN ISO 148-1.

	length [mm]	width [mm]	thickness [mm]	consumed impact energy [J]
Dimensions of each specimen	55.0	10.0	5.0	
Average of all samples				67.7

Table 2. Test results of the chemical analysis.

	C	Mn	P	S	Cu
Requirements S235 DIN EN 10025-2	≤ 0.17	≤ 1.40	≤ 0.035	≤ 0.035	≤ 0.55
Maximum of all samples	0.16	0.70	0.006	0.014	0.20

4.2. *Recycled glass products*

The use of glass in structural applications in Germany is governed by national standards (DIN 18008 Glass in Building). However, the standards only apply to the use of certain approved glass products. The panes from recycled glass used for the MWP are not covered by such product approval. Although technical approvals exist for certain building applications in facades, these differ from the type of use in the MWP. For this reason, applying for a ZiE for the use of recycled glass products in the MWP was essential. The application was based on the specifications of the existing glass standard and the stress analysis was carried out following the standard's design philosophy respectively. The ultimate stresses determined by standardized tests carried out by independent, accredited test laboratories provided the basic data for design stresses. In accordance with the glass standard, an additional mechanical safety measure was applied below the linearly mounted glass panes of the pavilion's roof through a close-meshed steel net. In addition, the manufacturer was obliged to issue a declaration of conformity for the quality control of the production by means of standardized mechanical tests.

5. Conclusions

MWP proofs the feasibility of re-used and recycled materials in structural applications within a full-scale prototypology. However, as described above, the process of planning and building according to CE principles currently still shows many administrative, financial, legislative and physiological hurdles which need to be reduced quickly in order to allow a paradigm shift. Common hurdles to recycling and re-using CDW in the EU are the lack of confidence in the quality of recycled materials, missing documentation on material composition and history, a mismatch of supply and demand (both qualitative and quantitative), insufficient time allocation for audits and deconstruction works, a lack of facilities and expertise and the often low value of high quantity products. There is also uncertainty about the potential health risk for workers both deconstructing and using recycled materials. This lack of confidence reduces and restricts the demand for recycled materials, which inhibits the development of waste management and recycling infrastructures in the EU [21]. Analysing these hurdles, many of the mentioned restriction can be addressed through increased and better documentation and declaration/ certification measures.

5.1. *Material documentation*

The built environment represents a massive stock of material resources, which is in most cases unfortunately undocumented and unspecified. Even though much research is currently undertaken towards the development of material passports or cadastres [22], the status quo of building construction still continues undocumented. In order to prevent the costly and timely steps of section 4 and allow a circular use of materials and products, it is essential that we begin detailed libraries of materials, their specifications, dimensions, locations, connections, durability, and treatment over the time of use, regarding all buildings as material depots for future constructions [9]. Material documentation is equally essential for both recycling and re-use, whereby in the first case a focus is placed on the exact chemical composition of the material and toxicity, while the second case requires a focus on a detailed history of the materials' or products' life. Both cases require detailed information on the necessary steps in disassembly to return to pure-type material cycles. Additionally, material documentation can significantly reduce building costs if done properly and consistently [23].

5.2. *Product declarations*

The level of building products offers an additional chance for increased documentation through extended product declarations. Especially on EU level, much research efforts are invested into the development of harmonized Environmental Product Declaration (EPD) or Product Environmental Footprint (PEF) which not only include the above mentioned data points but additionally a description and Life Cycle Analysis (LCA) calculation of the products' recycling potential (module D) [24]. Such information can help steer decision makers and designers in their material and product selection towards elements, which are designed for re-use and recycling in closed material loops, as long as they are also applied according to CE design and construction principles. Integrating such information into Building Information Modelling (BIM) could offer a possible tool for the communication and documentation of material and product specifications, in connection to their location and disassembly guidelines.

6. Acknowledgements

The authors would like to acknowledge all partners in the development and realization of Mehr.WERT.Pavillon, specifically the Entsorgungsbetriebe der Stadt Heilbronn, Ministerium für Umwelt, Klima und Energiewirtschaft Baden-Württemberg and Bundesgartenschau Heilbronn 2019 GmbH; the academic design team Lisa Krämer, Simon Sommer, Philipp Staab, Sophie Welter, Katna Wiese, and Fachgebiet Nachhaltiges Bauen KIT Karlsruhe; Prof. Rosemarie Wagner KIT Karlsruhe; Prof. Matthias Pfeifer, Karlsruhe; 2hs Architekten und Ingenieur PartGmbB; all participating industry partners: AMF Theaterbauten GmbH, Deutsche Foamglas GmbH, Glas Trösch GmbH, GrünRaum GmbH, Hagedorn GmbH, Heinrich Feeß GmbH & Co. Abstract. The first signs of considering green infrastructure in the process of urban planning appeared long before WWII with the developments of Chicago and Paris, for example, in the late 19th century. In order to relieve the increasingly crowded centres of fast-growing cities, the afforestation of public spaces and the creation of more liveable existing spaces became increasingly important; this includes the development and renovation of parks and water surfaces to adapt to urban needs and requirements, making the development of urban green infrastructure more important than in the past. Over time, green infrastructure developments grew more detailed and complex; since the end of the 20th century, they have become one of the most important goals of urban development, focusing on the environment and healthy living conditions. In the early stages of project development, the needs of urban residents and the active utilisation of green areas are factors of growing importance; refining design and construction has also become a more intricate process. Significant changes to the original style of plans has taken place over the past decades, evolving with the needs of the era and technological advances, requiring suitable action to maintain pace with enhanced developments.

1. Introduction

The increase in city dwellers and the expansion of urban areas has been an accelerating process since the industrial revolution. The development of urban habitation was most significant in the twentieth century. In 1900 there were 16 cities with over 1 million inhabitants (Montgomery et al. 2003), and in 2010 this number grew to 449 as a result of the continuous urbanisation process. These changes in urban development are mainly due to social and economic transitions that have occurred in the last 150 years. The dimension of urbanised areas has also grown immensely (Seto et al. 2014; UN 2018), due to the population increase in cities. New socio-economic factors have recently brought about novel urban patterns usually put under the term polycentric development (Clark 2003). As a result, the structure of suburban areas has changed (new industrial, logistic and residential areas have been erected within a very short time), and thus new forms and functions – mainly due to digitalisation and post-Fordist economic transformation – have appeared.

Suburban areas usually occupy territories with traditional green belts around cities, resulting in enormous and contiguous urban areas; this increases both the territorial dimensions of urbanised areas and the diameter of urban heat islands. In fact, the Urban Heat Island (UHI) (Unger 1999), is one of the most important challenges to address. An urban heat island is traditionally defined as closed isotherms that delineate an area warmer than its surroundings (Unger et al. 2010; Voogt and Oke 1997). UHI is a complex result of various interrelated phenomena (Unger et al. 2000). Among many, one cause of the urban heat island is global warming, which has steadily accelerated in past decades; however, disappearance and lack of surfaces with cooling effects due to expansion of built areas and new trends in urban design are among the key factors. The effects of an urban heat island become particularly unbearable in summer when heat stress occurs. Besides this, a related index contains significant by measurements of UHI with satellite imagery - this is the NDVI (Normalised Difference Vegetation Index) (Chen et al. 2006; Dezso et al. 2005; Owen, Carlson, and Gillies 1998).
There are many other concerns in urban areas. First, cities usually have a great deal of sealed surfaces which enable quick stormwater runoff, causing severe problems such as infrastructure overload, quick evaporation, and a low albedo. According to Oke (Oke 1987), cities tend to have an albedo 5-10 per cent lower than the surrounding rural areas. Second, from a social perspective, traffic is believed to be a major, if not the biggest, source of stress in our lives. (APS 2008). Third, those living in less developed neighbourhoods are particularly vulnerable, as they have limited access to good quality green areas and housing estates tend to be of poorer technical conditions. Finally, and importantly, urbanisation has a negative effect on biodiversity (McKinney 2006).

2. Aims of research

The aim of this paper is to collect and analyse the processes that lead to successful green infrastructure development in the cities of London, Copenhagen, Budapest and Graz. The hypothesis posits that success lies not only in the coherence and consistency of plans, but also in governance that ensures the implementation of community priorities. To underline this, an investigation of strategic plans, governance and participation projects was conducted. The intention is to find differences and similarities on how the four cities are reacting to the drastic changes of recent decades, such as the ongoing urbanisation process and climate issues described above.
The main driver of this study was to check the effectiveness of different approaches towards green infrastructure planning and highlight those planning and governance tools that led to success in the past.

3. Methodology

In order to analyse the current situation of green space development, a multi-method approach was used. This was mainly carried out by literature research (studying documents, webpages and other grey literature). For this, operative and valid plans of the investigated municipalities and linked organisations were analysed. Aside from plans, policy implementations in each city were examined, which gave a rough impression on the process of green space management; however, local characteristics could also be understood through examining the green and nature-based projects of linked third parties and non-governmental organisations. A society's sensitivity can be also measured through bottom-up projects not directly initiated or funded by the local authority and not linked to official processes. Civic engagement into municipal decision-making processes is an issue not only in planning activities but also in managing green spaces. Based on these understandings and through the literature review, a framework of key factors for success in green development was constructed. For a graphic organising and explaining these factors, see *Figure 1,* below.

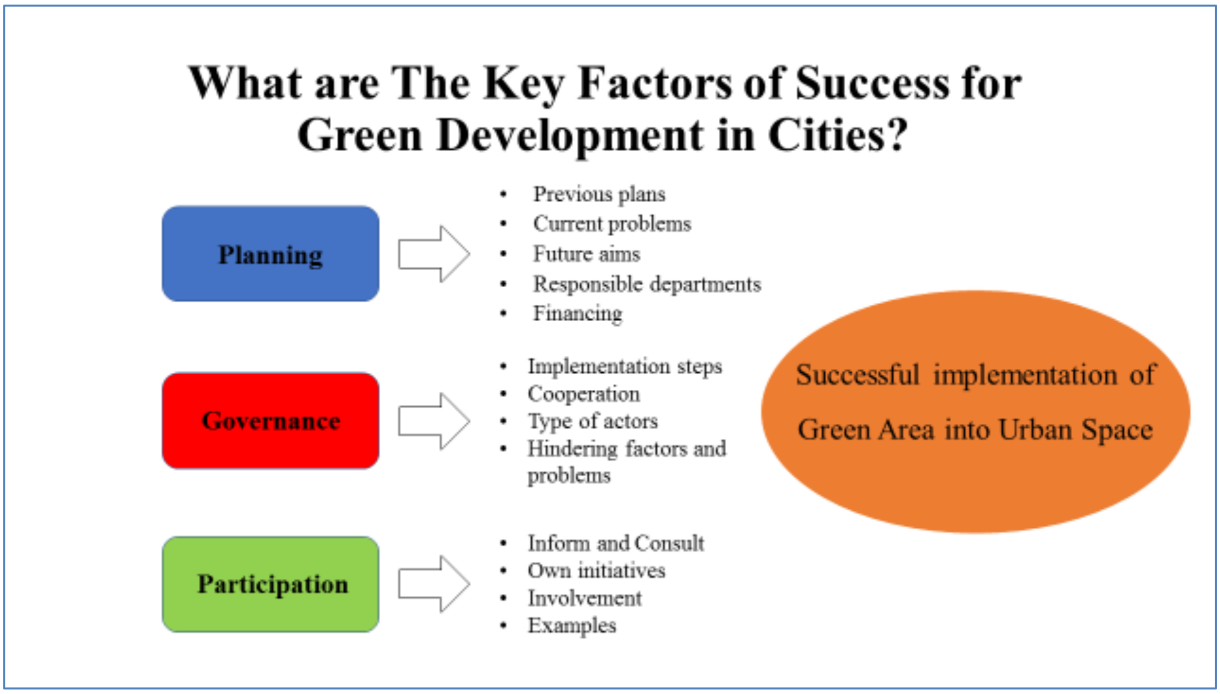

Figure 1: Key Factors of Success for Green Development in Cities; Developed by Jennifer Tempfli

Given these factors, comprehensive interviews were conducted with partners involved specifically in green infrastructure planning within municipalities. From the four selected cities, tow partners answered; therefore, the Greater London Authority and the Green Office of the 12th District of Budapest were approached. During the interviews we focused on the following topics:

- What is the main political motivation towards nature-conscious or green infrastructure planning?
- What is the governmental background of green planning at the municipality?
- What is the financial background of plans?
- Which types of actors are involved and to what extent do they have a hand in the planning process?
- To what extent can residents participate in programs and how successful is this involvement?
- Are there any issues that hinder or cause problems in the participatory process?

4. Understanding the planning context

To understand the context of green infrastructure planning, differences and similarities in planning must be highlighted. Europe has a long history of urban planning that differs due to the varied history, culture, economics and social development of the countries. We can distinguish four different planning traditions according to the literature (European Commission 1997; Newman and Thornley 1996; Williams 1984). The four traditions originated from different countries; however, during the European integration of planning systems, they have become widespread and a country's planning is surely influenced by more than one approach. *Figure 2* highlights the four distinct traditions and the countries that utilise them. We will explain the various plans in the context of our focus cities in greater detail below.

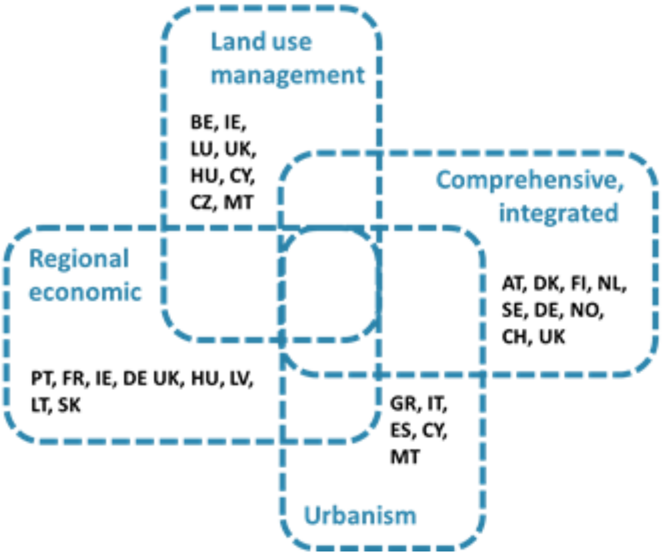

Figure 2. The four planning traditions of Europe. (Salamin 2018)

London represents the ***land use management*** approach, which emphasises the regulation of changing land-use by utilising strategic and local plans. This approach focuses on the management of physical space by applying urban planning tools as regulations. In this respect, green infrastructure planning is a basic and well-used tool to influence land use. Green infrastructure planning exists on multiple scales: regional (for example, Abercrombie's *Greater London Plan,* 1944), local and object scales (where the share of green space is defined when giving a planning permit). One should also not forget the importance of neighbourhood planning in the UK, in which Ebenizer Howard left an influential legacy (Howard, 1902).

Copenhagen's Fingerplan is one of the most famous urban plans in Europe and has been a success story due to its easy-to-understand metaphor: using a human hand to cover urban patterns (Vejre, Primdahl, and Brandt 2007). The Finger plan was established in 1947 and emphasises that Danish planning systems are characterised by a ***comprehensive integrated*** approach, a Dutch tradition that involves the various tools of space-shaping. The focus lies in the spatial effects of policies and the coordination of actors and sectors; further, vertical and horizontal coordination is highly important.

Austrian planning is also based on a ***comprehensive integrated*** approach. Spatial planning is the autonomous responsibility of the states, but the plans are only binding for state administration and public administration at the lower levels. Municipalities and cities have autonomy in local planning. They have enacted three plans: Local Development Programme, a strategy plan determining the needs of communities; the Zoning Plan, defining the types of use for different spaces; and the Development Plan, which defines the requirements of buildings on a plot-scale.

Hungarian planning is nearest to the ***land-use management*** approach. However, in Hungary, physical spatial planning is very much divided from urban development planning. This duality is well represented in the fact that physical land-use planning and building control activities are regulated, but urban development activities are not well defined. Green infrastructure planning usually is represented in conceptual planning. Deficiencies occur because overall concepts should be broken down into smaller levels and scales of decision-making. Recently, many small-scale green projects have been implemented; however, it is still difficult to integrate plans to achieve connectivity of green spaces through the city. Regarding Budapest, the capital city (also an independent municipality) is divided to 23 district local authorities. This leads to multiple problems, especially in green infrastructure management.

4.1. Historical overview

London and Copenhagen were the first pioneers in terms of urban green planning in Europe in the 19th and 20th centuries, respectively. More space for better provisions and infrastructural function were among the main concerns, as huge growth in the city's population was expected in the coming years. London`s first attempts towards a green planning were made in 1829 when the "Breathing Places Plan" by John Loudon was published (Johnson, 2012). He was initiating a tenfold expansion of the city and planned on implementing infrastructure for water, gas, fresh air and removal of filth, while planning alternate rings of green space around London. This was pursued later in Abercrombie and Forshaw`s County of London Plan (Forshaw &; Abercrombie, 1943), which focused on the quality of green spaces, their separation from industries and the cultural relationship. These plans are considered the cornerstone of London`s green space development. London's Green belt came to existence in 1955 and the whole planning of the city was aligned with the concept.

A similar approach is represented in Copenhagen`s Finger plan. The Finger plan was established in 1947 (Cervero 1998), and aimed mainly to manage a mass of commuters in the area and provide suitable places for industrial and commercial activities. Today, the master plan affects over 30 municipalities in the metropolitan area of Copenhagen. The importance of the Finger plan in green space network development is that the plan designated the areas between the "fingers" as green spaces, preserving them from urban sprawl, creating well-defined green corridors around the city. The finger plan concept was later adapted by Helsinki and Stockholm. Looking at the development of the last years, we can see a clear focus of the city's policies. The aim is to enable people to stay in public places and use them for a multitude of activities. But also, the green spaces should be liveable and accessible for tourists and residents. Future needs of modern businesses must also be considered. Copenhagen puts a big emphasis on the disassembling of open spaces and its accessibility for people. Copenhagen even received the Green City award in 2014. The city's overall aim is to combine natural and urban development to impact people's well-being on a long-term basis.

In 1989 a regime change took place in Hungary, and this shift from the previous socialist regime led to big changes in the country. Urban areas were in want of green space and Budapest itself was densely built without equally distributed open spaces. The city offers great potential in restructuring brownfield areas that are located throughout the city, especially in a ring around its eastern parts (Kocsis, 2015). The utilisation of these places promises to transform regions partly used for green spaces and would, at the very least, integrate green infrastructure. Research has been done on this topic, and first attempts at implementation are already occurring. Other potentials can be found in widening river fronts or improving parks. Further, existing parks located in the city centre can be rearranged or provided with other functions that contribute to the greening of the city. Similar measures were part of local plans in several districts of Budapest, in an effort by local authorities to address the greening of the city. But also, several policies were set up by the capital municipality to make Budapest more adaptable to address the issues of urban heat island, climate change and lowering greenhouse emissions. Since one solution for these problems is to integrate green spaces, there is a large focus in this area.

Looking at Graz, we see parallels in the development of cities and green areas over time, but these areas were not planned in the same extent as in the other cities. The central green are of historical significance and are still the most important and frequently used nowadays (Hlawka, 1990). The city of Graz also has developed several campaigns for greening the city, while supporting other campaigns with similar aims. The city relies on already existing resources and green areas, with attempts to improve or reclaim them. The aim is to bring green areas closer to the citizens and develop an average area of 3 -10 square metres per person.

4.2. Governance

Although development policies initiated by city councils are usually based on green development, other actors should not be discounted, as they can have a large influence. Recent changes in development policy have raised. Especially the last years made a change in rising the awareness on environmental problems like air pollution, and the involvement of other actors besides city councils can better address these concerns.

Governance is successful if the different levels of decision-making, planning and implementation are harmonised. While the governance of green infrastructure developments can be coordinated at city level, so individual projects can be harmonized to multiply the effectiveness of this process. All cities seek the best solutions and good practices, but conscious development requires a lot of time.

For example, in London, the Greater London Authority (GLA) is mostly responsible for the key planning. In order to increase their impact, the Authority frequently exchanges and collaborates with London's boroughs and other non-profit organisations. Since subsidies for green infrastructure projects have increased in recent years, it is important to find applicable solutions to problems related to green infrastructure and flood management. Also, we see that economic players have a larger role in green infrastructure development; these are players willing to invest in green development based on individual aims of companies and the results of cost-benefit analyses. Additionally, housing association owners that invest money into measures like green roofs in order to profit from rising rent prices, fall into this category.

Emanating from London`s example, we see that all four cities use extensive concepts and policies. Since it is not always possible to reach project aims with city plans alone, due to city size and growth, other actors need to be involved. These actors deepen involvement and help accomplish district-based initiatives and smaller project-focused plans through increased cooperation.

4.3. Participation

In recent years, several public engagement projects are partly cooperating with or financed by municipalities or other non-profit organisations. It is possible to see similar developments, in terms of public engagement, that are independent from countries or cities. These developments focus on initiatives like urban gardening, addressing environmental issues, but also contribute to the well-being of residents, as we can see in the 'Guardianship Programme' ('gondnokság program'), established by the Municipality of the 12th District in Budapest. The programme allows residents to take part in replanting and taking care of self-chosen green spaces in the district. The municipality develops a plan to manage these areas and provides tools and assistance in cooperation with professional gardeners. The challenge that the Green Office of the district has faced was to provide enough incentives to make people participate in these programmes. Changes have been made in the concept has changed since its first introduction, and it now aims at offering more transparency about the whole project and mediating between the municipality and the needs and goals of residents. In general, municipalities tend to focus on the improvement of ecological concerns, whereas residents are more inclined to focus on the enhancement of social well-being.

Besides, movements like urban garden initiatives have arisen in past years in many cities. Topics like air pollution and concerns about urban heat islands have been gaining weight and presence in urban discourses. These concerns may be different and dependent on local resources and circumstances, but we still see increasing environmental awareness in society as a whole. As a result, people are more willing to take part in planning decisions. The number of private-led initiatives and collaborations in this vein are accumulating.

An example of a city-led campaign that involves the public relates to front-garden culture in Graz. It attempts to enthuse people to take part in revitalising these private areas with monetary incentives. Also, the project "Jacky_Cool_Jack" originated in the city. This project aims to override the urban heat islands in the Jakomini district, an area which lacks green infrastructure and spaces.

Table I. shows a selection of interesting projects from the cities where public engagement was essential.

City	Name of campaign	Aim
London	London Environmental Network	Supporting local Non-profit and community groups with an environmental focus
	Capital Growth	Supporting people to grow food in London, whether at home, on allotments or as part of a community group.
	Skip Garden at King`s Cross	A community garden that uses recycled materials and connects people of all ages and backgrounds
	Urban Farms in London	Urban Farms that make a positive impact on the environment and social well-being. Connecting people and creating communities
	South West London Environment Network (SWLEN)	Focus on preserving green spaces and biodiversity, promoting sustainability and supporting environmental groups
	Urban Bees	Encourage people and businesses to plant more pollinator-friendly trees and flowers
Graz	Bürgerinitiative für die Erhaltung von Grünflächen	Preserve south Graz from industrialisation. Make the area more liveable, improve the air quality and calm traffic pollution
	Mehr Zeit für Graz. Themengruppe Grün- und Stadtentwicklung	Preservation existing and safeguarding new urban green areas
	Several Urban Gardening Projects	Projects that are establishing urban gardens
	Förderung urbanen Begrünung	Promotion of urban greening like urban gardens, green roofs or walls
Budapest	Revitalization of Mátyás square	An initiative of the 8^{th} District of Budapest, which involved local people to plan and plant the open space of the square in a deprived area. Social security improved and the neighbourhood developed a lot through the project.
	Zöldfelület Gondnokság Program	Improve the green space in the 12^{th} District of Budapest (Hegyvidék) district with involving residents in the fostering process
	Revitalization of Teleki square	Transform the till then decrepit parc into a public parc with residents' participation. The project has an important social aspect. (8^{th} District of Budapest)
	Közösségi Kertek	Inform people about climate change and processes that harm the cities environment. Creation of about 30 urban gardens
Copenhagen	Urban Beekeepers of Copenhagen	Possibility to host hives and join events and skill training in return
	DYRK Nørrebro	Urban Farming Initiative in Copenhagen to expand vegetable cultivation. Focus on sustainability with the intention "think globally and acting local"
	GivRum	Facilitation of user-driven urban development with local communities. Social mobility and activation of local resources, people and stakeholder is intended.
	Outdoor Council	Request to spend more time in the nature and improve the circumstances and frame conditions for this
	KlimaKvarter Østerbro	Turn the neighbourhood into the greenest inner-city area and integration urban spaces, courtyards, buildings, streets and the neighbourhood within this

Table I. An overview of important participation projects in the four cities.

5. Results

Our analysis shows that **coherence of consistency plans** is an important part of the implementation of green space development. These plans are the cornerstones of implementation. We also need to consider that most plans were formulated around the beginning of the 20th century. As such, the whole process of green space implementation was more focused on architectural, and in some cases symbolic, values and concerns. This was minting infrastructural development, primarily. These plans were developed on a more objective basis due to geographical location and other circumstances.
As a result of the social and economic changes of the past centuries, the **planning process** has become more complex and involves more actors and fields than ever before. City councils are limited in different ways, such as lack of monetary support or other constraints; therefore, the complexity of social and economic situations requires that other methods and measures be found to ensure the integration of green areas into the urban infrastructure. This makes the involvement of other actors necessary in the entirety of the planning process. The question is: Are all affected people profiting in an appropriate way and have a say in the planning process?
In order to successfully introduce new structures, other local stakeholders or residents should be involved in the **participation process, especially in the case of small-scale projects**. The focus here lies on discovering and considering all the needs and interests that will influence the effectiveness of the implementation of the programmes. Moreover, people tend to favour such actions and take more care of the result if they feel their needs and interests are met. Transparency of all steps in the process is crucial to gain participation and acceptance for all involved actors.
From an interferential point of view, one must draw attention to the fact that cooperation has gained much weight in past years. Practice of green space planning is to incorporate, and make essential part of, cooperation and combined efforts of stakeholders and local actors. For a good implementation, the right communication with transparency is important, since the size of cities and the dissimilarities and distinct characteristics between districts, for example, may create a big difference.
A novel phenomenon of recent years is the connection of green infrastructure and climate issues in planning. In the past, green areas were more preferred in residential quarters mostly due to aesthetic values, but nowadays the positive effects in abating negative effects (e.g. heat in summer and cold in winter, dust and noise) have been realised, and thus green infrastructure has become an acknowledged measure in urban planning against climate issues.

Abstract. The Urbanocene, a proposed new geological epoch characterized by the urban living condition, is pressing the humanity to respond shortly to important challenges. Cities are at the same time the places where we live in and the big dissipators of the final energy to the environment. The simultaneous rules of heat dissipator and place to live are quite contradictory, because of the increasing temperatures of the dissipator surfaces, phenomenon known as Urban Heat Island (UHI). Mediterranean climates should suffer, in the next years, changes in the thermal needs of buildings and in the outdoor comfort sensations. A change in the energy demand from heating to cooling is probable and overheating reduction could be a priority in the future. Many mitigation strategies of UHI are being discussed in these years, such as the city greening, the use of cool materials for roofs and soils, the reduction of automobile dependence, the shift to new urban morphologies. In this paper an evaluation of impacts of different possible strategies is done, by using computational simulations for various sectors of Rome and Valparaiso. Results show the importance of greening and traffic reduction to achieve better comfort; while to reduce building energy consumption changes in urban morphology and traffic are suggested as the best strategies.

1. Introduction

The domain of our specie on the planet has been continuously rising since we appear on the Earth. Today, the concept of Anthropocene is being proposed as a new geological epoch (and even as a new stratigraphic epoch [1]). Besides geological discussion on the appropriateness of the concept, one of the characteristics of the last 1.000 years has been the urban condition of the humans, and this condition is growing so fast since the "great acceleration" times that some scientist propose the name "Urbanocene" as an alternative to "Anthropocene" [2]. One of the specific aspects of living in cities is that such adaptive complex system has the behavior of a dissipative structure [3]. So, cities are the places where most of the humans live; the places where most of the final energy is consumed; and the most important: the places where the heat that results by all these energy transformations is dissipated to the environment. The phenomenon is known as Urban Heat Island and has been investigated since the 19th Century, but it was formalized under an energetic point of view recently at the end of the 20th Century [4-5]. Recent studies underlined the possible impact of UHI on the cooling needs of buildings

[6-7] and on the summer outdoor comfort [8]. Even the interrelationship between extreme events (heat waves) and UHI has been assessed [9]. Advancing in urban climate studies, many models and methodologies to estimate temperature and other environmental parameters variations in urban conditions have been developed [10]. Specifically focusing on UHI, one of the validated tools that is being used to generate weather files is the Urban Weather Generator [11]. This tool couples an atmospheric model whit a building simulation model to generate a weather file useful to conduct building energy simulation considering the UHI effect.

2. Methodology

In this paper the Urban Weather Generator tool is used to obtain urban weather data to be used in comfort and building energy simulations. Four cases of study are explored, two in the city of Rome, Italy and two in Valparaiso, Chile. Comfort evaluations have been done using PMV calculator [12], while building energy simulations have been carried out using the TRNSYS tool (version17). Then, three possible mitigation strategies (greening the cities, reducing traffic, and changing pavements and roofs materials) have been tested to obtain the improvement in outdoor comfort and the reduction of cooling needs generated by each and combining all.

2.1. Cases of study

Rome (lat. 41.54 N, long. 12.29 E) and Valparaiso (lat. 33.02 S, long. 71.36 O) are both placed in Mediterranean climatic context, whit dry hot summer and cold wet winter. Koppen climate classification for both cities is Csa (a climate that is present in the Mediterranean area, in Chile, in California and in some parts of Australia and South Afica). Such climates present some sensitivities to climate change and to urban heat island phenomenon [13]. Cities' morphologies are different: Valparaiso is smaller than Rome and it is placed on the coast, while Rome locates about 20 km far from the Sea. Mediterranean Sea and Pacific Ocean have also a very different impact on urban microclimate: the Humboldt Current is cooling both air and water of the Chilean coast much more than the Mediterranean Sea currents could do in the case of the coast close to Rome. Orography presents some similarities: both cities have many small mountains that obviously influenced the urban planning. In Rome two sectors have been selected for this analysis, one corresponding to the center of the city (Tridente) and other corresponding to a residential neighbor close to the center (Prati). In Valparaiso, the selected sectors are the city center (Center), with its system of places, and a residential neighbor sparsely built (Recreo). Figures 1 and 2 shows both cities and their sectors selected for analysis.

2.2. Urban weather and building energy simulation

Urban Weather Generator is a tool developed at MIT. The tool couples an atmospheric model and a building performance simulator to obtain modified urban weather files from a base rural weather file. Many information is needed by the tool to conduct simulations, however some of the most sensitive parameters are: the anthropogenic heat production, the morphology parameters (built up area, façade ratio, average building height, green areas) and the material properties (albedo and emissivity) of streets, walls and roofs [14-15]. Table 2 resumes the parameters used in UWG simulations for the four cases. Building energy simulations have been carried out using the TRNSYS tool (version17). A five stories building is used as test building, E-W oriented, with windows representing a 27% of the main façades. Each story is divided in four apartments of 50 m^2. Table 1 resumes parameters used in BES.

Table 1: Building Simulation Parameters

U wall (W/m^2K)	U roof (W/m^2K)	U floor (W/m^2K)	Infiltration (h^{-1})	Glazed surface main façade (%)	Occupancy (people)	Gains ($W7m^2$)	Cooling set point (ºC)
2.15	0.57	1.88	0.7	27	2	5	26

Vegetation coverage (%)	48			

2.3. Outdoor comfort evaluation

Comfort evaluations have been done using PMV method initially proposed by Fanger and then developed by many authors. Please notice that actually PMV is not the most appropriated method to assess outdoor comfort, as noticed by many authors that proposed alternative adaptive evaluations [16-17]. However, the obtention of a value for the body stress generated by gains or losses of heat, is correct in both indoor and outdoor conditions. It is only the thermal sensation vote that changes, influenced by phycological expectations, culture and adaptation. We take PMV results just as indicative of a theorical situation that in reality could be felt as a little more comfortable because of adaptation. The estimations have been done without considering short wave radiation, this means, always on shadow. The variables considered are: metabolism, clothing, air temperature, relative humidity, wind velocity and mean radiant temperature. MRT was assessed as the average weighted by view factors of surfaces temperatures of the urban environment (walls and pavements). View factors are representative of a person placed close to one of the building walls on shadow.

2.4. Improvements

Considered possible improvements that should be done in order to build adaptive capacity and mitigate urban heat island are:

- Increasing the green areas of neighbours in a 100% respect to actuality
- Changing the materials of pavements and roofs for selective cool materials
- Reducing anthropogenic heat generation by cars in a 50%

To test the impact of each improvement on thermal comfort and cooling needs in summer period, a new set of UWG simulations is done, changing the respective parameters. In the case of city greening the "vegetation coverage" and the "trees coverage" parameter are changed UWG. In the case of the pavements and roofs, "albedo" parameters for urban streets are changed in UWG and "albedo" parameters for roof are changed in TRNSYS. In the case of anthropogenic heat, "sensible heat" is changed in UWG.

3. Results and discussion

3.1. Comfort

Table 3 resumes the environmental parameters (air velocity, relative humidity, air temperature and mean radiant temperature) used in the PMV evaluation for the case of Rome. Metabolic activity was set to 2 met (116 W/m^2) and the mechanic efficiency of the human body is considered 50%. Respect to clothing, thermal resistance of the clothes is set to 0.5 Clo and the clothes factor is set to 1.15. As stated in the methodology section, the evaluation is done without consider direct radiation from the Sun. Wind velocity value was approximated to 0.5 m/s for the rural case and 0.2 m/s for the urban.

Table 3: PMV parameters, Rome

	Rural Rome	Prati	Tridente	Prati green	Tridente green	Parti 50% traffic	Tridente 50% traffic	Prati cool pavement	Tridente cool pavement	Prati combined	Tridente combined
V (m/s)	0.5	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2
Hr (%)	45	40	38	41	40	40	38	40	40	41	40
T (ºC)	28	30	31	29.5	29.8	29.9	30.9	30	31	29.3	30.8
Tmr (ºC)	30	32	33	28	29.5	29.9	32.9	31	32	27	28.3

Figure 3 shows the results in terms of PMV and PPD. It can be observed that the rural outdoor comfort evaluation leads to an acceptable situation, very close to thermal neutrality and with a PPD of 5%. Urban conditions are worse, with a PMV value close to 1 (slightly warm) and a PPD of 20-25% depending on specific urban environment. Proposed improvements combined permits to reach an intermediate situation (PMV 0.6-0.7 and PPD 11-15%). The best improvement is obtained by increase the green (trees) surface of a 100%.

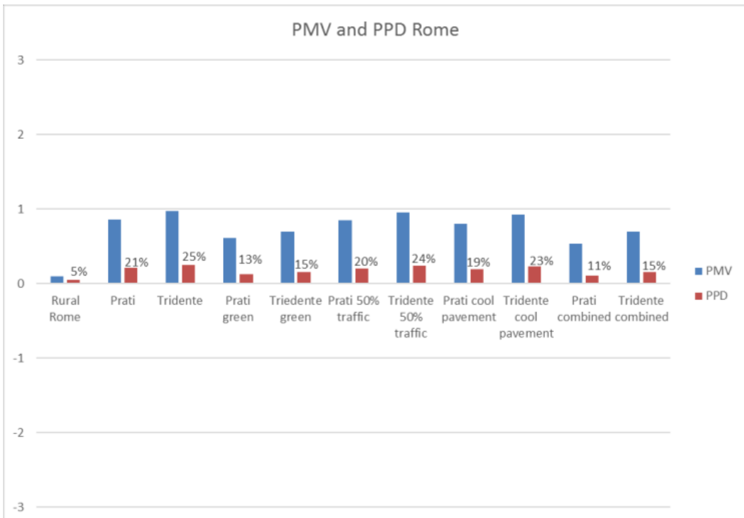

Figure 3: PMV and PPD, Rome

Table 4 resumes the same parameter for Valparaíso. The same metabolism and clothing of the Rome case are used. Because of the city emplacement, on the Pacific Ocean, air speed is considered 1 m/s in the rural case and 0.5 m/s in the urban configurations.

Table 4: PMV parameters, Valparaíso

	Rural Valparaíso	Centre	Recreo	Centre green	Recreo green	Centre 50% traffic	Recreo 50% traffic	Centre cool pavement	Recreo cool pavement	Centre combined	Recreo combined
V (m/s)	1	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5	0.5
Hr (%)	30	28	28	29	29	28	28	28	28	29	29
T (ºC)	33	34	33.5	33.5	33	33.9	33.4	34	33.5	33.3	32.8
Tmr (ºC)	34	37	35.5	35	30	36	32	36	34.5	34	29

Figure 4 shows the PMV and PPD values obtained. Comfort situation seems to be a little more difficult to be reached in this case. However, the green improvement is again the best strategy between tested improvements.

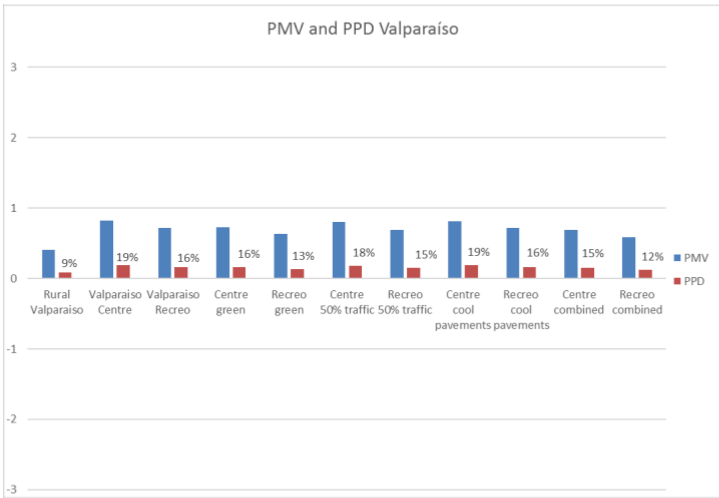

Figure 4: PMV and PPD, Valparaíso

3.2. Cooling needs

Figures 5 and 6 show the cooling needs across the year for Rome and Valparaíso. It can be observed that if Valparaíso has maximum values of temperature higher than Rome (as detected for the comfort analysis), this case has also lower temperatures during the nights, leading to a total cooling need quite lower than the case of Rome. The effect of city morphology (density and façades) is detected as the most important factor in the case of Rome. In Valparaíso, the increase in height of building of the Centre is counteracted by the reduction in density respect to Recreo case. Cool pavements and roofs are suggested as the best strategy to reduce cooling needs in both cases, but especially in Valparaiso.

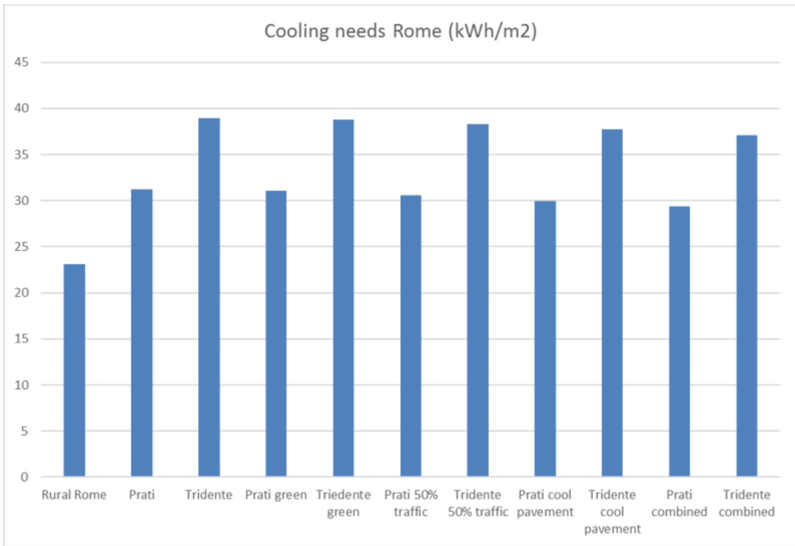

Figure 5: cooling needs, Rome

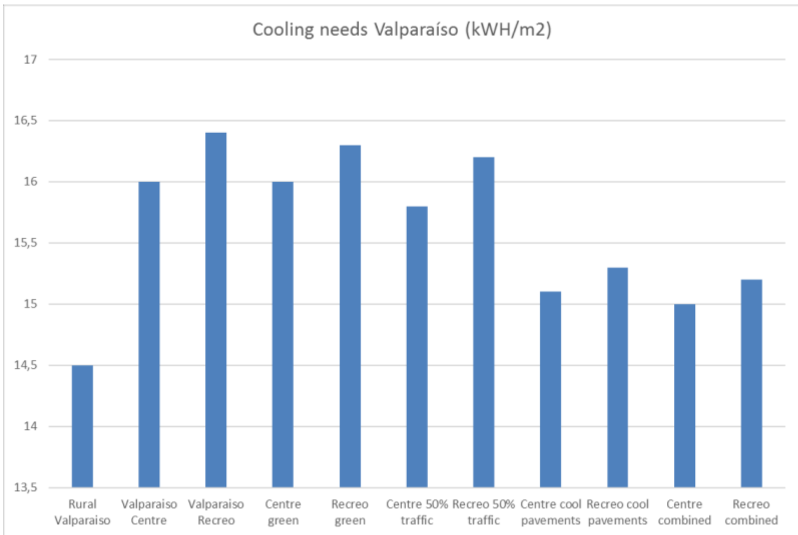

Figure 6: cooling needs, Valparaíso

4. Conclusion

This paper analyzed comfort and cooling implications of the urban environment in Mediterranean climates, by studying the cases of Rome, Italy and Valparaíso, Chile. Results show that the impact of urbanization is important both on outdoor comfort than on cooling needs. A set of mitigation strategies has been tested, suggesting that greening the city is the best strategy to improve outdoor habitability, while using cool selective materials on the pavements and (especially) roofs the total cooling need could be reduced up to the 40%. Research limitations suggest also that the effect of traffic reduction and city greening could be in reality more than detected in this study. If a more exhaustive comfort evaluation would be done, including direct Sun radiation, it is very probable that the use of trees should evidence an impact on psychological perceived temperature of more than the difference between “neutrality” and “slightly warm” detected by approximate PMV analysis. Respect to traffic, this is a very local condition. The average impact on the urban area is clearly reduced. However, outdoor comfort close to a busy street would be probably influenced mainly by the quantity of cars present. Future studies should be addressed to these observations. Cooling analysis can also be improved. In this paper, only the UHI effect has been considered replacing the “base” weather file with a “urban” weather file generated by UWG. Recent studies [18-19] put in evidence that also shadows, infra-red environment and wind distribution changes have to be included in analysis. However, the impact of city morphology and materials is a fact that has been stated clearly [20]. In any case, further research on the calibration of BES including urban climate effects is needed

Abstract. The use of Life Cycle Assessment (LCA) during the design phase can help to improve the environmental performance of buildings. However, designers and clients find it difficult to set environmental performance targets and interpret the results obtained through LCA in order to improve the building design. Therefore, performance levels or benchmarks are needed that provide design guidance towards reducing the environmental impacts of buildings in the life cycle. This paper uses a dual benchmark approach. The main concept consists in combining building-related top-down targets with building component-related bottom-up benchmarks. The overall top-down targets per capita and year are derived from the capacity of the global eco system. The bottom-up benchmarks for building elements are calculated following a best-in-class (top 5%) approach. A workflow of applying these benchmarks is proposed. It provides guidance on how to optimize the environmental performance of a building and its components efficiently by differentiating between material and design-related options. The approach is exemplified by means of a case study of a multi-family house.

1. Introduction

Until now, the efforts to reduce greenhouse gas (GHG) emissions in the building sector mainly focused on the use phase of buildings. Due to the achievements in reducing the operational energy demand, amongst other reasons, researchers have turned to other fields to investigate additional saving potentials. An important aspect are the so-called embodied GHG emissions related to the manufacturing of construction products and to the construction, maintenance and end of life of buildings. Early design decisions largely determine the environmental performance of the building [1] for the next 50 to 100 years. Therefore, designers are key actors for reducing global GHG emissions during the life cycle of individual buildings. Life Cycle Assessment (LCA) is a suitable method for evaluating the building's environmental performance, however, currently, designers often find it difficult to interpret the LCA results and use them to improve the building design. The importance of environmental benchmarks has been recognized early [2]. There is a demand for benchmarks on GHG emissions in the different phases of the building's life cycle that serve as an orientation for designers [3]. Therefore, benchmarks should provide design guidance from the beginning of the design. A number of software to facilitate LCA for designers has been published in the last years, e.g. Tally [4], oneClickLCA [5], Athena [6], or CAALA [7]. However, they do not provide benchmarks that indicate the potential for improvement during the design.

The goal of this paper is to propose the application of LCA-based benchmarks in the design process to support the reduction of the environmental impact of buildings - mainly through the choice of construction type and materials.

2. Method

This paper uses a *dual benchmark approach,* developed by the authors and described in detail in [8]. The main concept consists in combining top-down targets with bottom-up benchmarks. The top-down targets per capita and year are derived from the capacity of the global eco system. The bottom-up benchmarks for building elements are calculated following a best-in-class (top 5%) approach. In this paper, the overall target of 1 t CO_2-e per capita and year by the year 2050 is used to define a top-down target. According to the Swiss 2000 Watt society [9], but also according to the German Environment Agency [10], this value is sufficient to achieve "climate neutrality". The target values as defined in SIA 2040 [11] are employed, however, they are adapted to meet the global target of 1 t CO_2-e/(c·a). To describe the potential impact on climate change the indicator Global Warming Potential 100 (GWP) expressed in kg CO_2-equivalent as defined by IPCC [12] is used. The target values per capita and year for the domain of housing in Switzerland are shown in Table 1.

Table 1. Target values for GWP per capita and year for the domain of housing in Switzerland based on SIA2040 and adapted to the global target of 1 t CO_2-e per capita and year

	GWP [kg CO_2-e/(c·a)]
Embodied (including manufacturing, replacement and end of life)	270
Operation (building-related part)	90
Total	360

The bottom-up reference values for building elements are defined based on a statistical best-in-class approach (top 5%) using the market share of different construction products. The minimum, weighted mean and target values are shown in Table 2. The target values are based on 1 m^2 of surface area of the individual building element. Only the target values for columns are given per m length. Target values for technical equipment are provided per floor area of energy reference area (A_E), which corresponds to the gross floor area of the heated building zones.

Table 2. Minimum, weighted mean and target values (0.05 quantile) for GWP for the building elements for Swiss multi-family houses

Building element	Sample size	Reference unit (unit)	GWP [kg CO_2-e/(unit·a)] Minimum	W. mean	Target (0.05)
1. Base slab	80	$m^2_{element}$	1.32	2.23	1.87
2. Exterior walls underground	3	$m^2_{element}$	3.52	3.72	3.35
3. Exterior walls aboveground	404	$m^2_{element}$	0.82	2.11	1.37
4. Windows	16	$m^2_{element}$	1.49	3.16	1.85
5. Interior walls	35	$m^2_{element}$	0.59	1.28	0.82
6. Partition walls	30	$m^2_{element}$	0.58	1.05	0.83
7. Columns	7	m	0.43	2.01	0.64
8. Ceilings	1260	$m^2_{element}$	0.66	2.24	1.37
9. Balconies	4	$m^2_{element}$	1.2	1.48	1.13
10. Roof	273	$m^2_{element}$	0.79	4.05	2.32
11. Technical equipment*	29	m^2_{AE}	1.18	-	1.18*

* Due to a small number of solutions in the building component catalogue, no benchmark is calculated, but the minimum is used. The target value is the sum of minimum values for electric equipment, heat generation, heat distribution and delivery, ventilation equipment and water (sanitary) equipment of residential buildings.

The dual benchmark approach allows distinguishing between the different available options to reduce the embodied environmental impact of a building, namely the choice of type of construction/material and the design. Clearly, the choice of material is part of the design, however, in this context, both aspects are analysed separately. Design options refer to the shape and size of the building, but also the organization of floor plans or the window to wall ratio. Further aspects, such as the building's adaptability to react to changes in the use phase as well as building components' ability to be deconstructed and recycled are excluded here, but could be added in the future. Finally, the aim in the design phase should be reducing the environmental impact of the building holistically, including the operational part. There are many approaches for energy-efficient design described in the literature, see Energy Manual [13], for example. Here, the focus is therefore on the embodied part.

The proposed workflow of using the dual benchmark approach in the design process is visualized in Figure 1. EN 15643-1 [14] explicitly states that targets for the environmental performance shall be defined among others. Therefore, the workflow proposes to first calculate the environmental performance target based on the top-down benchmark. Then the environmental impact of the initial building design is calculated and compared to the top-down target. The impact of the individual building elements is calculated and compared to the bottom-up benchmarks to indicate the material-related optimization potential. If the selected "material/type of construction"-solution for an element is not within the top 5% of one or more assessment criteria – in this case the GWP, it is recommended to modify the material/type of construction and redo the analysis. There are exceptional cases where a specific material or type of construction cannot be changed due to other characteristics needed, e.g. fire or earthquake resistance. If the chosen solution is within the top 5% of a specific assessment criteria, the improvement potential is considered as small. In this case, it is assumed that the most efficient way to reduce the embodied impact is through design changes. For example, the compactness of the building can be increased, or the floor plans can be modified to decrease the built area. The change of the design has many consequences on other architectural and functional aspects, for example daylight availability and energy demand for lighting. These have to be considered, but are not within the scope of this paper. The aim of dividing between specific material/construction-type-related and overall design-related options is to provide guidance for environmental performance optimization of the building and its components. The proposed workflow is exemplified by means of a case study.

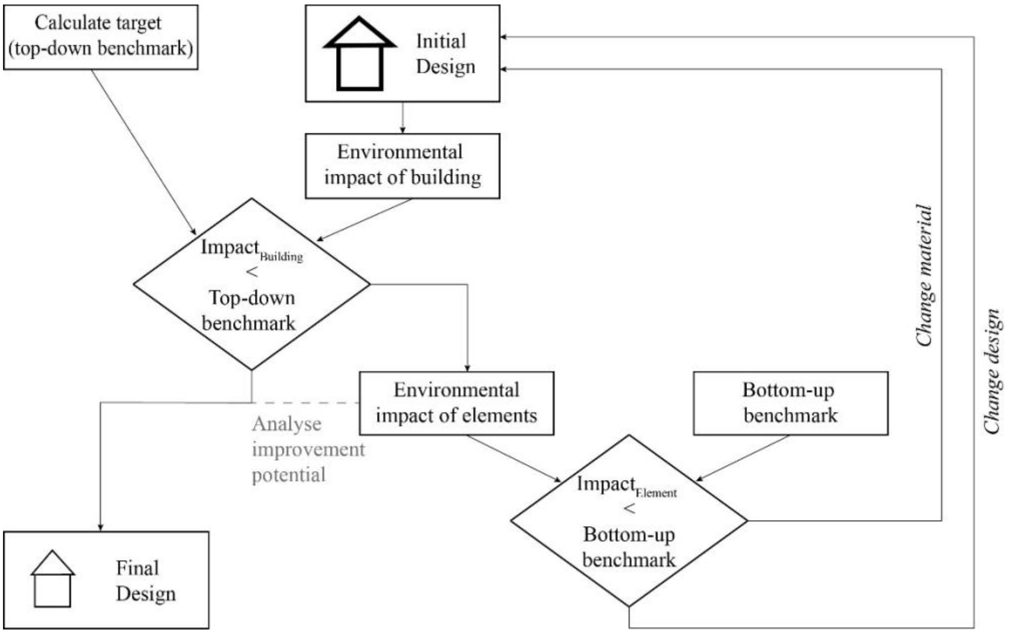

Figure 1. Flow chart of applying the dual benchmark approach in the design process

3. Case Study

To show the application of the benchmarks and validate the applicability of the proposed method, an existing building in Hamburg, Germany, called "Woodcube" is used as a case study. The reference study period is 60 years. The focus lies on analysing the embodied and the overall life cycle-related GWP and a comparison with the benchmarks. The operational GWP is calculated to provide the value in relation to the embodied part. Some small modifications to the geometry of the original building were made for simplification [15]. All material properties are taken from a published LCA report [16]. The quantities of the individual building components, respectively the areas of the building elements are taken off from a simplified 3D model, see Figure 2.

Figure 2. Left Woodcube (photo Hollberg), right simplified 3D model of the building

The assessment of the embodied impact for buildings in Switzerland is regulated in the standard SIA 2032 [17], which is currently revised and updated. The standard defines which building elements have to be included in the assessment. It refers to the elements defined in the Swiss standard for building cost regulation SN 506 500 [18] "Baukostenplan Hochbau" (BKP-H). In Switzerland, a building component catalogue [19] provides GWP factors for typical building components. It is based on the national Swiss database *KBOB Ökobilanzen im Baubereich* [20]. The building elements with the respective areas and related building components from the building component catalogue are listed in

Table 3. The GWP factors are provided including manufacturing (life cycle modules A1-A3 according to EN 15978 [21]) and end-of-life (modules C3 and C4). The values are provided per year taking the reference service life of the component declared in SIA 2032 [17] into account. When the values are multiplied with the reference study period of 60 years for residential buildings in Switzerland, the replacement (module B4) is implicitly considered.

Table 3. GWP factors per year and per m² of element area from the building component catalogue organized along Swiss BKP-H structure

Building element	Area [m²]	Component according to BKP-H	Code / ID	Component name according to catalogue	GWP [kg CO_2-e/(m^2·a)]
1. Foundation	228.0	C1 Base slab, foundation	C1 003	Flat foundation 5 or 6 storeys, Steel content 90 kg/m3, 35 cm	1.679
		G2 Floor covering	-	none	0.000
2. Exterior walls under ground	183.0	C2.1A Exterior wall under ground	C2.1A 029	Reinforced concrete wall, 20cm, Steel content 90 kg/m3	1.318
		E1 Exterior wall finishing under ground	-	none	0.000
3. Exterior walls above ground	723.5	C2.1B Exterior wall above ground	C2.1B 058	Timber frame construction	0.782
		E2 Exterior wall finishing above ground	-	Integrated in C2.1B	0.000
		G3 Interior wall finishing	G3 126	Timber cladding, painted	0.073
4. Window	200.7	E3 Window	E3 072	Double glazing, 10% timber frame	1.486
5. Interior walls	391.4	C2.2 Interior wall	C2.2 082	Reinforced concrete wall, Steel content 105 kg/m3	1.559
		G3 Interior wall finishing	-	none	0.000
6. Partition walls	643.0	G1 Partition wall	G1 107	Timber frame construction with insulation	0.541
		G3 Interior wall finishing	G3 127	Gypsum panel	0.170
7. Columns	0.0	C3 Column	-	none	0.000
8. Ceilings	1140.0	C4.1 Ceiling	C4.1 011	Timber frame ceiling	0.472
		G2 Floor covering	G2.2 108a	Sound insulation, anhydrite screed	0.321
		G4 Interior finishing	-	none	0.000
9. Balconies	90.0	C4.3 Balcony	C4.1 011	Timber frame ceiling	0.472
10. Roof	228.0	C4.4 Roof	C4.1 011	Timber frame ceiling	0.472
		F1 Roof covering	F1 017a	Foil sealing, EPS insulation	1.887
		G4 Interior finishing	-	none	0.000
11. Technical equipment	1099.0*	D1 Electric equipment	34.001	Electric installation, low requirements	0.310
		D5.2 Heat generation	31.002	Heat generation, power 30 W/m²	0.080
		D5.3 / D5.4 Heat distribution / delivery	31.024	Floor heating	0.290
		D7 Ventilation	32.003	Ventilation in kitchens and bathrooms	0.150
		D8 Sanitary equipment	33.003	Sanitary equipment	0.510

* The technical equipment is provided per floor area of energy reference area (A_E), which corresponds to the gross floor area of the heated building zones.

To define a GWP budget as the target value for the building, the top-down benchmarks in Table 1 are multiplied with the number of residents. In the design phase, an assumption for the number of residents is needed. The number of rooms in each apartment are analysed based on the architects' floor plans [16] and three scenarios are defined with the following assumptions: A) 24 residents; two persons for each master bedroom and one for each child and guest room; B) 18 residents; some master bedrooms are occupied by two, some by one person and not all guest rooms are continuously occupied; and C) 14 residents; one or two persons for each master bedroom depending on the size of the apartment and one person for each two child/guest rooms. In scenario B, the average living space of the residents is 45.8 m^2, which is close to the Swiss average value of 45.0 m^2 [22] and close to the German average of 46.5 m^2 in the years 2016 and 2017 [23]. Therefore, scenario B is assumed to be most realistic and employed for this paper. The influence of the floor area per resident on the top-down target is discussed later. The resulting benchmarks for the building are shown in Table 4.

Table 4. Top-down benchmarks for the case study building in GWP

	GWP [kg CO_2-e/a]
Embodied (including manufacturing, replacement and end of life)	4860
Operation (building-related part)	1620
Total	6480

4. LCA results of the case study building and discussion

Multiplying the areas of the eleven elements with the GWP factors for the components provides the results per building element shown in Table 5. The column *Actual value* shows the results for the selected materials as built. In addition, the other columns show the statistical values for minimum and target value based on the 0.05 quantile according to the bottom-up benchmark approach. These values are needed for the comparison later.

Table 5. Results for the embodied GWP of the building case study

Building element	GWP [kg CO_2-e/a]		
	Target (0.05)	Minimum	Actual value
1. Base slab	426	301	383
2. Exterior walls underground	613	644	241
3. Exterior walls aboveground	991	593	619
4. Windows	371	299	298
5. Interior wall	321	231	610
6. Partition walls	534	373	457
7. Columns	0	0	0
8. Ceilings	1562	752	857
9. Balconies	102	108	43
10. Roof	529	180	538
11. Technical equipment*	1297*	1297	1381
Total building	**6746**	**4779**	**5518**

* Due to a small number of solutions in the building component catalogue, no benchmark is calculated, but the minimum is used.

The building has a final energy demand for heating and hot water supply of 39674 kWh/a and an electricity demand (including auxiliary energy, ventilation, lighting and equipment) of 20212 kWh/a. The heating is provided though a wood chip boiler and the electricity by photovoltaic (PV) modules on the roof. The electricity demand can be fully covered by the building integrated PV on annual average. The factors for GWP are taken from the Swiss database *KBOB Ökobilanzen im Baubereich* [20]. The factors for the electricity from PV are based on a simplified approach of averaging all emissions within the life cycle such as production and disposal of the cells, but also the inverter and other parts of the system into one annual value per kWh. Excess energy exported into the grid is not considered to simplify the calculation. The benefit of exporting energy to the grid is highly dependent on the short-term variation of the electricity mix but also the long-term development in the next years. To assess the excess energy correctly, a dynamic approach considering the dynamic GWP factors for the Swiss grid would be needed [24], [25]. As this is not the focus of the paper, the calculation is simplified. The results are provided in Table 6.

Table 6. Results for GWP caused by operation of the case study building

	Final energy [kWh/a]	Final energy [kWh/(m^2_{AE}·a)]	Energy source	GWP Factor	GWP [kg CO_2-e/a]
Heating	39674	36.1	Wood chip boiler	0.027	436
Electricity	20212	18.4	PV on flat roof	0.081	1637
Total					**2073**

The total life cycle GWP of 7591 kg CO_2-e/a is 14.6 % higher than the top down target value of 6480 kg CO_2-e/a. Comparing the embodied and operational part separately shows that both parts are higher than the top-down benchmarks. Reductions of 11.9% for the embodied part and reductions of 21.8 % for the operational part are needed to meet the top-down benchmarks. As both parts do not meet the target values there is no opportunity to compensate one aspect with the other. Further alternatives to improve the building and reduce the environmental impacts are needed to make it compliant with the 1 t CO_2-e per capita and year approach.

Strategies to reduce the operational GHG emissions can be divided into approaches that influence the embodied impact e.g. increasing the insulation thickness and approaches that do not, such as choosing an alternative energy carrier. Here, it is assumed that approaches without influence on the embodied impact are followed. These could also include considering benefits from generating electricity onsite that is exported to others. As mentioned above, this raises further questions for example regarding system boundaries and allocation that cannot be discussed in detail is this paper. Furthermore, there are approaches that are beneficial for both operational and embodied impacts for example following a sufficiency strategy. This aspect is discussed later.

In the following, the case study focusses on the embodied impacts. To analyse how the embodied GHG emissions can be reduced best, the results for the building elements are compared to the bottom-up benchmarks. The results for the specific solutions are shown in the graph of the variability of the elements, see Figure 3, to indicate the improvement potential of each element. The points indicate the values for the specific solutions.

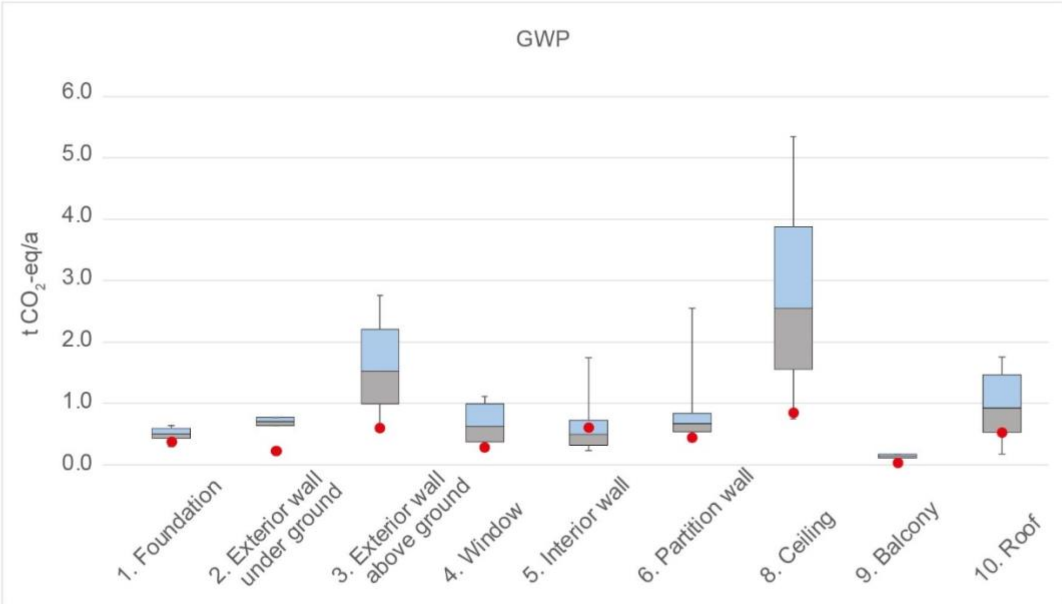

Figure 3. Benchmarks for the individual elements considering the surface areas of the building (points indicate the value for the specific material chosen in the case study)

For the *balconies* and the *exterior walls underground,* the specific values are smaller than the minimum values from the component catalogue. The specific balcony is made of wood, but only concrete is included in the component catalogue. For the *exterior walls underground*, the minimum is calculated including an exterior cladding and insulation for the wall. In the case study, the basement is not heated and therefore no insulation is included. As all selected solutions are close to the minimum, only the interior walls and the roof show a potential for improvement. Assuming the material of the internal walls could be exchanged to meet the benchmark this would save 289 kg CO_2-e/a. Doing the same for the roof would save another 9 kg CO_2-e/a. This means that the optimization of the material could save 298 kg CO_2-e. It is close, but not enough to reach the top-down target for the embodied part. Only, if the solutions with the minimum values are selected, the case study building achieves an embodied GWP of 4779 kg CO_2-e/a and the top-down benchmark is met. However, it is not clear whether this is technically feasible. Therefore, savings other than material optimization are needed. In this case study, the optimization potential of the building's shape is limited, because the building is very compact. One way to meet the top-down benchmarks is following a sufficiency strategy. If the floor area per resident can be reduced by 15% in this case study, for example through a higher efficiency of the floor plan, shared spaces or other design options, the top-down benchmark can be met.

Target values provided by certification systems and current national standards are usually based on the floor area (either the net floor area or the energy reference area). SIA 2040 currently provides targets for the so-called intermediate goal for the year 2050 which corresponds to total GHG emissions of 2 t CO_2-e/(c·a). Adapting these values to the goal of 1 t CO_2-e/(c·a) results in a target value of 6 kg CO_2-e/(m^2·a) for the sum of embodied and operational GWP. The DGNB target value for embodied GWP only is already 6.6 kg CO_2-e/(m^2·a) for residential buildings. The target value for the operational GWP in the DGNB-system is based on a reference building and is dynamic. Nevertheless, this shows that the current target values are too high to meet the "below 2 degree target" assuming a 1 t CO_2-e/c society. The case study building shows an embodied GWP of 5.0 kg CO_2-e/(m^2·a) and a total GWP of 6.9 kg CO_2-e/(m^2·a). A reduction of 15% is needed to meet the adapted SIA 2040 target. As such, the outcome of using the target values per floor area is similar in this case. However, the target per floor area does not allow to consider sufficiency strategies such as reducing the amount of floor area per resident. Therefore, a benchmark per capita is recommended here in addition

Finally, a building is more than a sum of its building components. As such, there are interdependencies between different components, for example load-bearing exterior or interior walls. Next to the embodied impact, the choice of materials and construction types influence many other building performance criteria. The presented approach is therefore an estimation in early design stages to provide guidance based on the currently available data.

5. Conclusion and outlook

As LCA is more commonly applied to assess the environmental performance of buildings, different actors have a need for LCA-based benchmarks. Investors, building owners and public funding institutions need them to define environmental performance targets and architects need them for design guidance. This paper shows how top-down and bottom-up benchmarks can be combined to provide design guidance. The top-down benchmark is based on the overall target of limiting GHG emissions to 1 t CO2-e per capita and year. The bottom-up benchmarks are statistically derived from typical building components for new residential buildings in Switzerland and the market share of different building materials following a best-in-class approach. A method for using this dual benchmark approach in the design process is proposed. The workflow suggests to first calculate the environmental performance target for the building based on the top-down benchmarks. Then the environmental impact of the building is calculated and it is checked whether the top-down benchmark can be met. If not, the impact of the individual building elements is calculated and compared to bottom-up benchmarks to indicate the material-related optimization potential. Depending on the result, decisions to change the material or the design parameters are taken. Differentiating between material and design-related options provides guidance on how to optimize the environmental performance of the building and its components efficiently. Of course, the approach can also be applied to reduce the impact, if the global target is met by the initial design. The method of using the dual benchmark approach in a case study of a multi-family house showed that the method is applicable. As such, the proposed approach can facilitate using LCA as a design-supporting method in design practice and promote environmental performance optimization of buildings.

Here, the method was applied for new residential buildings. The same method can be adapted to non-residential buildings as well as retrofit projects. The benchmarks should be regularly updated with the latest data. Furthermore, the benchmarks should be implemented into LCA tools applied during design to provide direct feedback on the optimization potential to decision makers. The proposed approach should be developed further including multi-criteria design decisions. In this paper, a top-down target for lifecycle-related GHG emissions has been used. In the future, the approach could be extended to include other environmental impacts besides climate change. The planetary boundary framework [26] could provide a basis for deriving additional target values for buildings. This will lead to a system of benchmarks. Furthermore, the dual benchmark approach could be linked to concepts such as “absolute sustainability” based on the carrying capacity of the ecosystem [27]. This would make sure that measures to lower the GHG emissions due not cause higher impacts in other categories. In the future, the method can also be transferred to other countries to derive national benchmarks for material-related environmental impacts as long as a building component catalogue and market share data are available.

Abstract. Increasing building demands from a growing world population puts enormous pressure on natural resources. Management of resource consumption and environmental impacts is therefore vital to secure contemporary and future well-being and progress. Circular Economy (CE) is perceived as an industrial economy model potentially minimizing resource consumption, waste production and environmental impacts by the means of increased material circularity e.g. reuse. In order to promote CE in buildings, there is a need for benchmarks to support building designers in choosing environmentally viable solutions. Although life cycle assessment (LCA) help policy makers and building practitioners to define such benchmarks, benchmark studies often rely on static LCA approaches. Hence, uncertain and unknown dynamic changes during a buildings' long service life influencing the performance of long term sustainable building design principles are not accounted for. Through a literature review the paper at hand identified dynamic technological progress such as resource and energy consumption, energy grid mix, waste management, design and innovation and production efficiency as potentially essential to include when defining realistic CE building strategy benchmarks. How these dynamic factors may affect LCA results were demonstrated through a case study of a concrete column based on a range of possible scenarios. This included estimated future projections and the uncertainty relating to prospective assessments resulting in an output in the form of a span of possible future developments and environmental impacts instead of a single output. Based on the literature review and case study, main challenges of incorporating dynamism within building LCA benchmarking were identified.

1. Introduction

Circular economy (CE) is an industrial economy where the resource flows are managed within a restoring and regenerating capacity by extending resource life thereby avoiding depletion and reducing environmental burdens induced by these resource flows [1]. Thus, CE is of interest to minimize the construction industry's significant contribution to environmental impacts, resource consumption and waste production and both political and industrial initiatives are beginning to form at a greater extent [3–5]. For that reason it is increasingly important to be able to show the designers and decision makers where/how large the environmental benefits of CE are. One way is to establish benchmarks which are essential for comparing performances and establishing future mitigation goals to support building designers choose environmentally viable solutions. Life cycle assessment (LCA) can help establish such benchmarks [2] and is increasingly used by the construction sector and in some recently published CE studies [3,4]. LCA is used in certification schemes such as DGNB that have established benchmarks for LCA using reference buildings i.e. representative buildings for the establishment of benchmarks [2]. LCA benchmark values may also become part of the new Danish voluntary sustainability class in the building regulations [5]. However, the problem is that LCA is a well-developed tool for assessing products with a short service lives and/or have no ongoing inputs and outputs that change in magnitude and origin over time [6] whereas buildings sometimes have a very long service life with ongoing inputs and outputs that change in magnitude and origin over the course of many years or decades. Hence, benchmark studies often rely on static LCA approaches i.e. dynamic factors that can affect the environmental impacts of buildings and building components are not considered clearly limiting the validity of the LCA results [7]. In terms of CE this poses a problem as CE is about prolonging resource life thus designing also for systems operating in the future, not only today. For that reason a forecasting perspective is important for assessing and quantifying the benefits of CE to help guide design decisions today. Although, comparison of LCA results are important in order to develop benchmarks, in terms of CE comparing buildings such as done in e.g. DGNB will not be enough to establish reliable benchmarks. Instead LCA results should be compared against realistic future points of reference to provide a level of confidence when basing the adoption of CE building design strategies on LCA results. Dynamic life cycle assessment (DLCA) is an LCA approach enabling incorporation of dynamic process modelling in the context of temporal and spatial variations in the surrounding society as well as industrial and environmental systems [8]. Hence, the use of DLCA can potentially more realistically predict buildings' environmental performance by acknowledging potentially significant dynamic factors and thus offer a better basis for benchmarks to guide design decisions. However, DLCA research is at its infancy and predominantly applied in other industries and cannot be directly applied to buildings due to their complexity and long service life resulting in dynamic factors having a much longer and more complicated influence on building LCA results [7].

Focusing on the embodied environmental impacts related to the buildings' material resource flow in line with the CE, the paper at hand does not attempt to develop benchmarks for CE building strategies sector but rather explore the difference between using traditional building LCA and forecasting principle from DLCA when developing benchmarks. The paper at hand aims at: 1) through a literature review to create an understanding of the DLCA approach in the context of buildings and DLCA's potential importance to developing relevant benchmarks by identifying which elements of a building LCA can be addressed dynamically as well as which dynamic factors are assumed to be of significant importance to the environmental impacts of buildings' material resource flows and 2) based on the findings of the literature review, conduct a case study of a CE designed concrete column demonstrating how significant dynamic factors may affect LCA results. Furthermore, challenges of incorporating dynamic modelling principles within building LCA benchmarks are discussed.

2. Literature review

The literature review is not intended as an exhaustive study but a summarising representation of the state of art by covering the most recently published and relevant literature on the subject of DLCA focusing on quantifying the environmental burdens from buildings' energy and material flows. The literature review indicates that although DLCA studies within buildings exist dynamism is not incorporated in LCA benchmarks. Additionally, DLCA publications addressing temporal properties in building related LCAs is rapidly increasing, however, DLCAs are performed in various ways resulting in inconsistency and risk of undermining method validity and provide misleading results [6] and DLCA is still in its infancy [7]. Previous studies have found that DLCA results varied greatly when compared equivalent to static results[8]. Furthermore, changes during a buildings service life can in some cases influence the LCA result greatly compared to the production and construction phases [8]. From the literature two perspectives on dynamism are found i.e. dynamism related to the LCA framework and dynamism related to building life cycle stage specific processes such as production, operation and end-of-life. The LCA framework oriented DLCA approaches identified suggest that it is possible to treat any one or multiple of the four ISO 14040 LCA phases dynamically: 1) Goal and scope definition, 2) Inventory analysis, 3) Impact assessment and 4) Interpretation using different modelling methods: a) dynamic process inventories where future potential developments are incorporated into single unit processes, b) dynamic systems where future potential changes in terms of components of systems are accounted for by changing between unit processes, c) dynamic characterisation factors applied in the impact assessment to reflect impact potential change over time, d) dynamic scope and e) and dynamic weighting [6–9]. However, c) and e) have weak links to construction and insufficient research basis [7,8]. A full DLCA i.e. that covers dynamic aspects in all applicable phases and parts of the LCA for all unit processes are in most cases not feasible [6–8]. This is due to excessive data demands compared to conventional LCA, lack of adequate data, increased model complexity, lack of an established methodology, challenges in terms of incorporating dynamic aspect in existing LCA (static) software, or high uncertainty of dynamic process or system properties that is better omitted [6–8]. DLCA that does not exhibit dynamism in all phases or parts of an LCA results in a partially dynamic life cycle assessment (PDLCA) but can however still in many cases provide better/more realistic decision support compared to static LCA [6]. However, appropriate measures must be taken to ensure that use of PDLCA does not bias the results [6]. To avoid potential bias of results by applying PDLCA, system dynamics can be accounted for via the sensitivity analysis i.e. by exploring the effects of dynamisms on the system via sensitivity analysis facilitating illumination of potential issues i.e. temporal dependencies of the result [6]. The other DLCA approach accounts for building life cycle related processes that occurs during production, use, end-of-life and next product system. As previous LCA studies have consistently found that the operational energy consumption dominates most environmental impact categories DLCA in buildings has also mainly focused on buildings' operational energy consumption [10]. E.g. the Danish LCA software LCAbyg calculates both a static and dynamic energy consumption for operation based on a future Danish grid mix scenario for 2050 [11]. However, as some new low-energy buildings have radically reduced energy consumption the operational energy consumption is no longer considered to be the most important contributor to building-related environmental impacts [10,12]. This shifts focus to the buildings' embodied energy and environmental impacts [10,12] which is also in line with the CEs focus on resources. From the literature the dynamic factors related to specific temporal process developments in the building life cycle that are identified to be of significance for the embodied impacts as well as extraordinary relevance to CE are the technological progress related to: resource and energy consumption, compositional changes in energy structures and grid mix where the share of renewable energy is expected to increase in the future, waste management in terms of recovery and renewable rate of resources, design and innovation production efficiency [7,9]. Additionally, dynamic factors such as variation in occupancy behaviour, emissions/resources, environmental systems are also mentioned [5], [8]. Common for all of these dynamic factors are that they are related to (large) uncertainties, mainly related to future technological and political developments yielding many plausible futures. One way to handle future uncertainties is to build scenarios (i.e. scenario exploration) based on possible future trends or even likely trends based on predictive/prospective policies or historic trends (i.e. prospective scenario development based on back-casting) indicating realistic future developments with high probabilities that might have an influence on the environmental performance [6,8]. In addition, several scenarios that encompass a best or worst case scenario could be presented yielding a result span in which future environmental performance are expected to take place [6].

Another issue with building benchmarks is that they can be misguiding as different buildings may show similar results on the overall building level but for different reasons. This is because each building materials' and components' embodied environmental impacts are dependent on different factors such as different service lives, life cycles, dimensions, weight, functions etc. [13]. A systematic decomposition of buildings into their separate functions facilitating the identification of how the relationship of the embodied environmental impacts building elements relate to different building attributes may help predict and may greatly benefit the effort of reducing the embodied environmental impact of buildings even in the early design phase [13]. Ideally benchmarks could be established based on the specific conditions for every building element e.g. the embodied environmental impacts of a foundation is among others dependant on the weight it has to carry [13]. However, an adequate pool/sample of representative buildings are needed to base statistics on and standardize embodied environmental impacts to develop representative and specific benchmarks for e.g. building elements, functions, typologies, geographies, etc. in order relate to other building projects.

3. Case study method

Several studies show that concrete structures generally account for a large share of buildings' embodied impacts [14]. Hence, based on the findings of the literature review the use of dynamic process inventories and dynamic systems within DLCA focusing on energy grid mix, waste management, design changes and production efficiency are explored in a case study of a concrete column, building on an existing static LCA study where two scenarios sT and sD were modelled [15]. sT is a traditional design where the concrete column is casted together with the other concrete making it impossible to separate the column into its constituents for reuse without damage e.g. crushing of the column into concrete gravel for use as road filling and recycling the reinforcement steel to new steel products after a service life of 80 years. sD is where the column is designed for disassembly using large bolted mechanical steel connections from the Finnish company, Peikko, enabling reuse in a new future building after 80 years thereby prolonging the elements' service life and avoiding environmentally burdensome production of new concrete elements based on already existing marketed solutions [16]. Both sT and sD are modelled using a contemporary energy grid mix in all processes. The Danish 2050 energy grid mix scenarios forecast increased shares of waste incineration and renewable energy from wind i.e. the thermal energy will come from: 7% biomass and 93% waste, and electricity will come from: 10% biomass, 7% waste, 3% biogas, 1% natural gas, 76% wind and 3% solar [11,17]. New developments in cement production suggests a future reduction of up to 30% of its current embodied greenhouse gas emission (GHG) [18]. In addition, research on recycling of concrete into new concrete is currently ongoing [19]. Furthermore, future reductions in construction waste are expected as a result of the Danish government's CE strategy [5]. Additionally, with the increase of wind power it is expected that electricity will play an important role in future transport technology [17]. Adding these likely technological progresses to sT and sD resulted in two dynamic scenarios, dT and dD, modelled in accordance with the PDLCA approach. dT is similar to sT however assuming application of the 2050 energy grid in future life cycle processes, 30% less embodied GHG from cement production and higher quality recycling rates in year 80 which further increases in year 160. dD is similar to sD however assuming 2050 energy grid mix for future life cycle processes and 50% lower embodied GHG from transportation in year 80 and similar high quality recycling rates in year 160 as for dT. In year 1 sT and sD are modelled the same as is sD and dD using present grid mix. In year 80 for dT and year 160 for dT and dD, it is assumed that recycling of concrete substitutes a certain amount of virgin concrete that otherwise would have been produced using cement with 30% decreased embodied GHG. For D, the transportation distance is set to the longest possible transportation distance in Denmark of approximately 480 km. Table 1 and 2 provides an overview of how different processes within each life cycle phase are modelled for year 1, 80 and 160 for each scenario. The embodied GHG obtained from the dynamic models, d, are compared to the static models, s, where d reflects a best case scenario and s reflects a worst case scenario where we proceed as we do today. This provides a span in which the future embodied GHG can be expected to take place. All four scenarios were modelled following the LCA methodology stated in the standard EN 15978 using the openLCA v1.4 software and baseline characterization factors from the Centre for Environmental Studies (CML) baseline 2001.

Table 1. Traditional column scenario

		1st life cycle			2nd life cycle		
Life cycle phase		**P 1**	**E 80**	**N 80**	**P 80**	**E 160**	**N 160**
sT[4]	Grid mix	Present	Present	Present	Present	Present	Present
	Reinforce-ment steel	76 kg	99% recycling, 1 % landfill	-	76 kg	99% recycling, 1 % landfill	-
	Concrete 35MPa	1489 kg	90% recycling, 10% landfill	90% virgin gravel substitution	1489 kg	90% recycling, 10% landfill	90% recycling substituting virgin gravel
dT	Grid mix	Present	2050[1]	2050[1]	2050[1]	2050[1]	2050[1]
	Reinforce-ment steel	76 kg	99% recycling, 1 % landfill	-	76 kg	99% recycling, 1 % landfill	-

	Concrete 35MPa	1489 kg		100% recycling	50% / 50% virgin concrete/ gravel substituting[2]

Abbreviations: s =static, d= dynamic, T = traditional, D = design for disassembly, - = no substitution, P = Production, U = Use, T = Transport, E = End-of-life, N = Next product system, Present = Ecoinvent dataset energy grid mix. Sources: [1][11,17], [2][18], [3][17] and [4][15].

As CE focus on resource life extension the functional unit was set to provide the function/service of the column across two component life cycles (i.e. 2 times 80 years). The life cycle inventory (LCI) of the background system was based on the Ecoinvent 3.2 database using system processes to obtain aggregated results, however, switching between unit processes were used to model the dynamic aspects. The foreground system was compiled using the manufacturers' product specifications. The system boundaries include production, waste recovery for reuse, recycling or incineration and disposal by landfilling at end-of-life, and credits for potential reuse, energy recovery and recycling of materials and components in a next product system. Allocation of environmental impacts and credits are modelled following the 100:0 (cut-off) approach of EN 15978. As steel is assumed produced using scrap steel, no environmental crediting is achieved when recycled again [20]. To address uncertainties of the dynamic scenarios dT and dD a sensitivity analysis evaluates the influence of possible sensitive material and energy source input parameters resulting from a 10% input value increase [21].

4. Case study results

Figure 1 shows the life cycle embodied GHG and material flows resulting from the static LCA represented by sT and sD and the PDLCA represented by dT and dD where the size of the arrows approximately represents the amount of the material inputs and output flows. The highest material embodied GHG originates from production of concrete in year 1 for both T and D. However, the embodied GHG of producing column D in year 1 is slightly higher compared to column T due to the use of extra steel for the connections to allow assembly and disassembly. Considering sT, where column T is not suitable for reuse at the first use cycles' end-of-life, supplying a second use cycle with the same kind of column requires production of a new column. Hence, the embodied GHG of column sT originates from production in year 1, and at end-of-life in year 80 treatment of 90% concrete substituting virgin gravel resulting in negative embodied GHG, furthermore 99% reinforcement steel for recycling and 10% concrete and 1% reinforcement steel for landfilling at . During the second use cycle this is repeated. The similar processes are repeated for dT, however, differing as the dynamic aspects stated in Table 1 have been added. Hence, the embodied GHG of column dT comes from production in year 1, and at end-of-life in year 80 treatment of 100% concrete for recycling, where 25% and 75% substitutes virgin concrete and gravel respectively resulting in negative embodied GHG, 99% reinforcement steel for recycling and 1% reinforcement steel for landfilling. In the second use cycle the embodied GHG in year 80 comes from the production of a new concrete column however with 30% less GHG from the production of cement. And at the end-of life in year 160 the embodied GHG comes from treatment of 100% concrete, where 50% substitutes virgin concrete and 50% substitutes gravel resulting in negative embodied GHG, 99% reinforcement steel for recycling and 1% reinforcement ending up in landfills. For sD, the embodied GHG originates from production in year 1, transportation to a subsequent building in year 80 and end-of-life in year 160 from treatment of 90% concrete substituting virgin gravel resulting in negative embodied GHG, 99% reinforcement steel for recycling, 10% concrete and 1% reinforcement steel being. The similar processes are repeated for dD, however, differing as the dynamic aspects stated in Table 2 have been added. Hence, the embodied GHG comes from production in year 1 and transportation to a subsequent building at end-of-life in year 80, however, with 50% less GHG. At the final end-of-life in year 160 the GHG comes from treatment of 100% concrete for recycling, where 50% substitutes virgin concrete and 50% substitutes gravel resulting in negative embodied GHG, 99% reinforcement steel for recycling and 1% reinforcement deposited in landfills. From the accumulated embodied GHG it is seen that the scenario exhibiting the highest embodied GHG is sT with 488 kg CO_2 eq. and the scenario with the lowest embodied GHG is dD with 257 kg CO_2 eq. The accumulated graphs for the static scenarios clearly reveals that that reuse of the column sD to supply two life cycles is less burdensome compared to producing two column sT to supply the same two life cycles. However, when simultaneously looking at the accumulated graphs for the dynamic scenarios, this is no longer the case as the technological progress over time results in dT and dD exhibiting close to a similar performance with 297 kg CO_2 eq. and 257 kg CO_2 eq. respectively.

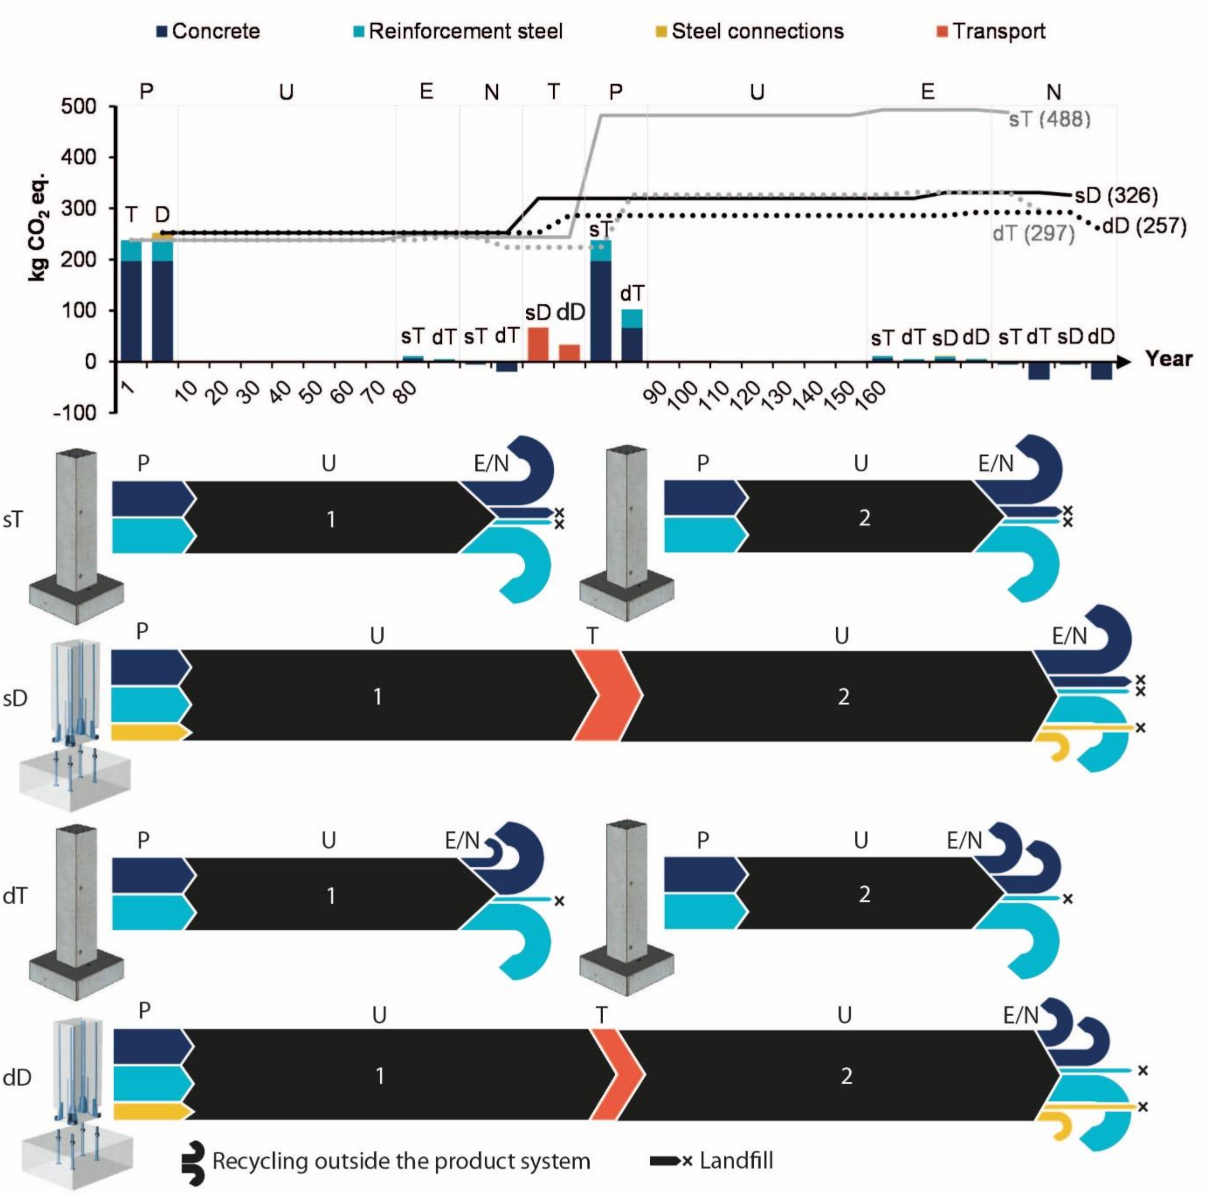

Figure 1. Comparison of life cycle embodied GHG and material flows of the modelled scenarios. Abbreviations: P = Production, U = Use, T = Transport, E = End-of-life, N = Next product system, 1 = first use cycle, 2 = second use cycle, s=static, d=dynamic, T=traditional, D= design for disassembly.

5. Discussion and conclusion

From the example of the concrete column provided here taking into account several life cycles, the static LCA results supports the CE idea that design for disassembly for reuse of building component is environmentally preferable over production of new components. However, when incorporating the technological progress in the dynamic LCA, results show that the environmental performance of a newly manufactured column performs close to the same as reusing an old column, but reuse of the column still performs slightly better. For CE design concepts such as design for disassembly, this could potentially mean that complete neglection of dynamic aspects when developing CE benchmarks can evidently provide false guidance on which design strategies to use on component level and how to best meet future mitigation goals. From the sensitivity analysis it was tested to which extent the output parameters of dT and dD were sensitive towards any of the material and energy source input parameters i.e. if a small change of a 10% increase in the input parameter value would result in a large change in the model results. Table 3 shows that, although the energy source input parameters related to electricity and thermal energy can be qualitatively associated with a high uncertainty, the model output is insensitive to these parameter as the sensitivity coefficients are below 10%, hence, the uncertainty of them will not affect the overall results. However, the output parameters of both dT and dD were found to be very sensitive to a 10% increase in the material input parameters, especially concrete which exhibited a sensitivity coefficient of 75% and 78% for dT and dD respectively. This could be due to the fact that for the column scenario the dynamic technological progresses explored mostly affects the concrete e.g. changes in waste management and production efficiency. For that reason the uncertainty of other technological progresses may influence the results even more compared to the future energy grid mix.

Table 3. Parameter sensitivity coefficient of dynamic scenarios dT and dD

Material parameters	**Scenario**	**Concrete**		**Reinforcement steel**		**Steel connections**	
	dT	74%		30%		-	
	dD	78%		19%		7%	
Electricity parameters	**Scenario**	**Biogas**	**Biomass**	**Natural gas**	**Solar**	**Waste**	**Wind**
	dT	0.004%	0.019%	0.019%	0.011%	0.115%	0.045%
	dD	0.000%	-0.021%	0.021%	0.013%	0.146%	0.056%
Thermal energy parameters	**Scenario**	**Biomass**				**Waste**	
	dT	0.04%				9.96%	
	dD	0.01%				2.13%	

However, the study at hand is limited in its scope as it only explores the influence of incorporating dynamism in an LCA of a concrete column focusing only on embodied GHG and may obviously overlook other potentially important aspects of incorporating dynamic aspects in CE benchmarks. E.g. in terms of CE, dynamic LCA does not show how the column performs in terms of resource scarcity. Furthermore, this study includes technological progress relevant in a Danish perspective for the particular column in question; however, influencing dynamic factors may differ greatly depending on the geography. Other developments relevant for the concrete column may also have been overlooked. The technological development and influence of dynamism on the environmental impacts of another CE designed building component may also differ greatly from that of the column making it difficult to define general benchmarks both on building and component level. Thus, CE benchmarks could, as a starting point, focus on where the largest environmental and resource burden improvement potentials lies and in this way facilitate the progression to a more sustainable development of buildings. In addition, the study only considers embodied GHGs, however, the performance of the column may differ when considering another environmental impact category. However, it is difficult to develop benchmarks on the basis of the majority of impact categories due to burden shifting between the impact categories. Although, some LCA software tools include dynamic factors for buildings such as the Danish LCAbyg software which includes forecasted Danish energy grid mixes for 2050 for the operational energy consumption of the building, implementing the dynamic factors' influencing the embodied environmental impacts of each building component is a (much) larger challenge as it requires many alterations to a vast number of (inventory) datasets. However, as a starting point datasets could be designed in a more modular way to also implement dynamic energy grid mix(es) influencing the embodied energy and environmental impacts and thus allow for easier exchange of energy processes. The study at hand also shows that CE requires a different way of conducting LCA in order to quantify future benefits of CE for long-lived building components i.e. accounting for several component life cycles instead of just the first. Despite the limitations of the study, basing benchmarks *on* a more dynamic LCA approach i.e. a range of possible scenarios including estimated future projections and the uncertainty relating to prospective assessments results in an output in the form of a range of possible future developments and hence a range of environmental impacts as demonstrated herein. Such a probabilistic set of results is likely to provide a more meaningful, realistic and accurate decision basis supporting a sustainable development in the building sector.

Abstract. Reducing the embodied carbon of the building stock requires a better understanding of the life cycle impacts of the materials used in those buildings. However, the characteristics of the building stock vary significantly by geography and building type. The "Carbon heroes benchmark program" is a cooperative initiative for carbon profiling by building type across different countries. The program's aim is to create uniform, full life-cycle of materials benchmarks for common building types. The benchmark program is on track to achieve 1000 fully completed and verified buildings by end of 2019, and contains data breakdowns for over 100 different material types and essential structural parts of a building. All data used in the program is rigorously anonymized and statistically small sets of data are also not used to protect data anonymity. The program implements the EN 15978/ISO 21930 standards as the basis of measurement, and includes life-cycle stages A1-A3, A4, B4-B5, and C1-C4. This presentation will share the preliminary findings of this project. 659 verified buildings (February 2019 cut-off), with substantial datasets for many European countries for some of the most common building types. The benchmark is generated using One Click LCA.

1. Introduction

Embodied carbon in the built environment is not well understood, and designers and project teams lack reference points to analyze their project performance. When a subject is at the same time new, and it does not have a clearly established reference point, it's easy to get lost and the issue of embodied carbon remains unaddressed.

Among the findings of the Embodied Carbon Review [1], five (5) methodologies were identified that help deal with embodied carbon in the building sector. These methodologies are carbon reporting, carbon comparison (in design), carbon rating, carbon caps, and decarbonization. With the exception of the first method, all share the need to develop a benchmark or baseline to measure or compare against to drive carbon reductions. Thus, carbon benchmarks can become instrumental for policy-making as they serve to set actionable targets.

The present study shares the preliminary results of the Carbon Heroes Benchmark program developed with anonymized building data. The article will describe the design of the data collection procedure, the assumptions in the organization of data, and the challenges found to this date in the program.

2. Developing embodied carbon benchmarks for buildings

The role of embodied carbon benchmarks for buildings is recognized as an important instrument for policy makers to help reduce the impacts of the building stock. However, a single benchmark cannot be applied across the all buildings as the normalization of embodied carbon per unit area ignores the impact

of building type on its carbon footprint [2]. Moreover, previous attempts at establishing carbon benchmarks, several challenges have been identified in their creation. Some of these challenges include the use of different life cycle inventory (LCI) databases, variability in the reported LCA methodologies used and variability in the material scopes of existing studies, inconsistent meta data to properly classify the data, and the reduced sample size to make significant statements [3,4]. Another study for multi-unit residential buildings done in Canada also highlighted the limitations of sample size and the impact of regionalization in the development of the benchmarks [5].
In order to address these issues, the Carbon Heroes Benchmark program is capable of leveraging the use of a single LCA software platform, One Click LCA, to guarantee consistency in the input of data and the calculation of its impacts.

2.1. Pre-requisites for the quality of embodied carbon benchmarks for buildings
As previous experiences have shown, ensuring consistency of embodied carbon benchmarks is all but easy. Carbon Heroes Benchmark Program is designed to ensure high quality control and robustness of the results. These include:

2.1.1. Consistent building information meta data. Each project includes information on building type (refer to Table 1), LCA scope reported according to EN-15978 standard, and gross internal floor area.

2.1.2. Relevant material classification. The materials included are classified by types and sub-types. For example, metals as a type is sub-divided into reinforcement steel, structural steel, aluminium, copper, etc.

2.1.3. Automated material feedback. An internal algorithm checks the quantities of materials per building element and the ratio between material sub-types to guarantee that the quantities reported are plausible and/or fall within expected ranges. This information is provided to the users so they may review the data introduced and make necessary corrections. For example, ratio of concrete mix to steel reinforcement.

2.1.4. Anonymized data. All identifiable information is removed before generating the dataset for statistical analysis. This is to ensure privacy and avoid bias in the analysis. Only the country location of the building is reported for the development of national and regional benchmarks.

2.1.5. Expert verification and removal of incomplete datapoints. An LCA expert reviews the scope of materials and results. Some potential sources of errors include incomplete scope for calculation, unusual quantities by building area, or suspected values. If errors or incomplete data cannot be resolved, the building is withdrawn from the sample.

2.2. Scope of benchmark program
The aim of this program is to create uniform, life-cycle embodied carbon benchmarks for common building types. The benchmark program is on track to achieve 1000 anonymized, verified buildings by end of 2019, and contains data breakdowns for over 100 different material subtypes and essential structural parts of a building. The benchmarks are generated and updated approximately every six months.
This program is operated in cooperation with Green Building Council Ireland, Green Building Council Italia, Green Building Council Hungary, Dutch Green Building Council, Romanian Green Building Council and Norwegian government real estate organization Statsbygg. Also, Chile Green Building Council has joined the program, but no verified datapoints from Chile are available. The synthetized results of the program are made available to the participating partners and software users.
The benchmark is developed by building type through a standardized life cycle model. Results are regionalized and communicated in a clear way to the non-expert public.

2.2.1. Building typologies. Currently, the program is collecting data for 18 building types. These typologies are listed in Table 1.

Table 1. Building typologies in Carbon Heroes Benchmark program

Building group	Building Type
Residential	Apartment buildings
	Attached or row houses
	One-dwelling buildings
	Social welfare buildings
Educational / Institutional	Cultural buildings
	Day care centres for children
	Educational buildings
	Historic or protected monuments
	Hospitals and healthcare centers
	Schools (primary education)
	Sports halls
Commercial	Hotels and similar buildings
	Industrial production buildings
	Office buildings
	Retail and wholesale buildings
	Transport buildings
	Warehouses
	Other buildings

2.2.2. Standardised life cycle model. The scope of the analysis follows the EN-15978 / ISO-21930 standard as the basis of measurement. The system boundary and essential methodology of the benchmark calculations is standardized. All calculations included in the program are uniform and cover life-cycle stages A1-A3, A4, B4-B5, and C1-C4; it excludes the module D. In other words, this covers the impacts from material production, the replacement and/or refurbishment due to the end of the material service life, and the end of life stage. Figure 1 includes the information modules described in the EN-15978 standard.

Participants in the program pursue specific requirements in green building certifications such as BREEAM [6] and LEED [7], that require a whole building life cycle assessment to measure the environmental impacts of the materials used to build and operate the building. As a requirement of these certifications, the period of study is 60 years. Also, the certifications require the report of embodied carbon as Global Warming Potential (GWP) 100 years in Kg CO_2-eq. Other environmental categories differ between the certifications. As a consequence, this benchmark was developed with GWP as a common denominator and easy to understand indicator associated with climate change.

Moreover, the benefits of biogenic carbon are not included in the benchmark. This is a result of the uncertainty associated with the disposal method or end of life scenario. For example, the incineration of vegetated products releases the stored carbon back to the atmosphere and results in a zero sum for the purposes of the analysis. Consequently, the assumed carbon storage benefits reported in module A1 are added back in module C. Nevertheless, biogenic carbon is calculated and reported as a separate indicator in One Click LCA.

Product Stage			Construction Process Stage		Use Stage							End-of-Life Stage				Benefits and loads beyond the system boundary		
Raw material supply	Transport	Manufacturing	Transport to building site	Installation into building	Use/application	Maintenance	Repair	Replacement	Refurbishment	Operational energy use	Operational water use	Deconstruction/demolition	Transport	Waste processing	Disposal	Reuse	Recovery	Recycling
A1	A2	A3	A4	A5	B1	B2	B3	B4	B5	B6	B7	C1	C2	C3	C4	D	D	D

Figure 1. Life cycle stages according to EN-15978

2.2.3. Regionalized samples. The sample is classified by countries at the moment with the aim at grouping buildings with similar construction techniques. Table 2 shows the breakdown of countries for the sample of European projects. Additional data is available for North America, Middle East, and Asia.

Table 2. Countries by region, Europe

Region	Countries
Northern Europe	Denmark, Finland, Iceland, Norway, Sweden
Eastern Europe	Croatia, Czech Rep., Estonia, Hungary, Latvia, Lithuania, Poland, Romania, Serbia, Slovak Rep., Slovenia, Ukraine
Southern Europe	Italy, Portugal, Spain
Western Europe	Austria, Belgium, France, Germany, Luxembourg, Netherlands, Switzerland
British Isles	Ireland, United Kingdom

2.2.4. Facilitate the consistent input of building data. The collection of building information for the development of these benchmarks are the result of material quantity inputs made by users of One Click LCA. To assist the users in the correct input of information, the software includes two tools: Model Checker and LCA Checker. The Model Checker reviews the quality of the geometric information found in the Building Information Models (BIM) during the import process into One Click LCA. And, LCA Checker reviews that the material quantities are plausible using a set of proprietary algorithms and automated verifications.

2.2.5. Sample size. Currently, there are 659 buildings included in the program. The aim of the Carbon Heroes Benchmark Program is to reach 1000 buildings by the end of 2019, at which point the analysis is repeated. The results included in section 3 show the preliminary findings of this study for a limited number of building types: multi-family apartment, office, and warehouse/industrial. Also, this analysis will include only buildings in Eastern Europe Another review/update is expected at the end of 2019 and it will determine which building types will be reported based on their statistical significance.

2.3. Communicating results

Results are reported in two graphical forms that are easy to read. First, in a Boxplot with whiskers showing the median and range, including outliers. And, second as a performance metric as shown in Figure 2. The performance metric includes the range of results at two standard deviations of the mean for the building type. The range is divided into 7 (seven) bands equally distributed. The mean of the results falls within band "D" and the lower and upper extremes of the range are in bands "A" and "G" respectively.

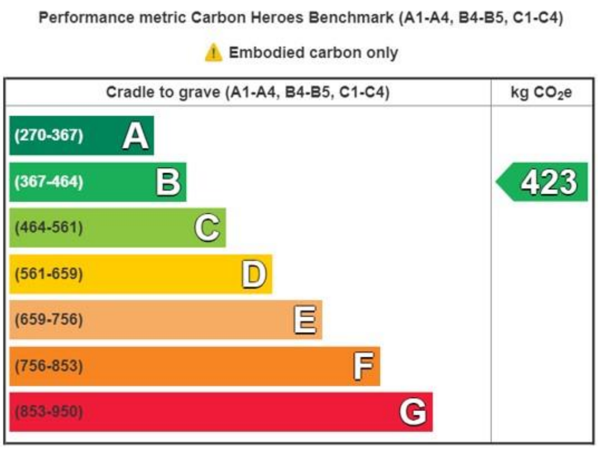

Figure 2. Performance metric Carbon Heroes Benchmark, example

3. Results & Discussion

For this article, three building types for Eastern Europe are presented here as an example of our data analysis process. In Table A1, the descriptive statistics for the sample of office buildings is included. The high values of Kurtosis and Skewness show the possibility that this dataset is not normally distributed. The histogram for the same dataset presented in Figure 3, seems to corroborate this assumption. The data shows positive skewness and a long tail to the left.

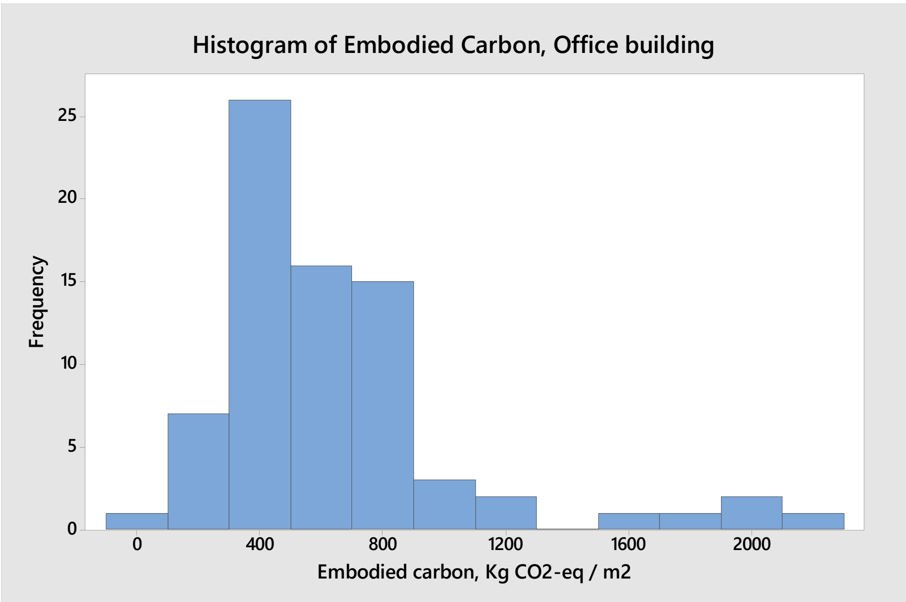

Figure 3. Histogram of office building, Eastern Europe

As a consequence, a 1-sample sign non-parametric test was applied to check if the median is a better test of central tendency for this dataset. The results of the test are included in Table 4, with similar test results for two other building types: "apartment buildings" and "warehouse/industrial facilities".

Overall, the median shows to be on target in its central tendency, and the resulting range (lower and upper values) captures with 95% confidence the values of the dataset.

Table 3. Median embodied carbon results per building type

Building type	Median embodied carbon, Kg-CO2-eq/m2	Confidence Interval, 95%
Apartment buildings	444	285, 886
Office	531	410, 591
Industrial & warehouses	609	357, 1115

Alternatively, additional building information can shed insights into the skewness of the distribution. This will be tested as the sample grows. Meanwhile, using the histogram of the office building subset, the outliers to the left were extracted from the sample, and a set of descriptive statistics were calculated. With a reduced sample (n=70), the mean and median were closer to each other, and the results are more normally distributed (M=538; SD=238) and range (63,1013) p=0.05. Figure 4 shows boxplot of the sample. Table A2 shows the descriptive statistics of this sub-sample.

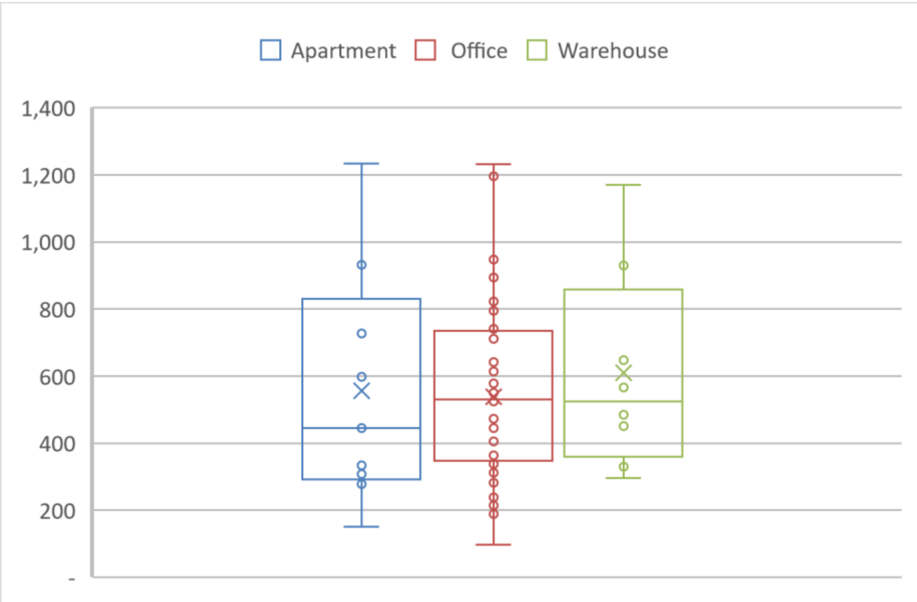

Figure 4. Boxplot of mean/median embodied carbon, Eastern Europe

In addition, global warming potential (GWP) is reported by information module as a percentage of overall embodied carbon (Kg CO_2-e) in Figure 5. It is not surprising that the largest share of GWP takes place during the construction phase. However, a study we conducted about modelling the impact of retrofit on accumulated impacts has shown that the impacts of module B4-B5 might be underrepresented [8]. At the moment, the results in B4-B5 represent changes in materials due to the technical service life of materials and do not consider changes in building renovations or retrofit scenarios. This can lead to a review of the scope of the analysis for module B.

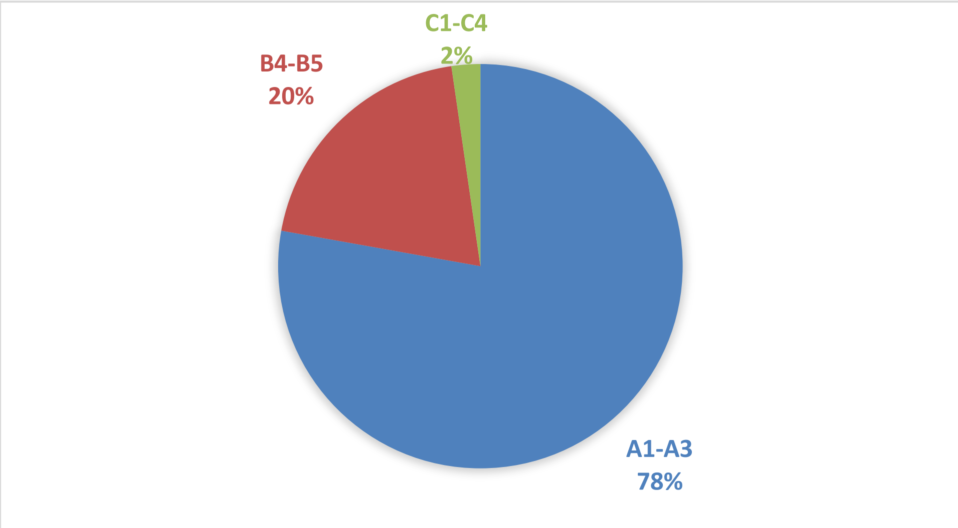

Figure 5. Distribution of %GWP, office buildings, Eastern Europe

Closing remarks

Finally, it is expected that as the sample grows the dataset will tend towards a normal distribution. This will facilitate its use in the performance metric shown in Figure 2. However, it is also possible that underlying effects are responsible for the spread in the dataset. This will be subject of future analysis and could lead to explain what other factors are correlated with the embodied carbon in buildings, and help improve its representation in the Carbon Heroes Benchmark.

Inventory of the existing residential building stock for the purpose of environmental benchmarking

Verellen E, Allacker K

KU Leuven, Faculty of Engineering Science, Department of Architecture, Kasteelpark Arenberg 1 – box 2431, 3001 Leuven, Belgium

evelien.verellen@kuleuven.be

Abstract. The current renovation rate in Belgium is less than 1% and should be increased to 2,5% to reach the European targets to reduce the GHG emissions by 2050. There is a need to rapidly increase the renovation rate and at the same time guarantee that these renovations reduce the environmental impact on our planet. In order to define environmental benchmarks for existing buildings and their renovation targets, a better understanding of the existing building stock is needed. In this paper, the approach used to model the existing building stock is presented for the specific case of Leuven. The methodological steps, challenges and data gaps are presented in detail. The proposed building stock model uses GIS data in order to gain insights in the geospatial distribution of the impacts of the stock. These spatial maps moreover allow to clearly visualise the impacts which can improve communication and contribute to policy actions.

1. Introduction

The construction sector is responsible for 30% of the resources used in Europe as well as for 40% of the energy used and 36% of greenhouse gas (GHG) emissions.[1] According to the European Commission, cities are responsible for the largest share of most environmental impacts, but provide also major opportunities for improvement.[2] Cities hence play a crucial role in the aim to move towards a more sustainable built environment.[3] The European Union targets to reduce the GHG emissions by 2050 with 80% to 95% compared to 1990.[4] Likewise, Flanders wants to evolve to low carbon, sustainable, reliable and affordable energy sources to achieve this European target.[5] The building sector has in many aspects already moved forward to a sustainable transition path as innovative products and new skills have been developed and the energy performance of new buildings has improved to a great extent. Nevertheless, the existing building stock in Europe, and likewise in Flanders, is still using a lot of energy and the refurbishment rate is too low to be able to reach the GHG emission reduction goals. Belgium aims at increasing the current (2016) annual renovation rate of less than 1% to 2,5%[6] through the 'Renovatiepact'. The Renovatiepact consists of various actions: increasing the renovation level of each building, gathering energy related information of each building and formulating renovation recommendations for each building. It is clear that a building-specific approach needs to be followed, mostly because of the highly privatized and hence very diverse building stock of Belgium.

This paper presents a methodology for a part of the inventory of the existing residential building stock in order to model its environmental impacts. The inventory focuses both on the geometry and energy performance of the buildings in order to have insights in the operational energy use of the buildings and to have all data required for a life cycle assessment of the buildings and renovation interventions. This forms the base of defining environmental benchmarks for the renovation of residential buildings in future research.

Building stock modelling typically uses either a top-down or bottom-up approach. In top-down methods the complete building stock is described at an aggregated level based on input-output modelling (urban metabolism). Bottom-up methods start with a set of individual stock components, buildings or building elements for example, and upscale these components to the complete stock level.[7] In this research the bottom-up approach will be used because this approach allows to identify the root causes of phenomena at stock level. So, this inventory consists of a detailed inventory at the individual building level which is then scaled up to the city level.

The methodology is elaborated for the city of Leuven which is selected as a case study due to its experience in carbon footprinting[8] and hence there is a relatively good data availability.[2] Leuven moreover has its own ambitious target to renovate 1000 buildings each year by 2030.[9] Which makes it an interesting case study. Finally, the carbon footprint of Leuven was previously calculated through a top-down approach[8] which will allow to (partially) validate our proposed bottom-up model. Although the research focuses on Leuven, the method is also applicable to other cities.

2. Methodology

2.1. Bottom-up approach

Two building stock aggregation models can be used in bottom-up approaches: the archetype and the building-by-building approach. The archetype approach uses reference buildings according to the characteristics of the building stock and represents the full stock based on these reference buildings. The building-by-building approach consists of modelling each building of the stock or a sample of the building stock in case of large building stocks (e.g. national level).[7]

For the goals of our study, the inventory of the existing building stock should be as detailed as possible in order to define an accurate environmental benchmark for the renovation of existing buildings. For this reason, the building-by-building approach is preferred over the archetype approach. Nevertheless, lacking building-by-building data are filled with proxy data from archetypes.

For the inventory of the building stock, data about the geometry, the location, the function and the energy performance are needed. The search for this data for each building of the building stock of the city of Leuven revealed that most of the data is directly available or can be derived in a sufficiently accurate way. Publically available Geographic Information System (GIS) data from Flanders[10] include the following information required for the stock model: ground floor area of each building, perimeter of each building and ridge hedge of each building. In addition, for the specific case of Leuven, more extended GIS data are available: construction year, building type, roof type, function of the building, number of floors and number of residential units. Energy consumption data (electricity and gas) are available from the energy distribution network operator (Fluvius) at street level together with the number of gas connection points per street. An overview of the available data is provided in table 1, indicating also which data are not directly available but can be derived from the other data. An important data gap for each of the buildings in the building stock is the thermal insulation level of the building envelope. For this data gap, proxies from the archetypes will be used in a next step of the research. The archetypes are defined based on the reference buildings of the IEE-Tabula project. In the subsequent sections the inventory of the various data is described in more detail.

Table 1 Overview of the sources of the data inventory.

Data	Available?	Data Source	Discussed in section

U-values	no	IEE-Tabula project	3

2.2. GIS
The building stock model developed for the city of Leuven is based on GIS data in order to gain insight in the geospatial distribution of the buildings and their current energy performance and environmental impact. Such geospatial inventory data have various benefits: these allow to identify priority neighbourhoods for renovation, allow to define archetypes for environmental benchmarking of existing buildings, allow to visualise results in a clear way and allow to model effects of future scenarios.[7] Mapping the energy consumption or life cycle environmental impact of buildings results in clear visualisations can be very helpful for public administrators regarding their policy plans[11] and to improve the communication and strengthen their decisions according to their policy.

The building-by-building data in our GIS stock model are a result of the combination of the GIS data from Flanders and the GIS data from Leuven. The building datasets of Flanders include the address and geometry data while the building datasets of Leuven contain the construction year, roof type and building function(s). The combination of these data are presented in the sections 2.3 to 2.7.

2.3. Data collection
The geometric data needed for each building in the stock model is partly provided by the open data of the Flemish region, and partly by the city of Leuven (not publicly available). The datasets from Leuven and the Flemish region are GIS data. With these data the building stock can be modelled regarding the area of the ground floor, the perimeter of the building, the building height, address, the number of floors, the number of residential units, the construction year, the building function and the roof type. These data is mostly available for 96,7% to 100% of the buildings, except for the number of residential units where the data availability is only 22% and for the construction year with an availability of 60%. This means that for 13.619 buildings the construction year is lacking. In section 2.7 it is described how these lacking data are filled. The area of the walls are unknown, but based on the perimeter of the building, the roof type and the building height, estimations can be made. In future, the assumptions can be replaced by real data when these become available in the GIS datasets of the city or region, or may be filled with real building-by-building data based on measurements of specific projects.

2.4. Energy consumption at street level
With the Fluvius data regarding gas consumption per street and number of gas connections per street, the gas consumption of each building in the stock can be estimated. A first estimate of the average gas consumption per square meter floor area of the residential building stock in 2017 is calculated and presented in figure 1. This average is calculated by dividing the total gas energy consumption of a street by the total area of the buildings of that street. This calculation does not take the energy performance of the buildings into account, so these values are street averages, not building specific values. In future the

allocation per building can be improved when the insulation of the buildings is known. This first estimate however already reveals where the largest energy consumers are located and hence allows to identify the energy problematic neighbourhoods of a city.

Figure 1 Overview of the average gross gas energy consumption of the residential buildings of each street per square meter in 2017 in Leuven (kWh/(m².year))

2.5. Building typology

The GIS data obtained from Leuven do not provide information about the building type. It is hence not clear if a building is a detached building, terraced building, semi-detached building or apartment. This information is however important to calculate the surface of the building envelope and the related energy transmission losses, since the energy transfer is different for separating walls and exterior walls.

To define the building type for each of the buildings in the stock model, the following approach is used. For each GIS dataset (building), the GIS software allows to define if the building (polygon) is attached to one or more neighbouring buildings (polygons). These results are combined with the available information regarding the building function (apartments and single-family houses) and the information in the dataset regarding the fact if it is a main building or an annex building. Annex buildings (e.g. garages) have been excluded from the datasets in order to ensure that two buildings with two garages in between (figure 2) are considered as detached instead of terraced buildings.

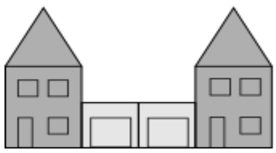

Figure 2 By excluding annex buildings (e.g. garages) from the GIS data, the main buildings (dark grey) are classified as detached houses.

The distribution of derived building types for Leuven is visualised in figure 3. By visualising buildings with similar properties, it becomes clear that the majority of the residential buildings are terraced buildings (13.521 (42,3%)), and the minority are apartment buildings (2.142 (6,7%)). The detached and semi-detached buildings are respectively 7.564 (23,7%) and 8.743 (27,3%) buildings. Further, in the visualisation it becomes clear that almost half of the terraced houses and apartment buildings are situated inside the city centre of Leuven, for the (semi)-detached houses only 20% are situated inside the city centre. So the distributions inside and outside the city centre are clearly different.

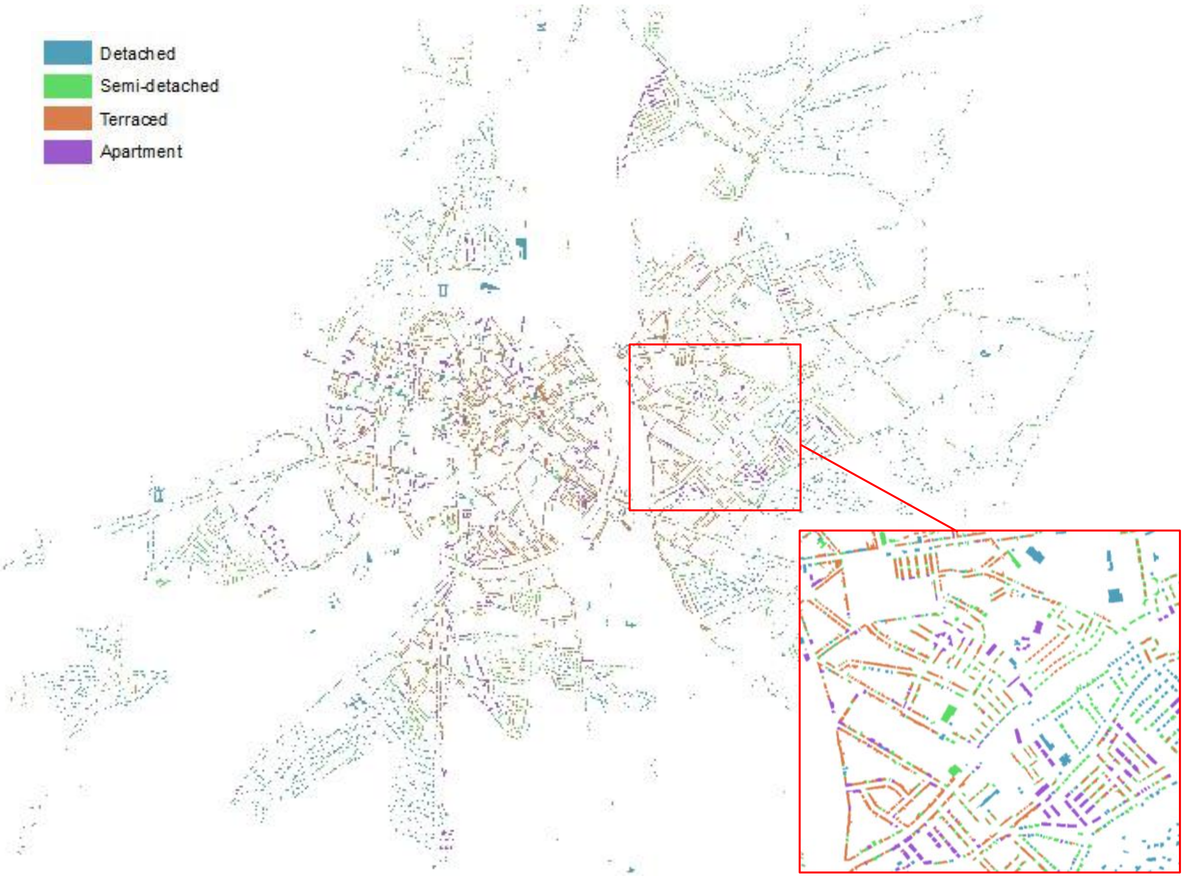

Figure 3 Overview of the building typologies of the residential buildings in the city of Leuven.

2.6. Coupling of GIS datasets from different sources

The datasets provided by Leuven and by Flanders were not compatible. The FME (Feature Manipulation Engine) software is a platform for data integration specialised in spatial data and has been used to couple both GIS datasets in our study. The following matching procedure is used (figure 4): for each polygon the coordinates of a central point are defined. In the FME software, the coordinates of the central points of both datasets are matched and the datasets are combined based on these matching coordinates.

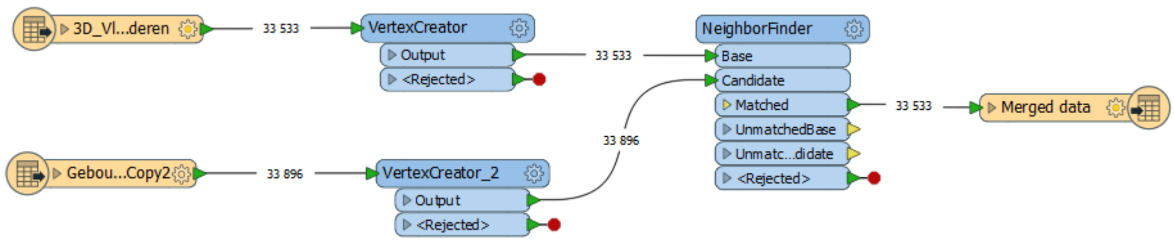

Figure 4 Matching procedure of the two datasets in FME.

2.7. Data gaps

As mentioned in section 2.3, for some buildings the roof type and/or construction year is lacking in the GIS data from of Leuven. These data had to be filled in to make a complete building stock model. The data gaps are filled in based on statistical data regarding construction years and roof types of buildings in Leuven for which these data are known.

2.7.1. Roof types Firstly, the buildings with undefined roof types are identified. Secondly, for each building type, the percentage of flat roofs and pitched roofs is calculated based on the dataset of Leuven. Thirdly, each building with an unknown roof type is assigned a roof type according to the percentages calculated. The unknown data of roof types are geospatially randomly allocated to the buildings belonging to the specific category.

Table 2 Distribution of the roof types and construction years of the detached buildings in Leuven.

detached							
<1945			% total known	% distribution of known		distribution of unknown

flat roof	pitched roof	% flat					
398	1812	18,01%	5354				
			total unknown				
			2210				

2.7.2. Construction years. Using a similar approach, the unknown construction years are defined. Of the 7.564 detached buildings, the construction year is unknown for 2.210 buildings (41%) (see table 2 for the detached houses). Firstly, the buildings with an unknown construction year are identified (2.210). Secondly, table 2 is set up for each of the building types, in this table all the buildings with a known construction year (5.354) are counted according to their construction year and roof type. For example, of all the 7.564 detached houses, 67 have flat roofs and are built before 1945. This means that for the period before 1945, only 12,41% of the detached houses have flat roofs. In a next step is defined how many detached houses are constructed in each construction period, for instance 10% of the detached houses is built before 1945. With these numbers, the distribution of the known construction years can be calculated according to their roof type. For example, 19% of the detached houses with pitched roofs are built in 1991-2005. When these percentages are multiplied with the number of buildings with an unknown construction year, the number of buildings for each construction period are known. So, table 2 shows that 183 buildings with an unknown construction year and a pitched roof have been assigned the construction period 'before 1945'. This allocation of construction years is done in a geospatial random way. These construction periods are in accordance with the construction period of the IEE-Tabula project: before 1945, 1946-1970, 1971-1990, 1991-2005, 2006-2011 and after 2012.[12]

3. Conclusions and future outlook

The building stock model developed in our study combines a building-by-building and an archetype approach to make a model that includes all data needed to model the energy performance, material amounts and environmental impact of the buildings, with information on their geospatial location. The geometric data of all buildings in the stock is mainly based on building-by-building data, either directly retrieved from GIS datasets from the city or the region or calculated based on other data from the GIS datasets. For the buildings where geometric information is lacking, statistical data were used to fill the data gaps. The FME software is used to couple the various GIS data sources.

Although the research focuses on the city of Leuven, the used approach to model building stocks is also applicable to other cities. The method proposed can however only be used if GIS data of (part of) a city are available. GIS data of building stocks are available for a growing number of Flemish cities and it is expected that in the near future the majority of the cities will have such GIS model.[13] In Flanders these data are combined in the GRB-tool (Grootschalig Referentie Bestand) and are publically available. The European Commission furthermore aims to create a European spatial data infrastructure with the tool INSPIRE (Infrastructure for Spatial Information in the European Community) to provide public sector data in a practical way.[14,15]

In a next step of the research, the geometry characteristics will be combined with energy performance characteristics. When the U-values of the construction elements are known, the energy losses of the buildings can be estimated, environmental benchmarks defined and renovation strategies proposed. Furthermore, this will allow to identify the main drivers of the total energy consumption of the building stock and consequently efficiently reduce the energy use of the building stock. The collection of the U-values is less obvious because of privacy issues. These data are not available for the various buildings in the stock and hence a building-by-building approach is not possible. The archetype approach will be used differentiating in U-value for the various elements of the building envelope per construction period, roof type and building type. Based on the statistical distribution of the building types and construction periods of each building in the stock, the representative values of the archetypes can be linked to the buildings in the stock. And based on these proposed U-values, the energy consumption can be calculated at the level of a building or for the whole building stock. Further investigation is needed on how renovations in the past can be included in the model. Potentially, the gas consumption at street level and at municipality level might be used to validate the estimated U-values and to correct these based on statistical data on renovation measures have already been done in the past. For the U-values of representative buildings, the IEE-Tabula project might be helpful. In the Tabula project, U-values are defined for different construction periods and building types.[12] Combining the U-values and the corresponding energy consumption with the geometric building stock model, will result in a complete building stock model including spatial data (SBSM – Spatial Building Stock Modelling)[16] where hotspots and improvement potentials can be defined for each neighbourhood of the model.[7]

The building stock model that is under development will allow to identify how future renovation measures will allow to reduce the energy consumption of the stock and its implications regarding the life cycle environmental impact of each building in the stock as well as for the stock as a whole. As the geometry of the building stock and the construction period of the buildings are collected, an inventory of the materials in the building stock can also be made and consequently the environmental impact of the stock can be assessed. In Europe, life cycle assessment (LCA) is more and more integrated in building practice to reduce the environmental impact of buildings.[17,18] As LCA is mostly used in comparative studies, benchmarks should be defined so that targets can be set to support policy making and tracking of the achievement of policy goals. In order to allow for defining such environmental benchmarks for existing buildings and their renovation, this paper presents how an inventory of the current building stock can be made that will allow to gain insight in their environmental impact.

Abstract. While ambitious environmental objectives are being set for new constructions in Switzerland, the assessment of urban-scale projects and comparison of their performance to national targets are made possible by a growing number of life-cycle assessment (LCA) tools. However, previous research emphasizes the lack of existing tools to support the decision-making process at the early design stage, characterized by a low level of project details. This paper presents a comparison between three LCA tools. The first, stemming from a research and development project (SETUP), is an exploration tool relying on a database of urban-level scenarios and their environmental performance, able to convert district targets (e.g. 2000-Watt society objectives) into specific sub-targets at the building or component levels. The other two are online LCA tools currently available to practitioners (Sméo and Calculation tool for 2000-Watt-society-sites RH II), that allow assessing the project and verifying its compliance with a given target. Each tool was applied to a low-carbon case study, the blueFactory district in Fribourg (Switzerland), in two hypothetical contexts corresponding to the schematic and detailed project development phases, characterized by different levels of details. When used for the assessment of a project at a more advanced development stage with a high resolution of detail, findings indicate that Smeo and RH II provide similar environmental performance results. However, in early planning stages, SETUP shows better abilities to support decision-making by providing ranges of results and highlighting uncertainties and the influence of design parameters that have not yet been fixed.

1. Introduction

On the global level, the building sector has a major impact on the environment, being responsible for approximately 32% of final energy consumption and 19% of related CO2 emissions [1]. In the context of climate change mitigation reinforced by the Paris Agreement [2], countries have been developing, implementing and strengthening national plans and targets for decreasing the environmental impact of the built environment. Switzerland introduced the 2000-Watt Society vision, that sets the pathway to limiting the total primary energy use to 2000 Watts per person and greenhouse gas emissions to 1 ton per person by the year 2100 [3], with intermediate goals for the year 2050 [4]. Accordingly, the Swiss

Society of Engineers and Architects (SIA) defined targets for the building sector, with non-renewable cumulative energy demand (CEDnr) and global warming potential (GWP) as the main assessment metrics [4].

Life-cycle assessment (LCA) is a well-recognized method for estimation of the environmental impacts from the product phases, over the construction process and use, and up to the end-of-life [5]. Even though LCA is widely used for benchmarking the finalized construction project to environmental targets, its application is essential for guiding the practitioners during the design process at early planning stages. As notably stated by the SIA, "*important decisions for the achievement of the target values are made in the early planning phases (strategic planning, preliminary studies and preliminary project)"* [4]. Moreover, the application of LCA is extending beyond the scale of individual buildings (building labels such as Minergie-ECO [6] or new concepts such as Life Cycle-Zero Energy Building LC-ZEB [7]), to considerations at larger scales such as neighborhoods and cities [1,8–10].

LCA-based tools for urban level projects need to fulfill numerous requirements [11], and their application at early design stages faces several challenges [12]. Tools are needed for exploration of interrelations between specific design choices and their influence on the project performance as early as the beginning of the project, in the context of high uncertainty, lack of information and low resolution of project details. The objective of this study is to assess the ability of LCA tools to support the decision-making process for urban–level projects, and to better understand the type of results they are able to provide.

Testing LCA tools is hardly possible by referring to empirical evidence from the real life context (e.g. analysis of energy bills within Building Energy Simulation Test (BESTEST) [13]), due to the system, spatial and temporal boundaries for life-cycle impact assessment of urban-level constructions. Therefore, the study compares LCA-based tools that are currently available to practitioners in Switzerland.

2. LCA-based tools

Three LCA-based urban-level tools developed for the Swiss built environment context are identified: SETUP, which stands for Specific Environmentally-conscious Targets for Urban Planning, Smeo Red thread for sustainable construction (Fr. Sméo Fil rouge pour la construction durable) [14], and Tool for 2000-Watt-Society-sites (Ger. Rechenhilfe II für 2000-Watt-Areale, RH II) [15]. The comparisons are possible because the environmental evaluation relies on national databases of life-cycle impact values and SIA standards and norms. The three tools are characterized and compared according to eight categories identified by Bach and Hildebrand [16]. Most important features of the tools are presented in Table 1.

The main purpose of SETUP is to decompose environmental targets from district- to building-, domain- (construction, operation, mobility) and component (e.g., windows) levels, and to facilitate exploration of databases of project alternatives and relating environmental impacts of individual plots within the district at early-planning phases [17]. A proof-of-concept was developed for the blueFactory district in Fribourg, which aims to be low carbon (Figure 1). Project alternatives for each plot were created by varying 17 building parameters (e.g. building shape, depth, height etc.), and assessing operational, embodied impacts and building-induced mobility. The database thus generated includes a large number of project alternatives, sampled through the Sobol low discrepancy method (for more information see: [17]). An Excel-based VBA prototype tool allows exploring these pre-simulated databases. Input-data comprises values for construction areas per plot and building use, and the selection of a reference target for the whole site (from a certification system or building label). Outputs include: decomposed site-level performance targets (CEDtot, CEDnr and GWP) into differentiated sub-targets per plot, building program, domain and component, frequency (number of occurrences) of scenarios that are meeting different target values, influence of variable parameters (geometry, components, technical installations, etc.), and graphical presentation of (un)favorable options through a decision tree.

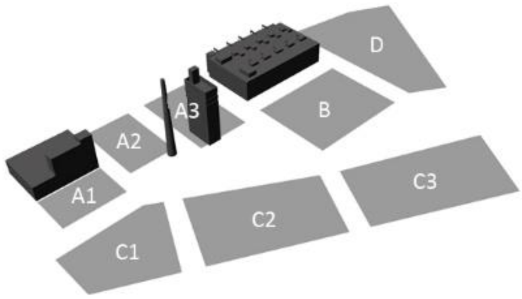

Figure 1. Existing buildings and plots on the blueFactory site, as defined for the SETUP tool.

Smeo assesses the sustainability of a project by addressing its environmental, economic and social domains and applying the Hermione method, which aggregates a number of quantitative and qualitative criteria [18]. Through a preliminary section of the internet platform, the project is characterized by selecting its scale (building or site), main program (residential, administration, etc.), type (new constructions, renovations, use, and transformation), phase (initiation, masterplan, district plan, realization, and use) and stakeholder. Accordingly, the suitable interface with input fields opens in the first out of several tool sections. For the purposes of this study, i.e. district-level new construction project at early and advanced planning phases, the interface offers three main sections. The General Data section is the same for both phases and it comprises input fields regarding urban-level parameters, embodied, operational impacts, mobility, etc. Beside dropdown lists with predefined data, required inputs often include aggregated parameter values, for all buildings within the studied district (e.g. floor space index, land use index, total footprint of assessed buildings, etc.), as well as adaptable default values. After entering the number of buildings within the district, the tool hypothesizes that all buildings have identical characteristics, thus not allowing the comparison of building alternatives and related impacts. The Detailed Results section is identically structured for both studied planning phases, and provides site-level results of the qualitative social and economic sustainability criteria, and the quantitative evaluation of environmental impacts (CEDnr, GWP and ecological scarcity points UBP for the entire site and per domain, illustrated in charts).

The main purpose of the third tool, RH II, is benchmarking the site-level project to 2000-Watt-Society targets. The data input begins with specifying the main project features, e.g. project type (new constructions, renovations, buildings in use), reference year for norms and targeted impacts (2030, 2050), project phase (according to SIA 112) and other data which determines the format of the user interface, requested input, software workflow, etc. Data is entered separately for each building. For the preliminary study phase, input is simple and intuitive with a lot of adaptable default values and dropdown lists, which requires only general knowledge from the user. In contrast, the module for the project execution phase requires more detailed input of numerical values for embodied and operational impacts, transferred from independent software, which might require expert skills. In this case, boundaries of LCA depend on the external software. The type of data outputs for both project phases is identical: on site and building scales, numeric values per impact category (CED, CEDnr and GWP) per domain and in total, with corresponding graphs for the site level indicating compliance or not with the 2000-Watt-Society targets.

Table 1. Comparison of three LCA-based tools according to [16].

	SETUP (prototype)	**Smeo**	**RH II**
Origin	EPFL Fribourg, Switzerland, 2019	City of Lausanne and Canton of Vaud, Switzerland (www.smeo.ch), 2009	Federal office of Energy OFEN, Zurich, Switzerland (www.local-energy.swiss), 2018

Data source	CEN EN 15978, KBOB 2009/1:2016, SIA 380/1:2016, etc.	SIA 112, KBOB 2009/1:2012, SIA 380/1:2009, etc.	SIA 112, KBOB 2009/1:2014, etc.
Required user's knowledge	No prior knowledge	Basic knowledge	Expert knowledge
Accessibility	Conditional access (project stakeholders)	Free access (registration needed)	Free access (registration needed)
Entry format	Spreadsheet	Input fields and dropdown lists	Input fields and dropdown lists
Level (scale)	District-, plot- and component-levels	District-level	District- and building-levels
Default settings	Default settings	Default settings partly available	Default settings partly available
Life cycle phases	According to CEN EN 15978: Product (A1-3), Use (B6), End-of-life (C1-4)	According to SIA 112 project phase; project planning construction and use phases	According to SIA 112 project phase, but also dependant of system boundaries of external software

3. Comparability of the tools

In order to better understand differences among workflows and discrepancies between impact assessment results, the tools are applied to the urban-level project in the advanced stage, characterized by a high resolution of project detail. The comparison is focused on embodied and operational impacts, without considerations of building-induced mobility, because these impacts do not influence the design process. The case study is the hypothetical project illustrated in Figure 2 for the blueFactory site introduced earlier.

Impact assessment of the blueFactory site focuses on ten administrative buildings, three of which also have residential use (plots C1 and C2, see Figure 1), with total area of approx. 126 000 m^2. Buildings have rectangular floorplans and north-south orientation of the longer facades. Buildings' depth is 18-30m and height 3-15 floors. Window-to-wall ratio on all facades is 0.65 for the office buildings and 0.5 for the apartment buildings. Triple glazed windows (U-value: 0.5 W/m^2K) have wooden frames (U-value: 1.3 W/m^2K), and the thermal transmittance of external walls and roof is of 0.1 W/m^2K. Construction of roof, interior floors and external walls are defined according to the Swiss construction catalogue (concrete slab [E0 B01] and wall [W W04]) [19]. Thermal insulation is polystyrene, covering slab material linoleum and covering material of external walls is cement panels. 90% of the total roof surface is covered with PV systems. The HVAC system is a heat pump, with coefficient of performance COP=2.43.

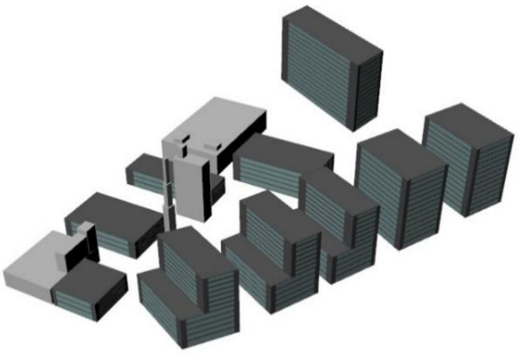

Figure 2. Urban massing volumes of the hypothetical project (blueFactory site case study) in the advanced planning phase.

The assessment of the environmental impacts of the hypothetical project in its advanced planning stage is performed in SETUP and Smeo, and the results are shown in Figure 3. RH II is excluded from this first experiment, as it requires inputs deriving from external simulation software.

	CEDnr Construction	CEDnr Operation	CEDnr Total	GWP Construction	GWP Operation	GWP Total
SETUP	47.84	34.50	82.34	14.01	0.86	14.87
Smeo	42.22	41.67	83.89	15.70	2.60	18.30
Impact target	38.69	77.37	116.06	9.00	3.74	12.74

Figure 3. Results in terms of CEDnr (left) and GWP (right) impacts computed with SETUP and Smeo, compared to environmental targets defined by SIA [4].

The construction CEDnr impacts computed with Smeo is 5.6 kWh/m^{2}a lower than the value obtained with SETUP, which corresponds to a relative change of 11.7% (compared to SETUP). In terms of GWP impacts, the Smeo result is higher by 1.7 kgCO_2/m^{2}a, which is equivalent to a relative change of 12% compared to the SETUP result. Discrepancy of embodied impacts of construction might be explained by the mismatch between component options offered in Smeo (e.g. external walls, floor slabs, roof, etc.) and those set for the case study, which were based on options available in SETUP. Therefore, the selection in Smeo was done to match the desired components as close as possible, in terms of types and thermal properties of materials.

Compared to SETUP, absolute increase of CEDnr operational impacts computed with Smeo is 7.2 kWh/m^{2}a, which is in terms of relative change 20.8%. Considering GWP impacts, the 1.74 kgCO_2/m^{2}a difference represents as much as a 202% increase from the Smeo to the SETUP result. This gap might be explained by different energy conversion coefficients derived from distinct versions of KBOB databases (data sources, see Figure 1), and different boundaries for the impact assessment of the electricity produced by the PV systems. Indeed, Smeo does not take into account positive impacts of electricity exported to the grid, in comparison to SETUP where the calculation is based on [20], which states that this positive impact should be accounted for.

Environmental impact assessment of the project in its advanced phase is possible, despite methodological differences and heterogeneous inputs and outputs between SETUP and Smeo. It should also be noted that impact results in SETUP are obtained by identifying a specific project alternative from the database of pre-simulated projects (see: [17]). However, due to the extent of the database (limited sample size), it is not always possible to identify the desired project alternative, because this particular scenario might not exist in the database.

4. Application of tools in early planning phase

At the beginning of the planning process, urbanists need to make decisions regarding the design parameters on building scales, and understand the implications of their design choices on the environmental performance of the site in later phases of its life cycle. The ability of the LCA tools SETUP, Smeo and RH II to facilitate the decision-making process is tested by answering a design question, formulated according the findings of a survey on the current use of LCA tools in building design [21]. More than 80% of survey respondents (out of 263 practitioners) are considering building shape and orientation as design parameters during the early project phase. Accordingly, our design question is: “Which design choices relating to building shape and orientation would increase the feasibility of the construction project and contribute to meeting environmental targets?” Tested variable parameters include bar-shaped buildings with north-south orientation of longer facades (I N-S), same shape with east-west orientation of longer façades (I E-W), “L” shape (L), “U” shape (U) and atrium shape (O).

To be able to answer the design question, the assessment in Smeo and RH II must be performed through an iterative process, in which only the tested parameter is changed while all other parameters are kept constant. Therefore, the hypothetical project for the blueFactory site in its early planning phase is defined by a set of assumptions. Impact assessment of the site level project comprises administrative buildings, with varying area according to the building shape. Other hypotheses correspond to those set for the project in the advanced design stage, excluding the PV systems, as the calculation of operational impacts between SETUP and Smeo significantly differs (see Section 3). Relating parameters are adapted according to the input format of each tool (e.g. Smeo requires inputs such as floor space index, length of buildings perimeters, etc., while RH II needs data regarding each building such as building footprint and thermal envelope factor). On the other hand, SETUP relies on the database of project alternatives (Section 2) and requires input of building program and area for each plot, which is in total 104 000 m^2.

5. Answer to the design question

The illustration of the impacts of masterplan alternatives with equally shaped buildings (Figure 4), shows an incoherence between selecting a building shape according to the mean and median (SETUP) and minimum (RH II and Smeo) impacts. Indeed, the shape with the lowest GWP differs according to the tool: it is I E-W for RH II, and I N-S for Smeo and SETUP (although there is an overlap with other distributions such as I E-W). A more detailed illustration of impacts related to project alternatives on individual plots (Figure 5) indicates more consistency among the three tools. Mean and median (SETUP) and minimum impact results (RH II and Smeo), presented in Table 2, indicate that the bar shape is most favorable for accomplishing compliance with the impact target. However, there is a mismatch in terms of selecting the building orientation (except on plots A2 and D).

Mean and median impacts are calculated in SETUP based on a high number of project alternatives, which are taking into consideration effects of the variation of other not yet defined design choices, and thus capturing the uncertainty aspect in early design. In contrast, the impacts computed with traditional tools derive from more definite range of results obtained from a manual iterative process in which only one parameter is varied. Therefore, higher reliability of making a decision on most favorable building shape and orientation according to SETUP results is argued by the representativeness of a distribution range of results.

SETUP indicates increase in feasibility indices from I N-S shape (FI = 8.1%) to O shape (FI = 10.1%) on the site level, and from plot A1 (FI = 4%) to plot D (FI = 64%) on the plot level (see Table 2). The compliant part of the distribution range of results includes variability of uncertain design parameters, and thus indicates a high number of feasible project alternatives. On the other hand, RH II results demonstrate that none of the considered project alternatives is feasible, while Smeo assumes uniformity between the buildings and demonstrates compliance in one project alternative with I N-S shape.

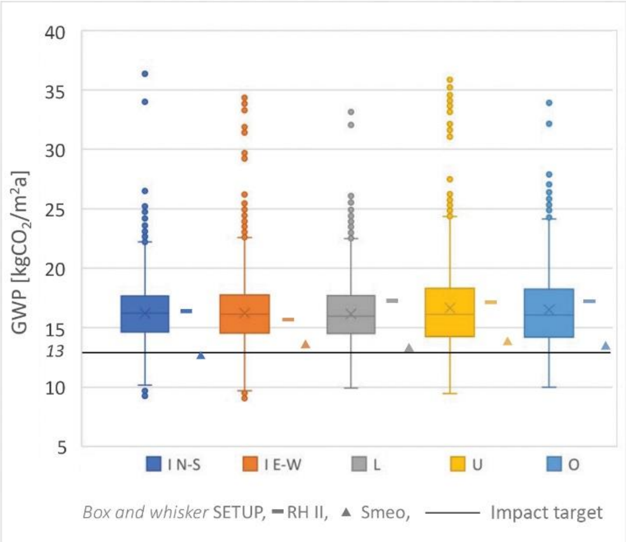

Figure 4. Site-level GWP impacts of master plan alternatives composed of buildings with uniform shape, compared to environmental targets defined by SIA [4].

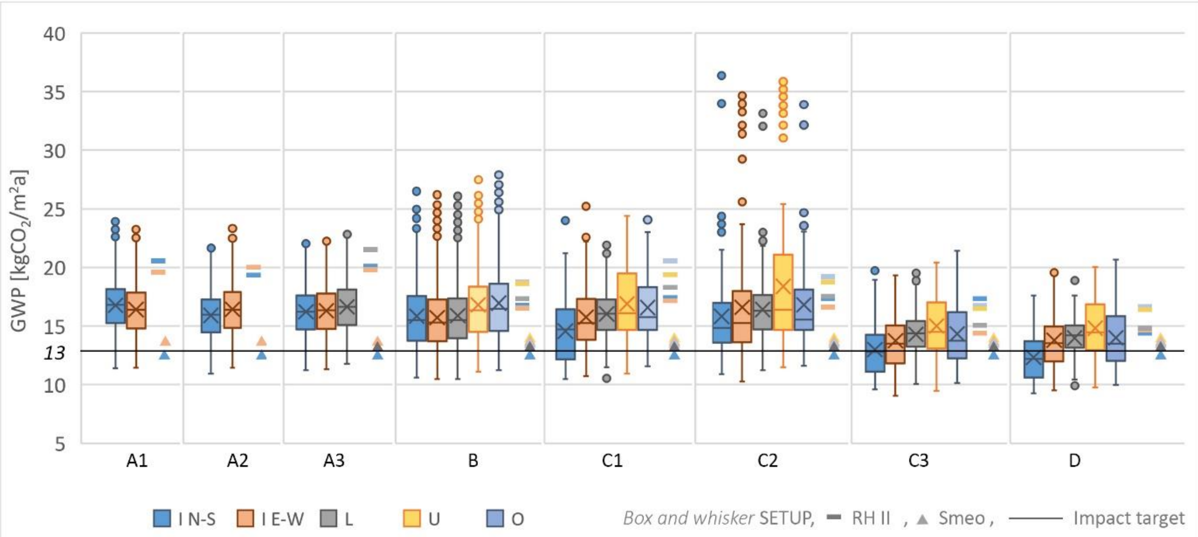

Figure 5. Plot-level GWP impacts of project alternatives with variable shapes.

Table 2. Building shapes and orientations, GWP impacts and feasibility indices for individual plots.

		A1	A2	A3	B	C1	C2	C3	D
Setup	Shape and orientation	I E-W	I N-S	I N-S	I E-W	I N-S	I N-S	I N-S	I N-S
	Mean GWP [$kgCO_2/m^2a$]	16.44	15.99	16.21	15.90	14.71	15.85	13.24	12.64
	Median GWP [$kgCO_2/m^2a$]	16.41	15.98	16.23	15.31	14.71	14.88	12.82	12.18
	Feasibility index [%]	3.95	8.11	5.46	18.49	36.65	20.37	54.32	64.20
RH II	Building shape	I E-W	I N-S	I E-W	I E-W	I E-W	I E-W	I E-W	I N-S
	Lowest GWP [$kgCO_2/m^2a$]	19.80	19.30	19.80	16.70	17.30	16.70	14.50	14.50
Smeo	Building shape	I N-S	I N-S	I N-S	I N-S	I N-S	I N-S	I N-S	I N-S
	Lowest GWP [$kgCO_2/m^2a$]	12.70	12.70	12.70	12.70	12.70	12.70	12.70	12.70

6. Discussion. Decision-support and ability to lead the design process

Difference between lowest (L) and highest (I N-S) median GWP values is 0.26 $kgCO2/m^2a$, and between lowest (L) and highest (U) mean GWP values is 0.5 $kgCO2/m^2a$. As SETUP results are more representative, they can be used for demonstrating the low sensitivity of building shape to GWP impacts, which can direct the attention of practitioners to another parameter in following steps of design process.

Increase in feasibility indices from simple bar shape to more complex atrium shape relating to the site level, and from smaller plot A1 to larger plot D, relating to the plot level, can be explained by embodied impacts normalized by m^2 which are disproportionate to size and complexity of constructible volumes. For instance, smaller plot A1 cannot facilitate construction of L, U and O shaped, but only bar buildings with maximum 5 floors, while larger plot D is suitable for all building shapes, with maximum height of 18 floors. SETUP reveals a wider approach to assessing the project compliance by exploring a series of project alternatives that are incorporating unknown design parameters. This uncertainty is opening the possibility for exploration of scenarios and identification of design parameter values that all feasible scenarios have in common.

Ranking of impacts calculated with traditional tools is matching the ranking of mean and median values within distribution range, however they do not fall into the interquartile range, for most of the alternatives. Limited insight to slightly differentiated or totally uncompliant project alternatives, might direct the design process to incorrectly defined assumptions regarding yet unknown parameters, and also point to the differences among contextual characteristics of plots (e.g. shading effects across the site).

Graphical representation of impact results with box and whisker plots illustrates a probabilistic approach in early design and reveals the richness of considering uncertainty. Compared to the limited number of results computed with traditional tools according to one variable parameter, mean and median, maximum and minimum impacts and interquartile range are integrating the effects of the design choices that have to be made in the following steps of the design process. Outliers theoretically represent false results that should be removed from the database. If we however assume that outliers here correspond to scenarios that are valid and not erroneous, this emphasizes that we might be misled by the initial assumptions about the project.

7. Conclusion. Importance of uncertainty in decision-support

LCA at early planning stages exposes several challenges. It is difficult for urbanists to fully anticipate the links between their design decisions and the later project performance when the resolution of project detail is low and the scale extends beyond a single building. In order to perform life cycle assessment, they need to define a high number of hypotheses regarding the unknown parameters. Even with project assumptions, it is not yet possible to demonstrate the robustness of impact results on life cycle scale, as the reference for validation of LCA method is missing (e.g. BESTTEST). Therefore, three methods developed to provide decision support in early stages (among other purposes) are tested in this study.

Traditional LCA-based tools used in Switzerland are applicable for the impact assessment of the urban-level project at advanced stages of design, with the main purpose to benchmark the project against environmental targets. In early design stages, testing the comparativeness of outputs reveals the value of distribution range of results and the importance of integrating the uncertainty aspect. Since we are unable to confirm that LCA results are absolutely correct, it is still challenging at this point to compare the project with the target. SETUP provides a broader view on project compliance with ranges of results representative of many design choices. The risk of making incorrect conclusions is decreased, as we are able to explore common design choices within feasible project alternatives. Wide space for exploration of the project is available precisely due to the presence of uncertainty linked to the project. In contrast, results from traditional tools are straightforward, as they derive from an iterative process that mainly focuses on the adaptation of input parameters in relation to the outputs (one-step at the time method which defines only several points in the planning process). Results may vary from totally compliant to totally uncompliant, therefore it might be premature to take decisions based on LCA at early design stages. Without the uncertainty aspect, traditional tools might be referred to as compliance or confirmation tools, rather than decision-support tools.

Abstract. To reduce the environmental impact of the building sector, environmental targets should be defined considering the full life cycle of buildings. In recent years various benchmarks based on Life Cycle Assessment (LCA) have been developed as part of regulations, labelling systems and sustainability rating tools. This paper presents the results of a critical analysis of six existing benchmarking systems. An overview is given of the different benchmark approaches, scope, applications and communication. The strengths and weaknesses of the various systems are highlighted. Based on the analysis, recommendations are formulated for the development of future LCA benchmarks for the building sector.

1. Introduction

The building sector has a major impact on the environment. In Europe, this sector is responsible for about 50% of the use of natural resources, 40% of the energy use and 16% of the water use [1]. Buildings are furthermore responsible for 36% of the total CO2 emissions in the EU [2].

As recommended by the European standard EN 15978 [3], Life Cycle Assessment (LCA) is an appropriate method to assess and optimize the environmental impacts of buildings over their entire life cycle. In Belgium, where this research was conducted, several steps have been taken to mainstream the use of LCA in building practice, including the development of a national LCA method, a database of Environmental Product Declarations (EPDs) and a web-based calculation tool for architects [4].

In a next step, reference values or benchmarks should be defined to support policy makers in the definition of environmental targets for buildings. These LCA benchmarks would allow architects and building stakeholders to position themselves in the market and consequently to further push the construction sector in reducing its environmental impacts.

In contrast to energy performance benchmarks which are well established in building practice, the development and implementation of LCA benchmarks is still in its early stages [5]. Since 2018, the life cycle environmental impact of new buildings in the Netherlands is restricted to a maximum value per m² floor area per year [6] and classes of environmental performance of residential buildings have been defined [7]. LCA benchmarks are furthermore used in a number of labelling systems such as the French initiative "E+/C-" [8, 9] and integrated in sustainability rating tools such as BREEAM [10].

The aim of this paper is to critically analyse existing benchmarking systems, focusing mainly on methodological aspects but also on their applications and how these are communicated. The strengths and the weaknesses of the various approaches and methods are highlighted. Based on this analysis, recommendations are formulated for the development of future LCA benchmarks.

2. Evaluation aspects

In order to critically analyse benchmarking systems and identify the main approaches and methods, a list of evaluation aspects is defined based on existing methodological reports and literature reviews on LCA benchmarks [11–13]. Four main aspects, including various sub-aspects are investigated:

- Definition of benchmark values: comparative base, benchmark approach, benchmark typology and sources for benchmark;
- Benchmark scope: life cycle stages and environmental indicators covered;
- Benchmark applications: building types, new construction and/or refurbishment projects;
- Benchmark communication.

3. Selected benchmarking systems

Six representative benchmarking systems are selected for a critical analysis. These include benchmarks from regulations, labelling systems and sustainability ratings tools. As regulatory tool, the legal requirements on the environmental performance of buildings in the Netherlands ("MilieuPrestatie Gebouwen" (MPG)) are evaluated [6, 7]. Two labelling systems are selected: the French initiative "E+/C-" [8, 9] and the Swiss SIA Energy Efficiency Path (SIA 2040) [14, 15]. Finally, LCA benchmarks implemented as part of three well-known sustainability rating tools are analysed: BREEAM Home Quality Mark (version 2018) [10], DGNB for new buildings (version 2018) [16] and LEED for Building Design and Construction (version 2019) [17].

The selection is based on existing review studies [11, 12] and aims at providing a wide overview of possible approaches and methods. It does not reflect any a priori preference between the benchmarking systems. Next to the implementation of benchmarks in regulations, labels and rating tools, various research studies focus on defining environmental benchmarks for buildings [18–26]. These studies are excluded from the critical review as benchmarks implemented in building practice were focused on.

4. Evaluation of the selected benchmarks

In this section the results of the critical analysis are presented, subdivided according to the four main aspects defined in section 2. For each aspect, the strengths and weaknesses of the different approaches are described and recommendations are formulated.

4.1. Definition of benchmark values

An overview of the approaches followed to define benchmark values is given in Table 1. Concerning the applied comparative base, the benchmarking systems can be classified in two groups: external and internal benchmarks [11]. External benchmarks are representative values for the environmental impact of a category of buildings within the building stock and serve as comparative base for buildings from that category. In case of internal benchmarks, an internal comparison is done based on a baseline building with geometrical and context features similar to the project. The majority of the analysed benchmarking systems are external benchmarks; only LEED falls into the second group.

Compared to internal benchmarks, two main advantages of external benchmarks are identified [12]. First, external benchmarks allow for a comparison between the environmental performance of the project and the building stock and hence a positioning within the market. Second, the impact of the full design in terms of building geometry, material choices and energy performance can be assessed while internal benchmarks are limited to the influence of material choices. Therefore internal benchmarks should only be preferred when there is a lack of data to model the impact of the building stock and derive representative external benchmark values.

In order to define external benchmark values, two approaches can be followed which are closely related to the data sources [13]. The first and most widespread one is a bottom-up approach consisting of values derived from a statistical analysis of the building stock. This can be done by analyzing a set of representative real buildings, as in E+/C- and DGNB, or by defining virtual (generic) buildings or archetypes, as in MPG. The second is a top-down approach which defines benchmarks based on global environmental goals or policy targets translated to the building sector. This approach is used in a number of research studies [18, 19], which are not analysed in this critical analysis. More rarely, a combined top-down and bottom-up approach is followed, such as in SIA 2040.

Both the bottom-up and top-down approaches have their strengths and weaknesses. The main strength of the bottom-up approach lies in the derivation of feasible benchmark values based on currently available construction methods and technologies. This approach however requires sufficient data to define representative reference buildings and market variations. The main advantage of the top-down approach is that it allows to derive long term target values to fulfill environmental goals and policy targets. The main drawback is that it implies the availability of global targets for the assessed impact indicators and an appropriate procedure to allocate part of these overall goals to the building sector. As both approaches provide complementary insights, a combined top-down and bottom-up approach is seen as the best way forward. Such hybrid approach allows to define long term target values (top-down) and to investigate their practical feasibility based on a statistical analysis of the building stock (bottom-up).

Table 1. Definition of benchmark values

	Comparative base	Benchmark approach	Benchmark typology	Sources for benchmark
MPG	External	Bottom-up	Limit value	Statistical analysis of 5 virtual residential buildings and 1200 virtual variations (dimensions, material and technical choices)
E+/C-	External	Bottom-up	- Reference value (Carbon level 1) - Best practice value (Carbon level 2)	Statistical analysis of 115 real buildings including various functions, climatic zones, construction types and energy performances
SIA 2040	External	Top-down and bottom-up	- Target value (whole life cycle) - Reference values (embodied impacts, energy use and user transport)	- 2000W Society goals for 2050 (top-down) - Scenario analysis (bottom-up)
BREEAM	External	Bottom-up	Benchmark scale for score allocation	Statistical analysis of a sample of buildings
DGNB	External	Bottom-up	- Limit value - Reference value - 2 target values (standard and over fulfilment)	- Statistical analysis of real buildings [27] - Results of DGNB certifications - Long-term DGNB objectives
LEED	Internal	Not applicable	Not applicable	Comparison with baseline building (building with comparable size, function, orientation and energy performance)

Concerning the benchmark typology, the majority of the analysed benchmarking systems combines different types of benchmark values. In general, these values can be classified in four types [13]:

- limit value: lowest value of an assessment scale (minimum acceptable performance);
- reference value: present state of the art (average or median value);
- best practice value: value reached in experimental or demonstration projects;
- target value: upper value of the assessment scale (highest theoretically possible level).

Limit and reference values can be characterized as short term values. Their strengths are to exclude buildings with high environmental impacts while addressing all stakeholders (level-playing field). However, it is expected that these values will not lead to major environmental improvement and will therefore require a regular update towards more severe benchmarks [12]. On the other hand, best practice and target values are characterized as medium- or long term values. These values allow to steer towards an improved environmental performance and policy target. Their main drawback is that they might not be feasible for all buildings due to a lack of knowledge or technology [12]. The use of a combination of at least two benchmark values to cover both short and long term objectives is therefore recommended. In addition, a stepwise implementation approach should be defined to gradually evolve from the current-state reference values towards more ambitious values in future.

4.2. Benchmark scope

The life cycle stages and environmental impacts covered by the six benchmarking systems being studied are described in Table 2.

Table 2. Benchmark scope

	Life cycle stages	Environmental indicators
MPG	Embodied impacts	Aggregated indicator expressed in environmental cost - based on 11 impact categories: global warming, ozone depletion, photochemical ozone formation, acidification, eutrophication, resource depletion (fossil and non-fossil), human toxicity, ecotoxicity (fresh water, marine and terrestrial)
E+/C-	- Whole life cycle - Embodied impacts	Global Warming
SIA 2040	- Whole life cycle including user transport (target value) - Whole life cycle excluding user transport (additional requirement) - Indicative values for embodied impacts, energy use and user transport (reference values)	Global warming and primary energy non renewable
BREEAM	Embodied impacts	Aggregated indicator expressed in Ecopoints - based on 11 indicators: global warming, ozone depletion, photochemical ozone formation, acidification, eutrophication, resource depletion (fossil and non-fossil), net use of fresh water, hazardous waste disposed, non-hazardous waste disposed, radioactive waste disposed
DGNB	- Whole life cycle - Indicative values for embodied impacts and energy use	- 5 impact indicators: global warming, ozone depletion, photochemical ozone formation, acidification, eutrophication - 3 LCI indicators: primary energy non-renewable and total, proportion of renewable primary energy
LEED	Whole life cycle	At least three of the following impact indicators: global warming, ozone depletion, photochemical ozone formation, acidification, eutrophication and depletion of non-renewable energy resources

When considering the life cycle stages (Figure 1 – left), the scope can be either limited to embodied impacts such as in MPG and BREEAM or cover the whole building life cycle (i.e. embodied and operational impacts), such as in E+/C-, SIA 2040, DGNB and LEED. Whole life cycle benchmarks are often combined with sub-benchmarks or indicative values for embodied impacts and energy use.

While embodied impacts benchmarks only focus on the impact of material use, whole life cycle benchmarks allow for a global optimization of the environmental performance considering the trade-offs between embodied and operational impacts. For example, the improvement of the building insulation level results in an increase of embodied impacts from insulation materials and a decrease of operational impacts for energy use. Whole life cycle benchmarks furthermore give more flexibility to architects to decide how to optimize their building design. We therefore recommend to define whole life cycle benchmarks. These benchmarks could be combined with indicative values for embodied and operational impact (e.g. energy use, water use) to guide designers towards lower environmental impacts throughout the various life cycle stages.

Concerning the environmental indicators (Figure 1 – right), the benchmarking systems can either define benchmark values per individual indicator, such as in E+/C-, SIA 2040, DGNB and LEED or rely on an aggregated indicator calculated based on a set of individual indicators, such as in MPG and BREEAM.

Compared to individual indicators, an aggregated indicator is easier to understand and communicate to a non-scientific audience. A huge set of individual indicators such as in DGNB can be difficult to handle. On the other hand, benchmarks per individual indicator allow to focus on specific issues which require urgent action such as for example global warming. If the LCA method includes the calculation of an aggregated score expressed in environmental costs (as is for example the case for the Belgian LCA method [28]), we recommend to use this single score indicator for benchmarking. This could be combined with sub-benchmarks or indicative values per individual indicator in order to fulfil international sustainability goals such as the greenhouse gas emission reduction targets.

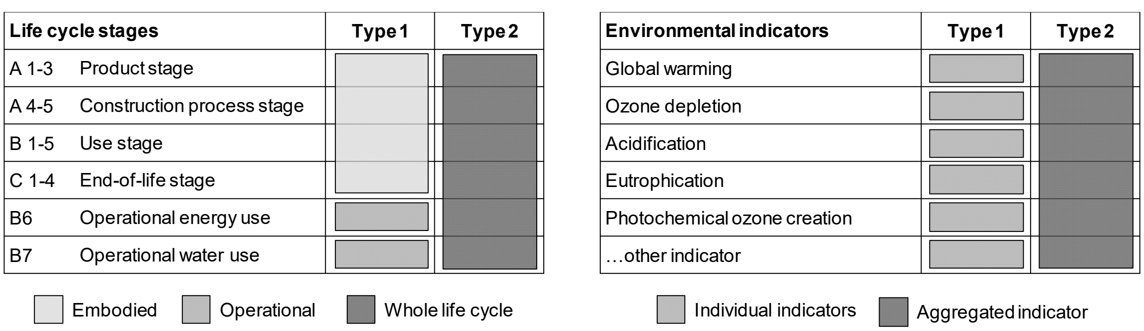

Figure 1. Benchmark scope in terms of life cycle stages (left) and environmental indicators (right)

4.3. Benchmark applications

The benchmarking systems can cover various building types and types of construction work (new construction versus refurbishment) (see Table 3). The benchmarking systems MPG and BREEAM are limited to one or two building typologies while the others are applicable to a wide range of typologies. Our recommendation for the development of future benchmarks is to use a stepwise approach starting with the most widespread typologies (i.e. residential and office buildings) which are then extended to other building types in subsequent steps.

The majority of the analysed benchmarking systems are limited to new construction. Only SIA 2040 includes benchmark values for both new construction and refurbishment. The latter should be preferred as the refurbishment of the existing building stock is seen as a policy priority for the coming years [29].

Table 3. Benchmark applications

	Building types	New construction and/or refurbishment?
MPG	Residential and office buildings	New construction
E+/C-	Single family houses, multi-family houses, office buildings and other buildings which are subject to the energy regulation	New construction
SIA 2040	Residential, administration, school, specialised store, food store and restaurant	New construction and refurbishment
BREEAM	Residential buildings	New construction
DGNB	Residential, office, education, hotel, consumer markets, shopping centres, business premises, logistics and production	New construction
LEED	Commercial, institutional, high-rise residential, schools, retail, data centers, warehouses and distribution centers, hospitality healthcare	New construction

4.4. Benchmark communication

Among existing benchmarking systems, three options can be distinguished for benchmark communication (see Table 4). The first option is to directly communicate benchmark values (e.g. kg CO_2 eq.). The second option is to use performance classes (e.g. label A to E). The third option, which is applied in sustainability rating tools, is to calculate a total score based on the benchmark values.

While benchmark values are more transparent in a scientific perspective, performance classes and scores are easier to communicate. Therefore we recommend a combination of both as applied in MPG.

Table 4. Benchmark communication

MPG	- Benchmark value - 5 performance classes (from A to E)
E+/C-	2 performance classes (Carbon level 1 and Carbon level 2)
SIA 2040	Benchmark values
BREEAM	Score based on benchmark scale
DGNB	Weighted score based on score per impact indicator
LEED	Score based on minimum impact reduction compared to baseline

5. Conclusions and further research

In this study six benchmarking systems were critically analysed considering the benchmark approach, scope, applications and communication. Based on this analysis, five main recommendations for the development of future benchmarks have been formulated. First, a combined top-down and bottom-up approach for defining benchmarks is recommended to ensure that benchmark values are in line with long term policy targets but still feasible based on currently available construction methods and technologies. Second, the benchmark system should include different performance levels (from limit to target values) to cover both short term and long term objectives. Third, the benchmark scope should be flexible in terms of life cycle stages and environmental indicators. This means a combination of whole life cycle benchmarks and indicative values for embodied and operational impacts but also a combination of aggregated indicator and indicative values for individual impact indicators. Fourth, the benchmarks should in a first phase at least cover the most widespread building typologies and be applicable to both new construction and refurbishments. Finally, benchmarks should be communicated in a transparent and user-friendly way based on a combination of benchmark values and performance classes.

In further research, the literature review will be extended to research studies [18–26]. This will provide in particular more insight into top-down approaches which are underrepresented in existing benchmarking systems. Furthermore, the results of the literature review will be presented to Belgian policy makers and building stakeholders in order to validate the formulated recommendations and define a methodology for benchmarks adapted to the Belgian context. In this context alignment with the ongoing harmonization works of IEA EBC Annex 72 and ISO/TC 59/SC 17/WG 2 ("Sustainability indicators and benchmarking") will be aimed for [30, 31].

Passive house-concept apartments: sustainability evaluation in a case study of Stockholm, Sweden

Khatibi M

PhD Candidate, Department of Architecture and Urban Studies, DAStU,
Politecnico di Milano, Piazza Leonardo da Vinci 26, Building 29, 20133 Milano, Italy.

maryam.khatibi@polimi.it

Abstract. The housing sector accounts for almost one-third of total energy use in Sweden; of this amount, the operation phase of a building is responsible for around 85% of its total energy use. The Swedish government aims to reduce the energy consumption in buildings by 50 % by the year 2050. One way to achieve this goal is the construction of the low-energy buildings. The purpose of the study has been to analyse the Blå Jungfrun passive house-concept, tenant occupied apartments in Stockholm, Sweden, through a blend of qualitative and quantitative research methodology. The Swedish energy-efficient buildings are considered as a platform for recommendations for improving the knowledge and practice of low-energy buildings grounded in sustainability science as the theoretical framework. The study has investigated the roles of the responsible architects and design features of the Blå Jungfrun. The economic viability of the apartments is calculated by the economic evaluation software OekoRat for a life span of 50 years. The annual energy requirements of the studied apartments are analysed in regard to their post-occupancy evaluations. The social inclusion of the Blå Jungfrun tenants is investigated considering the issue of their participation in planning stages of the apartments. The empirical findings of the study shows the inevitable correlations between the environmental, economic, and social dimensions of the passive house. The findings suggested that in order to achieve a successful sustainable system of the sustainable housing, a holistic approach in the low-energy buildings is necessary.

1. Introduction

Global warming, climate change, increasing energy costs, and decreasing resources availability are among the reasons, which have caused a focus on the building of environmentally friendly houses. The Swedish ratification of the Kyoto Protocol and the United Nations Framework Convention on Climate Change (UNFCCC) are applied as a basis for decision makings regarding the Swedish climate strategy [1]. The Swedish government agreed on 15 environmental goals in April 1999 and one additional goal was added in November 2005 [1]. The goals that are important for the building industry can be listed as *A Good Built Environment* and *Reduced Climate Impact*. In regard to the goals for the Swedish energy policy, which were provided in 1997 and consequently were confirmed in 2002 by the Swedish parliament; the Swedish energy supply should be effective and sustainable in both short and long term perspectives. In the directive for energy efficiency in the built environment, the European Union (EU) Commission declares that in order to decrease CO_2 emissions, the building sector must decrease its use of energy [2]. In June 2006, the Swedish government stated a goal, to reduce the energy consumption in buildings with 50% until the year 2050 [3]. One way to achieve this goal is the construction of the passive house-concept buildings.

1.1. Objective and methodology of the study

The analyses of the study is based on the case study of Blå Jungfrun passive house-concept project in Stockholm. The focus is on the design aspects, economic viability, and annual energy requirements of the project. The study also aims to explore the social inclusion of the users in the planning process of Blå Jungfrun in order to identify potential shortcomings.

To approach the challenge of this study, a blend of qualitative and quantitative data was needed. The qualitative data in regard to the social inclusion of the tenants of Blå Jungfrun apartments were collected through the interview sessions with the architects of the project and the environmental engineer of the construction company Skanska during years 2012-13. This qualitative data is coupled with quantitative data available from the post-occupancy evaluation of the project for the year 2011 (collected from Svenska Bostäder; the responsible housing company), the relevant statistical online databases, and Oeko-Rat software economic calculations. Hence, the sources of qualitative and quantitative data, analysis and discussion sections are not based on the marketing materials of Blå Jungfrun project but on the collected data from interviews, post-occupancy evaluations, statistical databases, and economic software calculations.

1.2. Swedish passive house definition and development

Forum för Energieffektiva Byggnader (FEBY) Passivhus defines passive houses as:
"Low energy buildings that aim to perform better than new built buildings regulated in BBR 16 (BFS 2008:20)" [4].

The earlier experiences of Swedish passive house projects were carried out in 1981 in Växjö and Färgelanda. Later, in the mid-80s, a German researcher Dr. Wolfgang Feist and a Swedish professor Dr. Bo Adamson developed the concept of present-day passive houses [1]. Ten years after the first positive experiences of passive house in Germany, the first modern passive house in Sweden was built in 2001 [1]. The Lindås project, which is a 20 terrace houses project in Göteborg (Lindås) as a part of CEPHEUS research project, became a milestone in the construction of Swedish low-energy buildings [5]. The experiences of Swedish modern passive house projects in 2001 demonstrated that this concept can be feasible in Scandinavian climate [5].

1.2.1. Energy demand of the passive house in Sweden

Space heating demand, domestic hot water, electricity for mechanical systems (fans and pumps), and general electricity utilized by the building such as common lighting and electricity used for elevators are included in the Swedish criteria regarding the energy consumption [6]. However, household electricity and the energy produced at the building from installed solar cells or panels are not included in the energy consumption demand of passive houses [6]. The Swedish criteria recommend a total energy consumption of maximum 45 kWh/m^{2}a for southern climate zone and a limit of 55 kWh/m^{2}a for northern climate zone of Sweden [7]. An additional 10 kWh/m^{2}a in both regions is allowed for detached houses with less than 200 m^2 [7].

This study aims to assess not only the specific energy requirements of the case study project, but also the energy consumption patterns of the tenants of the case study. This assessment should contribute to environmental and economic aspects of the passive house. That is because the very low energy demand of the passive house contributes to fulfil the economic and environmental components [8].

1.2.2. Economic efficiency of the passive house

The specific extra costs, which are related to passive houses compared to conventional buildings, can be divided into the categories such as costs for heating, ventilation, isolation, air tightness, ground works, differentiation in net floor surface and miscellaneous costs [9]. The extra costs of passive houses are invested in energy efficiency of these buildings and are supposed to be paid back through the annual energy savings, which is provided by this obtained energy efficiency [10].

1.2.3. Social sustainability and inclusion of the residents

The social issues linked to participation of a large range of actors such as occupants are considered as a component in the making of successful sustainable building [11]. Social sustainability need to include residents in the building processes [12]. Social sustainability is an important point in the development of passive houses. The social sustainability of passive houses deals not only with the protection of human health, well-being, and indoor thermal comfort, but also the behaviour of end-users of the passive house. To achieve the goal of social sustainability several issues should be taken into consideration [12]:

- The occupants of passive houses should get included during the planning and design stages of these buildings.
- Post-occupancy evaluations of these buildings should present data "both on what energy resources residents are using and why the pattern of use looked like that".
- Eventually, post-occupancy evaluations should yield "accurate and accessible" input to new developments.

The assessment of the social sustainability of the case study project, however, is limited. There were no studies carried out on the tenants of the case study apartments. Therefore, the effect of indoor air quality on the health and comfort of the tenants, and their views on energy consumption patterns have been not assessed.

2. Blå Jungfrun energy efficient apartment project in Stockholm

Blå Jungfrun is a pioneer passive house standard residential development with a total of 97 rental apartments, which was constructed by Skanska in 2010 first in Stockholm (see figure 1). It is located in the southeast part of Stockholm between Farsta and Hökarängen, which is about 10 km south of central Stockholm. The planning phase of the project started in October 2008 and tenants moved into the buildings during the second and final quarter of 2010 (see table 1).

Figure 1. Blå Jungfrun energy efficient apartment project in Stockholm.

Table 1. The project facts.

Project: Blå Jungfrun		
Client: Swedish housing association (Svenska Bostäder in Swedish)		
Construction company: Skanska		
Architect company: Reflex Architects		
Architects in charge: Kjell Mejhert and Pernilla Ivarsson		
Construction type: Prefabricated frame passive house		
Construction cost: (27000 SEK/m^2)* including value added tax (VAT)		
Year completed: 2010		
Location: Hökarängen, Stockholm; Sweden		
Development type: 4 blocks of 5 and 6-storeys high with 97 apartments		
Building type	Number	Area (Sqm)
2 Bedrooms apartment	21	53-55
3 Bedrooms apartment	36	73-85
4 Bedrooms apartment	20	88-105
5 Bedrooms apartment	20	111

*This amount is based on the data received from Svenska Bostäder (the responsible housing agency)

After the first year of the tenants' occupancy of the Blå Jungfrun apartments, the amount of energy consumption was calculated by Svenska Bostäder [13]. The calculations show that the energy consumption for heating has been reduced around 85% in comparison to the standard of BBR, legislation 2009 (see figure 2).

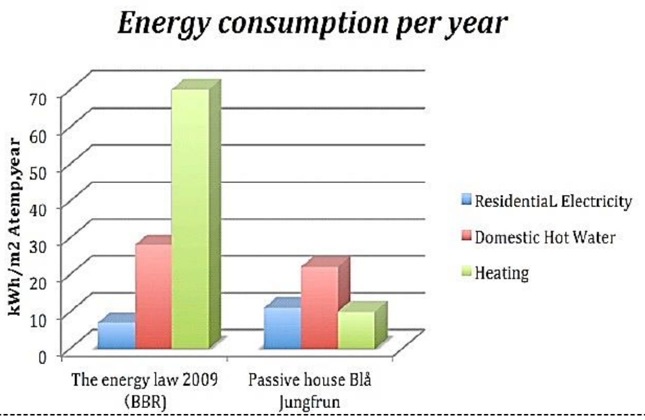

Figure 2. The comparison of energy consumption of the Blå Jungfrun with the requirements of the applicable BBR legislation 2009 [13].

3. Interview Study

From the start of the Blå Jungfrun project the architects team of the project have suggested Svenska Bostäder (the client) to develop an environmentally responsible building project. Further, Skanska as the developer and investor has entered the project and the financial comparison between conventional buildings and passive houses got calculated by Skanska. Eventually, the Blå Jungfrun project got to be constructed with passive house standards. Besides, the environmental development leader of Skanska, has explained that the driving forces for their customers of green houses have been lower energy costs during use, better in-door environment, higher value (financial benefits) of the building, and a green profile for the company.

3.1. Specific design aspects of Blå Jungfrun project

3.1.1. Architectural effect and form

Buildings have the southern orientation with most windows to the south, however, they are not the most compact buildings possible. The buildings were designed very simple in their form, while the architects could not add a lot of architectural effects to them. According to the architects, in spite of the fact that the focus of the first passive house designers has not been on architectural parts, rather on the technical parts, it is possible to design modern and attractive architectural forms for passive houses (Interview with architects).

3.1.2. Large south-facing balconies

The south-facing large balconies are designed to sunscreen the summer sun. According to architects, although, the large balconies and their connection to the buildings have been expensive to construct, they save costs in operation phase of the buildings (Interview with architects).

3.1.3. Placement of windows

There have been many calculations on the placement of windows. These buildings apply passive solar heating system through the windows for some part, thus it has been critical to decide to place the windows right in the façade (Interview with architects).

4. Economic evaluation of the Blå Jungfrun passive apartments

Construction costs of the passive house are more expensive than a conventional house, because of extra costs of a passive house such as: costs for ventilation, costs for insulation, costs for triple glazed windows and entry doors, costs for measuring air tightness, costs for ground works, etc. [10]. The additional costs of constructing passive houses are invested in energy-efficiency quality of these buildings. These extra costs are supposed to be paid back through the annual energy savings of passive house during its lifespan. The main factors that affect economic aspect of the passive house are considered as (see appendix 1) [14]:

- Initial investment costs
- Annual energy saving
- Energy costs
- Annual operation costs
- Considered period of time (Utilization of building)
- Interest rate
- General inflation rate
- Energy inflation rate

The economic efficiency of the passive house can be calculated regarding the payback time and internal interest rate of the investment [14]. The payback time of passive houses is directly dependent on the growth of the energy prices and inflation rate indirectly influences energy price and interest rate [10]. These factors are used in order to decide whether the construction of the Blå Jungfrun passive apartments is economically viable. As the first condition, the payback time must be shorter than the lifespan of the buildings [14]. Secondly, the internal interest rate, which depends on the lifespan of the buildings, has to be larger than or equal to the interest rate of the capital investment.

In order to evaluate the economic efficiency of the investment for Blå Jungfrun passive-house apartments, the software called Economic Evaluation (Oeko-Rat) is used. This software is specifically designed for economic calculations of energy savings and renewable energies and evaluates the economic efficiency of an investment in accordance with the capital value method [14].

The total cost difference of normal houses and the Blå Jungfrun passive apartments is used as initial investment costs. The annual energy saving is the annual difference of energy consumption of normal houses of Svenska Bostäder and the Blå Jungfrun passive apartments (see table 2; see appendix A for calculations). According to Nordic conditions, the basic lifespan of the buildings is considered to be 50 years and can be then renovated and used for another 50 years [15].

Table 2. Amount of factors used for economic evaluation of the Blå Jungfrun passive apartments

Factor	**Blå Jungfrun project passive house apartments**
Initial investment costs (SEK)	16065000 SEK= (160650 hSEK*)
Annual energy saving (kWh)	943500
Energy cost (Electricity) (SEK/ kWh)	1.6833= (0.016833 hSEK/kWh)
Annual operation costs (%)	2
Considered period of time (utilization) (Years)	50
Interest rate in 2011 (%)	1.625
Inflation rate in 2011 (general) (%)	3.0
Annual inflation rate of energy in 2011 (%)	6.1

*the unit h stands for Hecta (hundred) in calculations.

Sources of table 2:
Row 1: Based on data from Svenska Bostäder.
Row 2: Based on data from post-occupancy evaluations of Svenska Bostäder.
Row 3: Based on data from European statistics (Eurostat, 2012).
Row 4: [14].
Row 5: [15].
Row 6: Swedish central bank's interest rate (global-rates, 2012).
Rows 7 and 8: Based on data from Organization for Economic Co-operation and Development (see appendix B).

The economic evaluation with the energy price in Sweden shows that the investment for building the Blå Jungfrun passive apartments is economically viable, since the payback time for this investment is less than the lifespan (utilization time) of the houses. The internal interest rate of this investment is 14.4 %, which is more than the general interest rate in Sweden (see table 3).

Table 3. Factors of economic efficiency for the Blå Jungfrun passive apartments.

Considered period of time	Payback time	Interest rate	Internal interest rate of the investment	Result
50 years	**10.1 years**	1.65 %	**14.4 %**	**Economic**

The economic evaluation for all the 2 bedrooms apartments, 3 bedrooms apartments, 4 bedrooms apartments, and 5 bedrooms apartments of the Blå Jungfrun passive-house concept apartments has carried out, separately. The results for all calculations are the same with payback time of 10.1 years and internal interest rate of the investment, which is 14.4 %. This estimated payback period of 10.1 years could have been shorter, if the annual energy consumption of the project would have been lower than the measured requirement of 2011.

5. Energy requirements of the Blå Jungfrun passive apartments

According to the post-occupancy evaluation, which is carried out by Svenska Bostäder, the measured energy requirements of the Blå Jungfrun passive apartments for the year 2011 has been 59 kWh/m^2a for residential electricity, space heating and, hot water and 92 kWh/m^2a including tenant electricity (see table 4) (see appendix C).

Table 4. The measured energy requirement of Blå Jungfrun passive houses for 2011.

Residential electricity	9 kWh/m^2a
Heating ventilation and VVC (district heating) & Dehydration of concrete (electricity or district heating)	19 kWh/m^2a
The heating electric radiators	4 kWh/m^2a
The warm water (apartments and laundry)	27 kWh/m^2a
The household and laundry electricity	33 kWh/m^2a

Considering the Swedish criteria for energy consumption, the maximum amount of energy demand for passive apartments (excluding household electricity) is recommended not to exceed 45 kWh/m^2a in Southern climate zone of Sweden [7]. Therefore, the measured value of 59 kWh/m^2a for Blå Jungfrun in 2011 is not within the Swedish criteria of the passive houses.

On the other hand, it has been argued that the energy use, especially for space heating, can be higher during the first heating season in comparison to later during the continuous operation. Generally, this situation is caused by additional energy used for structural drying and also the phase when the occupants are learning how the system works might take more or less time [1].

6. Discussion

The vision of sustainability has been the driving force for constructing the Blå Jungfrun passive-concept apartments. The energy efficiency awareness of the residents is achieved by installing Smart box for each apartment unit in order to provide energy consumption feedback to tenants of the Blå Jungfrun passive apartments. However, the post-occupancy evaluations that have been carried out by Svenska Bostäder demonstrate that the tenants have not reduced their energy consumption patterns. In the Blå Jungfrun apartments, the rents are reduced and tenants have to pay for warm water and extra heating that they consume, separate from the rent amounts of the apartments. According to the architects of the project, when one reads about what tenants have answered to evaluation questions of the project, they have declared that they are more concerned now and they think more about environmental questions. However, when these answers and results are compared with the post occupancy energy statistics, it is seen that tenants have not reduced the energy consumption. Moreover, from interviews, it has been recognized that tenants of Blå Jungfrun apartments have received a lot of information about the buildings being passive house before signing their contracts. Since the tenants pay for their own use of hot and cold water, electricity and some of the heat, the hope has been that they would use less energy. One issue is that he residents of Blå Jungfrun project have got their apartments in Blå Jungfrun apartments through the regular Stockholm apartment queue. In this manner, Svenska Bostäder has no right to favour people who are environmentally interested and responsible and hence few of the tenants choose the apartments due to the house being passive.

According to Palm (2011), in low-energy buildings tenants and tenant/owners often identify actors other than themselves as responsible for energy efficiency [16]. For example, householders rely on the construction company regarding the energy efficiency issues [16]. The research by Pyrko and Darby on conditions of energy efficient behaviour identifies that citizens in Sweden trust their government and often expect that someone does something and that decisions are made for the society's best, thus people should be informed about the right and rational way to be effectively involved in the process [17]. Their research emphasizes the shortage of face-to-face advice in the home on the issue of energy efficiency, which is more effective but more expensive than normal procedures [17]. Likewise, Palm and Ellegård suggest “time diaries and visulaization tools” as useful tools for approaching inhabitants to target their energy behaviour [18].

The first modern passive house, which was built in 2001 in Sweden, was Lindås project. However, involving end-users was never an option in Lindås project [19]. Isaksson & Karlsson has conducted an interdisciplinary investigation on the thermal environment and space heating of low-energy terraced houses of Lindås project [20]. They have concluded that in developing the next generation of low-energy buildings, an interdisciplinary planning that takes the experiences of occupants as well as measurements into consideration is very important [20].

However, nine years after the completion of the Lindås project in south of Gothenburg in 2001, the Blå Jungfrun passive apartments are constructed in Stockholm in 2010 and still the residents are disconnected from the planning phase of the project. Moreover, the interview materials of this study revealed that Svenska Bostäder has compared the results of the post-occupancy evaluation forms of the tenants and the results of the energy statistics. The tenants have expressed their sustainability awareness intentions; however they have not acted in an environmentally sustainable manner. The reason for this disagreement can be that households want to answer for example survey questions in a way that is politically correct, but it may be difficult to translate that desire into practical action. One major problem with housing policies can be that the housing sector is dominated by a “techno-centric (top-down policy recommendations)” approach, while the “eco-centric (public participation and community involvement)” approach can result in more beneficial outcome [21].

7. Conclusion

The findings of this study show that the environmental, economic, and social aspects of the passive house are closely intertwined. The deficiency in each aspect affects the whole system of the passive house. Fifty percent energy consumption reductions in buildings to year 2050 in Sweden mean substantial changes in patterns of energy consumption in buildings with improvements in all environmental, economic, and social aspects of sustainable buildings. In order to achieve a sustainable system of the passive house, the government or public authorities at the national and local levels need to inform the public of such projects, mediate the involvement of the public, and provide support for the community involvement. The energy-saving behaviours of the passive house tenants can be facilitated by their early participation.

As the result of the increase in the world population from 7.0 billion to 9.3 billion by 2050, 70% of people will be living in urban areas [22]. Cities considered responsible for about 60-80% of global energy consumption and for 75% of global greenhouse gas emissions [22] are increasingly perceived as being crucial in addressing climate change and environmental problems. Accordingly, urban housing as a major component of the city has turned to the centre of attention with the potential to attain the essential strategies to achieve greater sustainability. Housing design that does not take into consideration the participation of its inhabitants, cannot be sustainable in long-term. The results of this study highlight that the of UN`s Agenda 2030 and Sustainable Development Goals (SDGs) [23] would not be achieved, when bottom-up approaches are not applied to urban housing development and planning.

An integrated approach can contribute to achieving the successful sustainable system of the passive house concept, which needs to be user-centred rather than just selling the technology. The purpose of this study has been to contribute to the development of knowledge regarding the best practices by which, a balanced sustainable system of the passive house can be achieved. Findings show that with the changes in both the housing company governance structure and community involvement, reductions in energy usage of the residents would be expected.

Appendix A

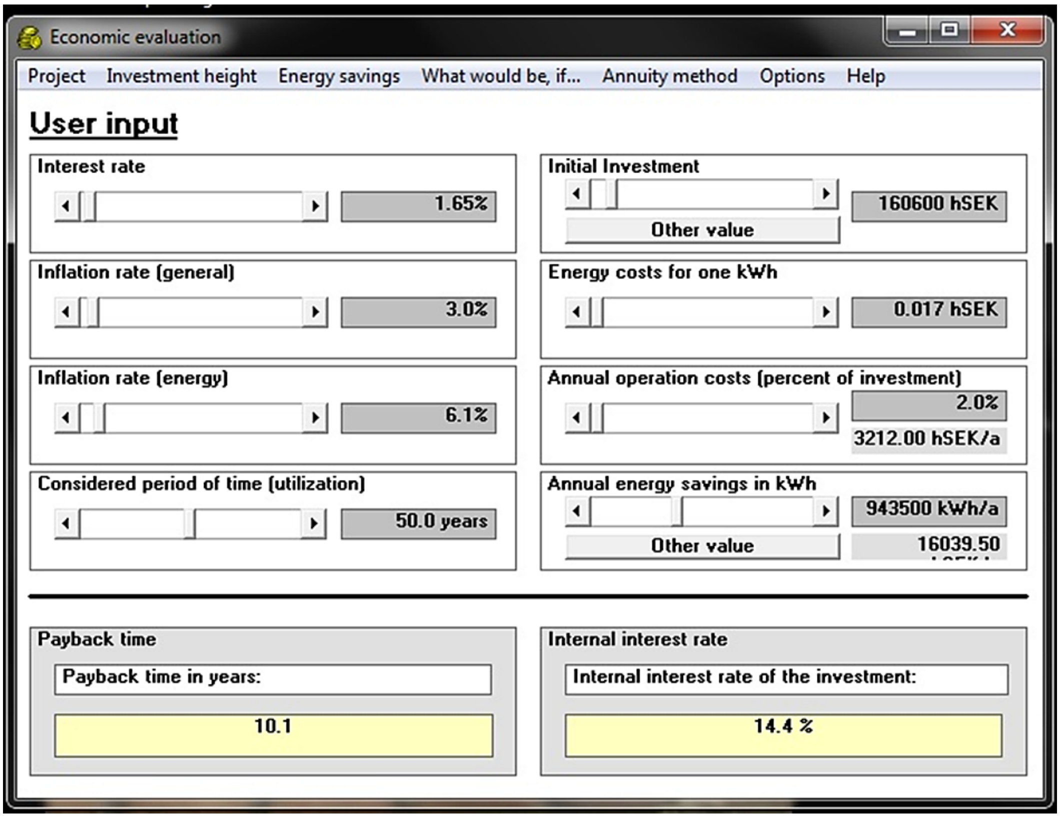

figure A1. The economic evaluation of Blå Jungfrun passive houses in software Oeko-Rat.

The input & output data and factors for the Blå Jungfrun passive apartments are summarized as below (see figure A 2):

Economic Evaluation

Input data

Interest rate:	1.65%
Inflation:	3.0%
Energy infaltion	6.1%
Period of using:	50.0 years
Costs of investment:	160600 hSEK
Costs of energy pro kWh:	0.017 hSEK
Savings of energy:	943500 kWh/a - 16039.50 hSEK/a
Operating costs per year:	2.0% - 3212.00 hSEK/a

Output data

Period of amortization:	10.1
Internal interest rate:	14.4 %

Figure A 2. the input & output data for economic evaluation of the Blå Jungfrun passive apartments [Oeko-Rat[1]]

1 Oeko-Rat. Economic Evaluation Software. Available at: http://nesa1.uni-siegen.de/index.htm?/projekte/OekoRat/Oeko-Rat.htm

The calculations procedure for economic evaluation of Blå Jungfrun passive houses:

In order to calculate the initial investment costs:
Construction cost of Blå Jungfrun passive houses including VAT = 27 000 SEK/m^2
This amount is 7 % more than construction costs of conventional buildings.
27 000 – 7 % = 25 110 SEK/m^2
Construction cost of conventional houses including VAT = 25 110 SEK/m^2
Living area of Blå Jungfrun passive houses = 8 500 m^2
27 000 SEK/m^2 - 25 110 SEK/m^2= 1890 SEK/m^2
1890 SEK/m^2 × 8500 m^2 = 16065000 SEK = 160650 hSEK = Initial investment costs

In order to calculate the annual energy saving:
The average energy requirements in conventional buildings of Svenska Bostäder (excluding household electricity) = 171 kWh/m^2.year
The measured energy requirements of Blå Jungfrun passive houses (excluding household electricity) = 60 kWh/m^2.year
171 KWh/m^2.year - 60 kWh/m^2.year = 111 KWh/m^2.year
111 KWh/m^2.year × 8500 m^2 = 943500 kWh/year = Annual energy saving

Energy costs:
0.204 Euro per kWh (in the year 2011) = 1.6833 SEK = 0.016833 hSEK ≈ 0.017 hSEK

The effect of insulation thickness on lifetime CO_2 emissions

Totland M, Kvande T and Bohne R A
Norwegian University of Science and Technology

marietot@stud.ntnu.no

Abstract. This paper assesses the total carbon emissions of a single-family home designed and built for Norwegian conditions, according to current standards (TEK 17), using an LCA approach. Various combinations of insulation thicknesses are assessed to identify which combination is most efficient in lowering the lifetime emissions as well as in which part of the building envelope additional insulation is most efficient in reducing the lifetime greenhouse gas emissions of the building. Overall, increased insulation resulted in lower lifetime emissions; the increased embodied emissions generally being outweighed by the energy savings resulting from the increased insulation thickness. The location of the insulation is the factor that was found to have the largest impact on the lifetime emissions. When increasing the insulation thickness from 100-500 mm, changing only one component at a time, the operational emissions were most sensitive to the insulation thickness in the walls, with a 26 % decrease compared to 7% and 3% for the roof and floor respectively. The most efficient cases tended to have little insulation in the floor (100 - 150 mm) and relatively high insulation thickness in the wall (350 mm). The most variable component was the roof, varying from 150 to 400 mm.

1. Introduction

According to the IPCC 19% of the global CO_2 emissions, and 32% of the final energy consumption in 2010 could be accounted to the building sector[1]. Due to the long lifetime of buildings, the efforts made to reduce these emissions can affect the world in decades to come. In recent years there has been an increasing focus on reducing the carbon footprint of buildings, which in colder climates like in Norway, focuses on reducing heat loss and thus lowering the operational energy consumption. Increasing the insulation thickness, ensuring airtightness and eliminating thermal bridges are steps taken to bring the use phase energy consumption down. These measures are indeed reducing the lifetime energy use and emissions, but at what cost? The solutions to reduce the carbon footprint of buildings are increasingly ”engineered”, relying on more materials to further reduce the emissions. Increasing the insulation thickness will potentially reach a limit where adding more material can not further decrease the energy use without it affecting the user-friendliness or increasing lifetime emissions.

The overall objective of the study is to investigate the effect of insulation thickness on lifetime greenhouse gas emissions. This is done through the case study of a single family home located in Norway. Life-cycle assessment (LCA) methodology is used to analyse the GHG emissions and to answer the following research questions:

(i) To what extent will increased insulation thickness reduce the lifetime GHG emissions?

(ii) In which part of the building envelope is additional insulation most efficient in reducing the lifetime GHG emissions of the building?

To assess the environmental impact of buildings, the embodied emissions; impacts that are ”built into” the building, are separated from those coming from the use phase of the building, also called the operational emissions. Traditionally, when the buildings were less insulated, the operation phase constituted between 70-90 % of the total environmental impact[2]. As the buildings have improved the operational energy consumption has been reduced, which increases the relative importance of the embodied emissions. For buildings of passive house standard the embodied emissions can constitute almost 50 % of the total emissions[3]. The impacts of the operational and embodied emissions are highly dependent. The choice of materials used in the construction can for instance decrease the heating requirements of the use phase, but increase the need for transportation or emissions related to the production of the materials[4].

2. Method

2.1. Case study

The case study for this project is a small, residential building designed by Norgeshus, called Trend 2. The house will, for the purpose of this analysis, be considered as a detached, single family house, but the design is also compatible as several adjacent units as a row house, and can therefore easily be scaled for further investigation.

The main part of the building has a rectangular shape with two stories and a flat roof. In addition there is a carport attached to the long side of the building, also serving as a terrace with access from the second floor.

The construction is placed on a concrete perimeter foundation, with timber frame walls insulated with mineral wool, and a flat, compact roof on glulam beams. The original house is built according to current Norwegian standards, TEK 17. The details and thermal properties of Trend 2 are presented in Table 1.

Table 1. Trend 2 building properties

Property	**Value**
U-value External wall [W/m^{2}K]	0.207
U-value Ground floor [W/m^{2}K]	0.092
U-value Roof [W/m^{2}K]	0.14
U-value Windows [W/m^{2}K]	0.81
Airtightness, n_{50} [1/h]	0.9
Heat recovery efficiency	85%

2.2. LCA methodology

Life-Cycle Assessment (LCA) is used to analyse the environmental impacts of a product or service during their entire lifetime [4]. The International Organization for Standardization (ISO) publishes standards for Principles and Framework - ISO 14040 [5] and Requirements and Guidelines - ISO 14044 [6] for life-cycle assessments, and the procedure for the LCA of this paper follows these standards.

The goal of this study is to investigate the effect of increased insulation on the lifetime GHG emissions and identify hot spots, components that contribute more than others to the life-cycle emissions. For this reason, only the impact category global warming potential (GWP) is assessed. According to NS-EN 15643 [7] the embodied emissions correspond to A1-A3 and the operational emissions to B1. The lifespan of the building is considered to be 60 years. Materials with a shorter lifespan than 60 years were multiplied with a lifetime factor to be included in the embodied emissions.

The functional unit is 1 m^2 heated floor area. A complete life-cycle inventory of Trend 2 as designed was performed based on a material list provided by Norgeshus, using a combination of EPDs from EPD

Norway and the Ecoinvent v3 database. The operational energy use was calculated using the energy calculation software SIMIEN. Trend 2 uses a combination of electric heating and biofuel (wood burning fireplace). The electricity mix is assumed to emit 132 g CO_2/kWh[8] and 22 g CO_2 eq/kWh for the biofuel [9].

Initially, two combination methods were used in the case study for the insulation thicknesses, hereafter called Case A and Case B. In Case A all insulation thicknesses were assumed to be identical, e.g. 100 mm insulation in the wall, the roof and the floor. Case B is a parameter study, where all values were kept as they were designed for Trend 2, and only one component was changed at a time. As the work progressed, it became apparent that other combinations of insulation thicknesses should be investigated, which became Case C. A total of 126 combinations were assessed with various combinations of insulation thicknesses, but for the purpose of this paper only the most efficient are presented in detail.

A sensitivity analysis was performed with regards to lifetime (± 30 years) and electricity mix (±30%).

3. Results

The life-cycle impact analysis of the building body of Trend 2 yielded an embodied emission of 25176 kg CO_2 eq, corresponding to 194,56 kg CO_2 eq/m^2.

The LCIA revealed that concrete was the greatest contributor to embodied GHG emissions despite the relatively small amount used in the construction. Concrete is used only in the perimeter foundation, yet constitutes almost 16 % of the total embodied emissions, emphasising the carbon intensity of the material. Insulation is the third most carbon intensive material in the construction.

The variations in embodied emissions for the case study was calculated for each case, and the difference is mainly due to the change in insulation quantity. Polystyrene insulation (EPS and XPS) is more carbon intensive than mineral wool. EPS provides a GWP of 2.2 kg CO_2 eq/m^2 for phases A1-A3, whereas Glava mineral wool provides 0.43 kg CO_2 eq/m^2. For Trend 2, insulation contributes 11 % of the total carbon emissions, including the mineral wool, XPS and EPS. For the most insulated case (A.500), the insulation accounts for 19 % of the total embodied emissions.

Table 2. Embodied and operational emissions

Insulation thickness [mm]	100	150	200	250	300	350	400	450	500
Case A: Same insulation thickness in all components									
Operational emissions [kg CO_2eq/m^{2}year]	18.7	15.7	14.2	13.2	12.5	12.1	11.8	11.6	11.4
Embodied emissions [kg CO_2eq/m^2]	184	188	191	194	198	201	204	208	211
Case B: Varying insulation thickness for single component, others unchanged									
Embodied emissions [kg CO_2eq/m^2]									
Wall	192	193	195	196	197	199	200	201	203
Roof	193	194	194	195	195	195	196	196	196
Floor	188	190	191	193	195	196	198	199	201
Operational emissions [kg CO_2eq/m^{2}year]									
Wall	17.0	14.9	13.9	13.2	12.7	12.4	12.2	12.0	11.5
Roof	14.8	14.3	14.1	13.9	13.7	13.7	13.6	13.5	13.5
Floor	14.5	14.2	14.1	13.9	13.9	13.8	13.8	13.8	13.8

The results for the embodied and operational emissions for cases A and B are presented in Table 2. For all insulation thicknesses in both cases the embodied emissions increase with the increased insulation, and the operational emissions decrease. The operational emissions were most sensitive to the insulation thickness in the walls. Thin walls (100 mm) resulted in lifetime emissions 15.2% higher than Trend 2 and when the walls had 500 mm insulation the lifetime emissions decreased with 14.9%. With the same insulation thicknesses in the roof and the floor the lifetime emissions varied from +5.1% to -1.5% and from +2.8% to -0.1% respectively. It is likely that this distribution is partly affected by the area difference, as the wall surface area is more than double those of the roof and floor and thus allows for more heat transmission.

Overall, the lifetime emissions decrease as the insulation amount increases, this applies for almost all case variants. Table 3 shows the results of Case A, displaying variations regarding lifespan and emission of the electricity mix. The baseline results, with a lifespan of 60 years, and 132 gCO_2 /kWh are shown in the middle. The difference between the least and most insulated cases increases as the electricity mix becomes more carbon intensive and as the lifetime increases. The size of the reduction of lifetime emissions as the insulation increases from 100 to 500 mm depends on the electricity mix (reduction of 25-38% for least and most carbon intensive electricity mix respectively) and expected lifetime (reduction of 26-31%).

Figure 1 shows the lifetime GHG emissions for Case B with a lifespan of 60 years. The insulation thickness in the wall has the greatest effect on the lifetime emissions. The lifetime emissions are less affected by the insulation thickness of the roof and floor, the greatest difference occurring when going from 100 to 150 mm in both components. The wall provides the most significant decrease in lifetime emissions per mm added insulation, with a 26 % decrease compared to 7% and 3% for the roof and floor respectively when the insulation is increased from 100 - 500 mm at a lifetime of 60 years.

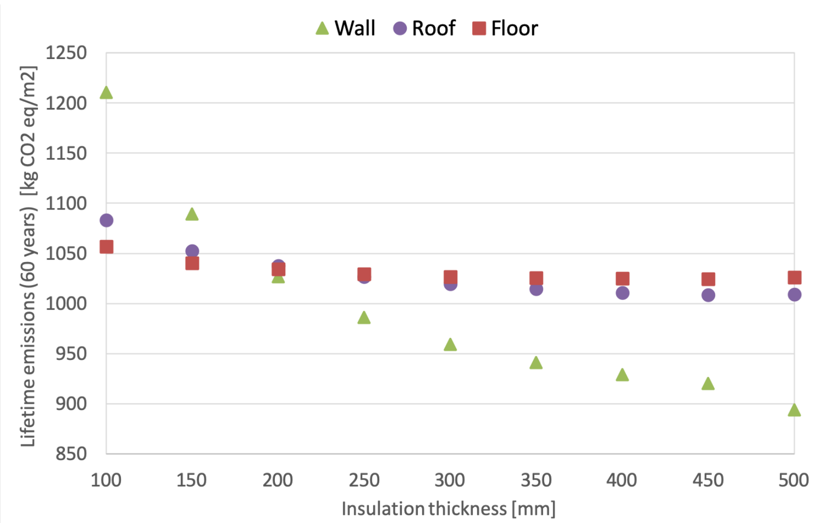

Figure 1. Case B Lifetime emissions (60 years) for the various insulation thicknesses changed in single component

Figure 2 shows the relationship between the lifetime embodied and operational GHG emissions with a life span of 60 years for all the assessed cases. The frontier along the leftmost data points in the figure is called the Pareto frontier. Pareto efficiency is a concept that stems from economics, describing an allocation that makes some individuals better off, and no individual worse off [10]. In the case of optimising insulation thickness, the Pareto frontier represents cases where the operational emission is as low as possible for a given embodied emission. Cases to the right of the frontier therefore have the same operational carbon emissions, but higher embodied emissions, and are thus less efficient than a case on the frontier. The simulations of Trend 2 and the three versions of the Norwegian building standards

Table 3. Annual CO_2 emissions for the Case A variants (insulation thickness in mm) as functions of different lifespans and electricity emissions

gCO_2 /kWh	Lifetime = 30 years	Lifetime = 60 years	Lifetime = 90 years
92			132			172			
■ Embodied [kg CO2 eq/year] ■ Operational [kg CO2 eq/year]

(TEK17, TEK07 and TEK 97)[1] all result in data points to the right of the Pareto frontier.

The insulation thicknesses and lifetime emissions of the cases on the Pareto front are presented in Table 4[2].

[1] TEK17 is the current standard, TEK07 and TEK97 are past standards, included to see the effect of the evolution of the insulation requirements

[2] The values are sorted alphabetically according to Case ID and the order does not represent Pareto efficiency

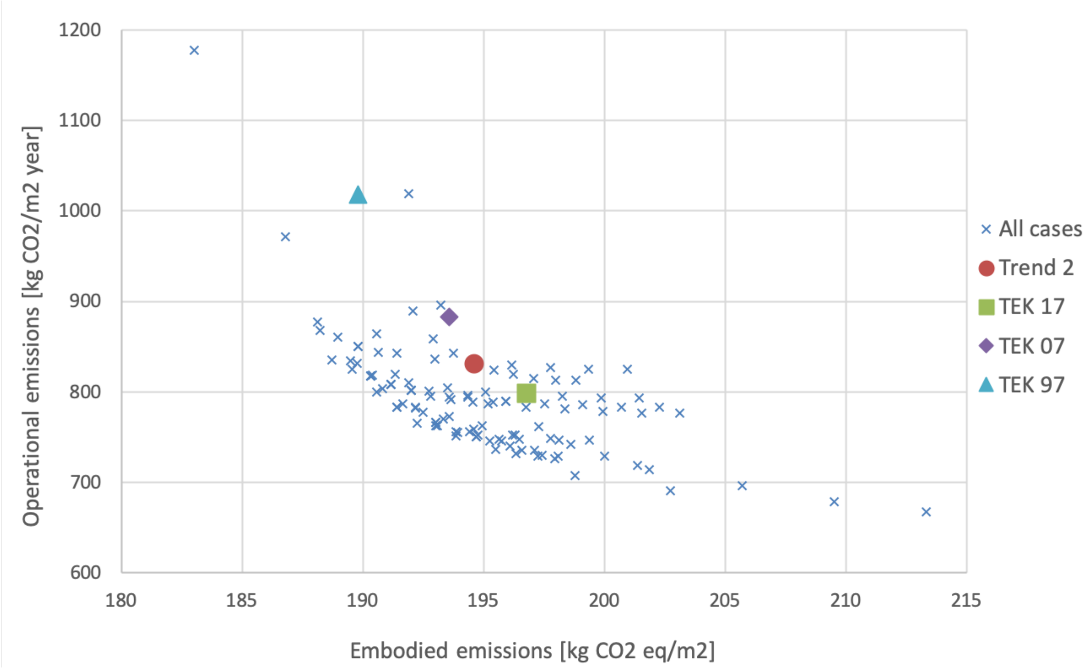

Figure 2. Relationship between embodied and operational carbon emissions

Table 4. Cases on the Pareto frontier with insulation thicknesses [mm] and lifetime emissions [$kgCO_2/m^2$]

Case ID	Insulation Roof	Insulation Wall	Insulation Floor	Operational	Embodied
All 100	100	100	100	1177,8	183,0

4. Discussion

The results are based on a theoretical framework, which can lead to discrepancies based on factors outside of the scope of this study. Some uncertainty is to be assumed as the study does not consider all phases of a life-cycle assessment. The sensitivity analysis with regards to lifespan in table 3 is especially uncertain as it is a purely theoretical analysis. When exceeding the original lifespan of 60 years no additional maintenance, repair or replacement is assumed, meaning that in reality the embodied emissions would increase as well as a possible change in operational emissions. Furthermore, the insulation thicknesses assessed in this study might exceed what is practical or economically feasible, however these aspects have not been considered for the purpose of this study.

The environmental impact of a building can vary greatly based on the geographical location, both as a result of the electricity mix used, both in use and for the material production, as well as transportation of the materials to the building site. As shown in Case A, the choice of electricity mix makes a significant impact on the lifetime emissions. The sensitivity ratio (SR) was calculated according following standard methodology [11], the results can be seen in Table 5. The results are clearly more sensitive to variations in lifespan and CO_2 factor, than the insulation variations studied, which corresponds to the findings in Table 3. The building sector might not be able to control the CO_2 factor from the grid, but it can affect the lifetime of the buildings. The findings show that no matter how optimally insulated the building is the annual CO_2 emissions will decrease for longer lifespans, so it is important to ensure that the building is robust enough to last for as long as possible.

Table 5. Sensitivity analysis

Parameter	**SR**
CO_2 factor	0.76-0.81
Lifespan	0.78-0.82
Insulation - roof	0 - 0.12
Insulation - wall	0.07 - 0.37
Insulation - floor	0 - 0.07

The results of this study are representative of a house built in Norway or the Nordic region, as most of the materials (and thus EPDs) considered are provided by Norwegian manufacturers.

Case B showed that the roof and the floor insulation did not contribute significantly to the decrease of lifetime emissions compared to that of the wall insulation. At around 200-250 mm, the slopes level out. Even though the lifetime emissions are decreasing after this point, the return on investment will be slight. If the electricity mix becomes less carbon intensive over time, this added insulation might even contribute to an increase in lifetime emissions. This study suggests that it is not given that the solution to reducing the carbon footprint of buildings can rely solely on adding more material. In passive houses it is not uncommon for the insulation thicknesses in the roof to exceed 400 mm and 300 mm in the floor. As Figure 1 shows, the slope of lifetime emissions has evened out long before reaching these thicknesses. It might therefore be beneficial to reconsider the amount of insulation used in these components.

The results of this study indicate that it is not necessarily beneficial to increase the insulation thickness uncritically and expect it to yield lower lifetime emissions. Trend 2 has 250 mm insulation in the roof, 200 mm in the walls and 300 mm in the floor. For this particular building, the results show that the insulation in the floor does not have a significant impact on the lifetime emissions, yet in the original building, the floor is the component with the most insulation. EPS insulation, which is used in the floor construction, is also more carbon intensive than mineral wool, used in the wall and the roof. For Trend 2 it would therefore be recommended to decrease the insulation in the floor construction, and increase it in the walls. Changing the insulation thicknesses to 150 mm in the roof, 350 mm in the walls and 100 mm in the floor leads to the same amount of delivered energy as a building with TEK 17 recommended insulation thicknesses, but with embodied emissions of 191 kg CO_2/m^2, 6 kg CO_2/m^2 less than the original. In total, this is actually less insulation than in the TEK 17 version. It is therefore possible to use less material, yet still achieve the same or even better energy performance.

5. Conclusion

The study concludes that overall, the calculated GHG emissions vary inverse proportionally with the material quantities - more insulation leads to lower operational emissions, and overall lower lifetime emissions. Although more insulation increases the embodied emissions, it generally does not outweigh the energy savings of the increased insulation.

The location of the insulation is the factor that was found to have the largest impact on the lifetime emissions. For this particular building, when changing only one component at a time, the operational emissions were most sensitive to the insulation thickness in the walls. Thin walls (100 mm) resulted in lifetime emissions 15.2% higher than Trend 2 and when the walls had 500 mm insulation the lifetime emissions decreased with 14.9%. With the same insulation thicknesses in the roof and the floor the lifetime emissions varied from +5.1% to -1.5% and from +2.8% to -0.1% respectively. It is likely that this distribution is partly affected by the area difference, as the wall surface area is more than double than those of the roof and floor and thus allows for more heat transmission.

While the increased embodied emissions generally is outweighed by the energy savings resulting from the increased insulation thickness, it is desirable to ensure that the embodied emissions are as low as possible for a given level of operational emissions. A Pareto distribution comparing the embodied to the operational emissions for each case was created to identify the most efficient combinations of insulation thickness. The most Pareto efficient cases tended to have little insulation in the floor (100 - 150 mm) and relatively high insulation thickness in the wall (350 mm), some cases having more and less. The most variable component was the roof, varying from 150 to 400 mm.

It is clear from the findings of this study, that increasing the insulation thickness uncritically does not necessarily yield an optimal solution for lowering the lifetime GHG emissions of a building. It can be enough to increase only one component (in this case the insulation in the wall) while keeping others constant or even decreasing them to lower the lifetime emissions.

Surface-to-volume ratio: How building geometry impacts solar energy production and heat gain through envelopes

Araji M T

Environmental Design Program, Faculty of Architecture, University of Manitoba, 201 John A. Russell Building, Winnipeg, MB R3T 2N2 Canada

Mohamad.Araji@umanitoba.ca

Abstract. This paper explored the relationship between building geometry and renewable energy production of building-integrated photovoltaics (BIPV). Heat gain was incorporated as a conflicting constraint with respect to energy performance. The building façade was mathematically analyzed by taking into account heat transfer pertaining to site conditions along with different parameters that included shading, orientation, PV tilts (β) and surface-to-volume ratio (S/V) as a measure of building compactness. The study involved calculating the impact of each parameter on the convection, conduction and radiation components of the incoming solar energy. S/V was shown to be directly proportional to the amount of solar energy received by the façades and gained by the building in the form of heat. The positive correlation of heat gain with S/V was nearly linear with a slope of around 41.8 kWh/m^2/m^{-1} and a mean of approximately 3.4 times more. With the most suitable geometry in terms of net energy gain, S/V of 0.14 m^{-1} yielded the highest difference between energy production and heat gain. In terms of β, the results demonstrated negative slope of energy production with respect to the tilt at about 2.12 times higher than that displayed by heat gain. Accounting for inter-building effects, a shading reduction equal to d percent can be estimated to an increase of $1.37d$ degrees in β at a building consumption of 60 kWh/m^2.

List of Abbreviations

H	Shading factor
h	Building height
E	Illuminance
C	Building consumption
E_e	Irradiance
v	Human sensitivity
λ	wavelength
Λ	Range of wavelengths from 450 nm to 750 nm
w	Length of the East-West façade
l	Length of the North-South façade
S/V	Surface-area-to-volume ratio
β	PV tilt
F_s	View factor from sky to PV surface
F_g	View factor from PV surface to ground
A_{facade}	Total area of façade
E_{prod}	Production from building integrated renewable energy
Q_{facade}	Heat gain through the façade per unit area
Q_{solar}	Heat gain through solar irradiation
Q_{cond}	Heat gain through conduction
U	The surface U-value
T_{out}	Outside temperature
T_{in}	Inside temperature
$Q_{solar,b}$	Heat gain through E_B
$Q_{solar,d}$	Heat gain through E_{diff}
$Q_{solar,r}$	Heat gain through E_r
$SHGC_\beta$	Solar Heat Gain Coefficient, dependent on β
E_B	Beam component of solar irradiation
E_{diff}	Diffused component of solar irradiation
E_r	Reflected component of solar irradiation

1. Introduction

BIPV's influence on the heat transfer through the building's envelope has been significant. This is because solar cell surfaces affect the overall thermal resistance of the envelope. Comparisons of energy performance and building cooling and heating loads were performed in [1]. Non-ventilated air duct BIPV was shown to have highest power output and lowest heat transfer. Hot wire anemometry measurements, coupled with CFD computations were utilized to calculate heat transfer coefficients in a BIPV/T setting [2]. It was concluded that heat transfer characteristics of PV's internal surface play a critical role in the performance of the façade. The impact of climate on BIPV production was studied in [3]. It was concluded that output is maximized on cold, clear days. Also, snow was found to be a positive factor in production since it can reflect light on to the solar panel from other surfaces. Using a series of experiments, a non-linear stochastic differential equation was developed for the heat transfer of a BIPV component [4]. The method was shown to be useful in modelling nonlinear stochastic thermal phenomena in BIPV systems. The impact of surface temperature of BIPV was mathematically investigated in [5]. It was established that heat transfer increased with forced ventilation, and a high forced velocity in the air gap contributed to increased heat transfer from the BIPV unit. A simulation model aimed at predicting energy production, thermal behaviour and transient interaction with the building envelope was presented in [6]. The accuracy of the model regarding surface temperatures was close to 0.6^{o}C, while for air temperature at the outlet of the system, the accuracy was slightly less than 1^{o}C. Suitability of BIPV in terms of thermal performance was studied in [7]. The study was based on real-time data monitoring supported by computer-based building simulation model. It was concluded that PV as a roofing material caused significant thermal discomfort to the occupants. A fully coupled PV model, integrated in a building simulation code was used to predict the temperature field in the complex wall constituted by BIPV façade in [8]. It was concluded that the performance of the BIPV was greatly dependant on the radiative heat transfer within the semi-transparent layers and the convective heat transfer in the fluid layers.

In terms of building form utilizations, the associated optimum geometry and composition in the presence of BIPV is still limited. Bostancioglu [9] confirmed that the building form along with thermophysical features of the envelope are among the significant factors affecting a building's energy performance. Depecker et al. [10] studied the ratio of the external skin surface and inner volume of the building as a representation of building geometry. This ratio was found to be inversely proportional to building's energy consumption in cold and scarcely sunny winters. A one-dimensional transient model for a BIPV system resulted in an overall energy efficiency of 53.7% by applying the PV modules for a fixed building form [11]. Hemsath et al. [12] studied energy consumption with multiple building geometry variations and material considerations. The outcomes of their research stressed the significance of formal variations in the early design phase to inform decision-making for best building performance. Hwang et al. [13] showed an analytic optimization for PV modules inclinations with relevant spacing between them in building façades. A genetic algorithm was recently developed to help designers determine the optimal envelope geometries with BIPV while considering the net building energy performance with both consumption and generation as the evaluation criteria [14]. The study tested features such as building dimensions, window-to-wall-ratio, orientation, and PV alignment.

Overall, focusing on the specification of PV components in relation to the envelope is no longer sufficient. There is a need for computational methods to advance building form optimization while integrating renewables for zero energy targets. Energy generation and heat gain have been studied separately in terms of the building geometry. This paper aims to answer the novel question of how to seek the most optimal geometry that *jointly* optimizes the conflicting constraints of BIPV performance and heat gain through the façade. Since there is no closed-form relationship between a building's geometry and these constraints, numerical studies are presented to estimate this correlation. The analysis involves mathematical modeling of parameters specific to additional contextual boundary factors of building consumption with various programs and forms with their applicability and feasibility analysis.

2. Methodology

A mathematical model is extended in the following subsections to examine the energy performance as related to building design optimization and integrated PV. The work comprises of procedures for heat gain calculation and the influence of building geometry.

2.1. Heat Gain Calculation

Let the rate of heat gain through the façade per unit area be given by $\dot{Q}_{facade}$ (units: W/m^2). Then,

$$\dot{Q}_{facade} = \dot{Q}_{solar} + \dot{Q}_{cond}, \tag{1}$$

where Q_{solar} and Q_{cond} represent the heat gain through solar irradiation and conduction respectively, and the dot operator is used to represent the rate. $\dot{Q}_{cond}$ depends on the U-value of the surface and the temperature difference across it:

$$\dot{Q}_{cond} = U(T_{out} - T_{in}), \tag{2}$$

where U, T_{out} and T_{in} represent the surface U-value (units: W/m^{2}K), outside temperature(units: K) and inside temperature(units: K) respectively.

The heat gain through solar irradiation is a product of incident solar irradiation and the solar heat gain coefficient (SHGC) of the surface. In order to account for $\dot{Q}_{solar}$, components of irradiation (beam, diffused and reflected) should be separately accounted for. In other words, $\dot{Q}_{solar}$ can be written as

$$\dot{Q}_{solar} = \dot{Q}_{solar,b} + \dot{Q}_{solar,d} + \dot{Q}_{solar,r}, \tag{3}$$

where $Q_{solar,b}$, $Q_{solar,d}$ and $Q_{solar,r}$ represent the heat gain through the beam, diffused and reflected components of solar irradiation (denoted by E_B, E_{diff} and E_r respectively). Studies have shown that SHGC for $Q_{solar,b}$ depends on the tilt of the surface [15]. $Q_{solar,b}$ will also be affected by the shading coefficient H. Thus,

$$\dot{Q}_{solar,b} = SHGC_\beta \cdot E_B \cdot H, \tag{4}$$

where the subscript β with SHGC is there to show the former's dependence on the latter. H takes values between 0 and 1, where 0 implies complete shading and 1 implies no shading. $\dot{Q}_{solar,d}$ is given by

$$\dot{Q}_{solar,d} = SHGC \cdot E_{diff} \cdot F_s, \tag{5}$$

where F_s is the sky view factor given by $F_s = \frac{1+\cos\beta}{2}$. $Q_{solar,r}$ is given by

$$\dot{Q}_{solar,r} = SHGC \cdot E_r \cdot F_g = SHGC \cdot \rho_g E_B \cdot F_g, \tag{6}$$

where ρ_g is the reflection coefficient (typically set as 0.2), and F_g is the view factor from the ground given by $F_g = \frac{1-\cos\beta}{2}$. Plugging Eqs. (2), (3), (4), (5) and (6) in Eq. (1), the total heat gain per unit area through the façade can be summarized as:

$$\dot{Q}_{facade} = SHGC_\beta \cdot E_B \cdot H + SHGC \cdot E_{diff} \cdot F_s + SHGC \cdot \rho_g E_B \cdot F_g + U(T_{out} - T_{in}). \tag{7}$$

The convention to calculate $SHGC_\beta$ utilizes angle correction factors [16]. If the correction factor for a specific β is given by f_β, then $SHGC_\beta = f_\beta \cdot SHGC$.

In conjunction with the above analysis on irradiation, a similar analysis can be done on lighting by noting that illuminance is obtained by averaging irradiance over the sensitivity of human eye for the full spectrum of wavelengths [17]. In other words,

$$E = 683 \cdot H \int_{\lambda \in \Lambda} E_e(\lambda) v(\lambda) d\lambda. \tag{8}$$

where E represents illuminance (units: lux), $E_e(\lambda)$ represents spectral irradiance (units: W/m^2), v represents human sensitivity, λ represents wavelength (units: m) and Λ represents the range of wavelengths from 450 nm to 700 nm, where spectral efficiency is prominent [17]. It is clear from Eq. (4) and Eq. (8) that the effect of shading on lighting will be similar to that on irradiance, i.e., shading factor H acts as a proportionality constant in both cases. This is in alignment with studies reported in the literature [18].

2.2. Influence of Building Geometry

It is noteworthy that $\dot{Q}_{facade}$ in Eq. (7) is represented per unit area. However, area of the façade alone does not provide the complete picture of a building performance in terms of its heat gain and energy production. Let E_{prod} (units: kWh/m^2) denote the energy production per unit area from the PV panels installed on the building's façade. Figure 1 shows two cases to demonstrate the influence of building's geometry. In the first case, two buildings with equal occupancy but unequal façade area (A_{facade}) are shown. In the second case, the reverse case is shown (unequal occupancy and equal A_{facade}). Both these cases allude to some correlation between a building's performance per capita and its compactness. A suitable measure of building's compactness is the surface-area-to-volume-ratio (S/V) which is defined as the ratio of A_{facade} to the volume of the building. For a rectangular building, this can be given by,

$$S/V = \frac{A_{facade}}{lwh} = \frac{2lh + 2wh}{lwh} = \frac{2}{w} + \frac{2}{l}. \tag{9}$$

A similar relationship between building shape and heat transfer through its façade is reported in [19], where the author used the term shape coefficient to represent the ratio of façade and roof surface area to its volume. In Figure 1, both cases yield a higher energy production and heat gain per capita when S/V is higher.

	Case 1		Case 2	
Width x Length x Height	1 x 2 x 1	1 x ½ x 4	1 x 2 x 1	1 x ½ x 2
Volume (cubic unit)	2	2	2	1
Façade Area (square unit)	8	12	6	6

Figure 1: Case 1: Equal volume but different façade areas. Case 2: Equal façade areas but different volume.

2.3. Assumptions and Input Parameters

To apply the mathematical model, some parameters need to be specified. For application purposes, the city of Chicago in the United States of America was considered with a latitude

41.87^{o}N and longitude 87.62^{o}W and a six-hour lag from Greenwich. The average solar irradiation on the PV modules was 2 to 3 kWh/m^2/day and the climate was classified as continental. Building orientation and PV tilt ranged from 0^o to 90^o and from site's latitude to vertical façade's application, respectively. T_{out} is taken to be 27^{o}C, which is the average temperature in Chicago for the month of August. T_{in} was chosen as 23^{o}C; typical indoor temperature. The U-value for a typical double glazed unit plus a transparent PV module was selected to be 1.2 kW/m^2 [20].

3. Result and Discussion

The positive correlation between a building's performance and its S/V value cannot be expressed in closed form analytically. However, numerical evaluation is conveniently done by changing l, w and h is equal proportions for E_{prod}, Q_{facade} and S/V. This trend is shown in Figure 2a, where the optimum number of occupants per square meter have been chosen to be 0.0286 [21]. The trend of Q_{facade} is fairly linear with a slope of 41.8. However, the behavior of E_{prod} can be divided into two separate (almost linear) regions. For $S/V < 0.13$, the slope of E_{prod} is steep with a value of 405, while for $S/V > 0.13$, slope decreases to about 30. Given that Q_{facade} contributes to the overall building consumption C, an optimum building geometry should be sought that maximizes the difference between E_{prod} and Q_{facade}. This difference is shown in Figure 2b. It can be observed that the relationship between S/V and $E_{prod} - Q_{facade}$ follows a convex path with a global maximum at some intermediate value (0.1407 in this case). It follows that the most optimal geometry for a building in terms of its energy performance and heat transfer will have S/V that maximizes $E_{prod} - Q_{facade}$. In order to achieve S/V values shown in Figure 2b, a range of values of h, l and w are $h \in [20,200]$(units: m), $lw = Area \in [400,2000]$ (units: m^2) and $AR = \frac{l}{w} \in [1,10]$ (unitless).

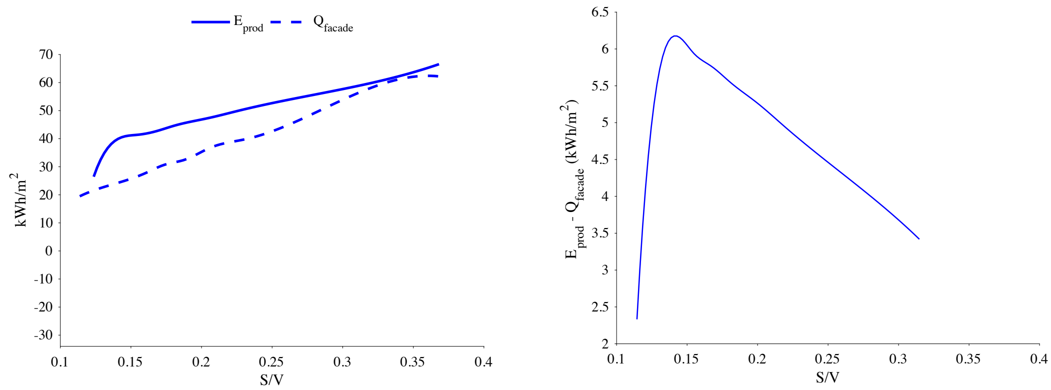

Figure 2: (a: Left) E_{prod} and Q_{facade} vs S/V (b: Right) S/V vs $E_{prod} - Q_{facade}$.

It is noteworthy from Eq. (9) that a specific value of S/V can be achieved by an infinite combinations of h, l and w. This flexibility is useful in case of any practical constraints that may limit a building's area or height. $E_{prod} - Q_{facade}$ starts from a minimum and increases linearly with a slope of about 8.45 before reaching its maximum of 98,700 kWh/person. Then, $E_{prod} - Q_{facade}$ begins to decrease in a non-linear fashion before reaching the minimum value at S/V of 0.28.

The dependence of β on Q_{facade} is evident from Eq. (7). Additionally, E_{prod} also depends on β since the incident angle of solar irradiation directly influences the amount of energy generated.

The quantification of this dependence is shown in Figure 3 for a south facing façade surface at a site location of latitude 41^o. E_b is calculated to be 23.93 kWh/m^2 through ASHRAE [22], and E_{diff} is taken to be 45% of E_b [23]. It is clear that $\beta = 40^o$ yields the highest energy production. This is in confirmation with the literature, that reports the site's latitude to be the most productive value of β [24]. The decrease in E_{prod} with β is observed to be almost linear. For every d unit increase in β, E_{prod} decreases by 28.3d units. With respect to Q_{facade}, the trend is constant till $\beta = 65^o$, after which it starts decreasing with a slope of 13.47 units.

In order to study the inter-building effects on BIPV production, Figure 4 displays the range of achievable energy thresholds as a function of β and H. These thresholds refer to the percentage of energy produced compared to the total consumption of 40 kWh/m^2 and 60 kWh/m^2. A threshold level of 100% or more would correspond to meeting the net-zero criterion. For each β, the lower and upper boundaries of the region correspond to full shading ($H = 0$) and no shading ($H = 1$) respectively. As β moves away from the site's latitude, shading level should decrease to stay at the same threshold level. For example, at 60% level and $C = 60$ kWh/m^2, $\beta = 40.6^o$ can allow for 59% shading, while $\beta = 89.9^o$ allows for only 15% shading. The net-zero region can be achieved for ($\beta < 49.49^o$, $H > 0.91$) for $C = 60$ kWh/m^2 and ($\beta < 90^o$, $H > 0.48$) for $C = 40$ kWh/m^2 as shown in the shaded region.

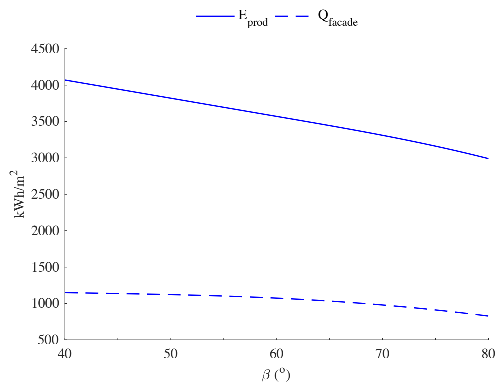

Figure 3: E_{prod} and Q_{facade} for various values of β.

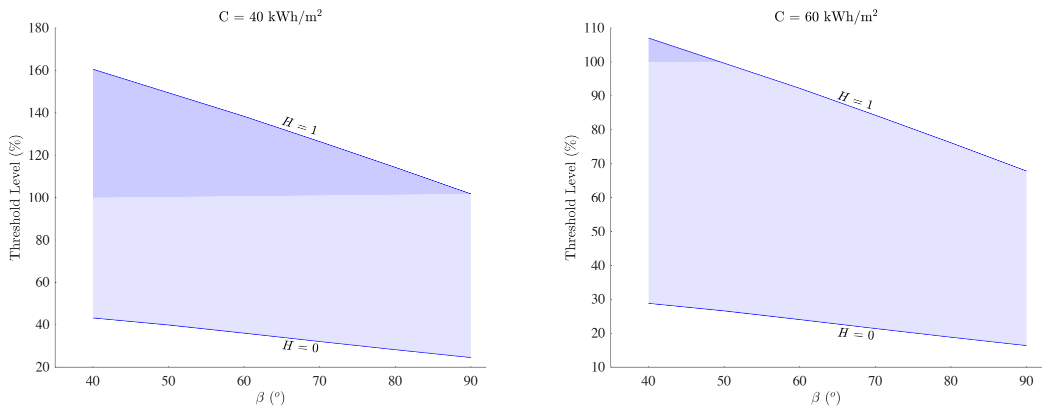

Figure 4: Energy production thresholds with shading factor H and tilt angle β. The darker region corresponds to fulfilling the net-zero criterion.

4. Conclusion

The design and implementation procedure of BIPV as a renewable energy system was carried out in order to find its best performance with various building conditions, taking into consideration comparison between different façade applications, orientations, and relevant tilt angles. In terms of parameters, the most effective methods of maximizing PV's energy production would involve factors such as specification of the building's surface-to-volume ratio (S/V), orientation, and the effect of PV tilt angle (β) on energy targets. The goal of this work was to establish a mathematical relationship for the heat transfer through a BIPV façade system. To this end, components of conduction and radiation were separately considered, and the dependence of β on the radiation component through the solar heat gain coefficient was described in detail.

This paper linked the BIPV performance to heat gain through the building envelope. It is suggested that heat gain is directly proportional. There is a considerable utility with such multidimensional problem of maximizing energy production and minimizing heat gain. Both E_{prod} and Q_{facade} were shown to be directly proportional to S/V. The positive correlation of Q_{facade} with S/V was nearly linear with a slope of around 41.8 kWh/m^2/m^{-1}. The average positive correlation of E_{prod} with S/V was approximately 3.4 times higher. The difference of E_{prod} and Q_{facade} was analyzed against S/V to investigate the most suitable geometry in terms of net energy gain. It was found that under continental conditions considered, S/V of 0.14 m^{-1} yielded the highest difference between energy production and heat gain. In terms of PV tilt β, the results demonstrated that both E_{prod} and Q_{facade} are maximized when β is close to the site's latitude. The negative slope of E_{prod} with respect to β was about 2.12 times higher than that displayed by Q_{facade}, concluding that the site's latitude is most optimal in terms of $E_{prod} - Q_{facade}$.

Heidemarie.Schuetz@BBR.Bund.de, Olaf.Boettcher@BBR.Bund.de

Abstract. An important criterion for Assessment of the sustainability of buildings owned and occupied by the Federal Government is the indoor air quality. The stated aim is to avoid pollutants from construction products and unacceptable carbon dioxide concentrations. Regarding the limitation of the carbon dioxide concentration especially in rooms with high occupancy the challenge is to find a suitable ventilation concept. That concerns natural ventilation as well as mechanical ventilation or the combination of both.
Although there are normative rules for the required air change it is hardly verifiable during building planning whether the proportion of natural ventilation is sufficient in practice. Various evaluation reports in the past have shown that natural ventilation comparability mostly did not work, especially in rooms with high occupancy. In addition, it was also shown that comparability of the test results was usually not given and therefore no conclusions could be drawn on functioning ventilation concepts.
To be able to determine and evaluate the air exchange (in case of natural ventilation) and the resulting development of the carbon dioxide concentration in a room, the development of a calculation tool is part of a recent research project. The tool is used to calculate the outdoor air volume flow with natural ventilation depending on multiple parameters (as examples: wind, temperature, window size, window opening). In the same step CO_2 concentration for a certain number of CO_2 sources in the room will be determined automatically. Thereby the tool will be very helpful in an early stage of planning to find a proper ventilation concept. In addition to its use as a planning aid, the tool offers two different applications for assessing carbon dioxide concentration in a room: The calculation under specified conditions provides the opportunity to classify the expected carbon dioxide emissions as part of the assessment of sustainable buildings. The tool is also suitable for checking the air exchange under extreme climatic or other individually selectable conditions. At the end the calculation results of each individual constellation are shown in graphical diagrams.

1. Introduction

For many years sustainable building has been a natural part of the planning and construction processes for Buildings which are owned and used by the Federal Government. In order to achieve future requirements for holistically optimized buildings the Federal Building Ministry has set up binding quality requirements and quality criteria which are described and constantly being developed in the Sustainable Building Guide and the Sustainable Building Assessment System (BNB). The Division

Sustainable Buildings in the Federal Institute of Research on Building, Urban Affairs and Spatial Development (BBSR) has the task to support the Federal Building Ministry in questions of sustainable construction. Therefor it elaborates the basics, is responsible for the continuation of the BNB and supervises corresponding research projects.

The BNB, which has been mandatory for federal building since October 2013, describes the building qualities in a transparent, comprehensible and verifiable manner. On the one hand it is an essential assessment system for defining the goals in the sustainability of a building and the integration of sustainability aspects into the planning process. On the other hand, the final assessment of sustainability after building completion leads to a certificate, which summarizes the evaluation of 46 individual criteria into an overall grade.

As human beings and their needs are an integral and important part of sustainable construction, equivalent to environmental and economic goals, the BNB also includes a number of criteria relating to the health and comfort of building users. The most important criterion in this regard is the indoor air quality [1] which assesses the pollutants from construction products and carbon dioxide emissions caused by room users. Failure to keep the boundary valuewill result in the exclusion of the BNB certification.

To ensure that the carbon dioxide concentration does not exceed the level of occupational health and safety regulations (max. 1000 ppm CO_2 in the interior – see also Table 1.) a sufficient air exchange is required.

Table 1. CO_2 concentration in the indoor air according to ASR [2] A3.6 and AIR [3].

CO_2 Concentration [ppm]	Hygienic Valuation	Measures
<1000	Hygienic inoffensive	• No further measures (as long as the room use causes no increase in concentration over 1000 ppm).
1000-2000	Hygienic conspicuous	• Check and improvement of airing habits • Preparing an airing plan (e.g.. to determine responsibilities) • Airing measures (e.g. outdoor air volume flow or raising air exchange)
>2000	Hygienic unacceptable	• Further measures necessary (z. B. enhanced airing, reduction of the number of people in the room)

2. Need for research / Purpose

Various evaluation reports in the past have shown that natural ventilation mostly did not work, especially in rooms with high occupancy. Nevertheless, for example school buildings in Germany are usually still built without a mechanical ventilation system. On the basis of this insight, existing measurement studies in German schools were analyzed on behalf of the BBSR according to the respective spatial conditions and the corresponding ventilation behavior. The aim was to draw conclusions about the practicability of various concepts of natural ventilation for rooms with difficult conditions [4]. The result of this investigation has shown that, although the measurements series presented the CO_2 concentrations, various determining boundary conditions of the respective room situation were not documented. Therefore, neither comparability nor evaluability were given and the desired conclusions impossible. But yet, it has been shown that a basic supply via a mechanical ventilation system in combination with natural ventilation seems quite practicable. Even with such so-called hybrid ventilation concepts, however, considering natural ventilation in planning is a particular challenge.

Although there are normative rules for the required outdoor air volume flow and for the calculation of required window opening area, in natural ventilation it is hardly verifiable during building planning whether the proportion of natural ventilation is sufficient in practice. By developing ventilation concepts the ventilation scenarios as well as the local spatial and climatic conditions (e.g. speed and direction of the wind, temperature difference inside / outside, internal thermal loads) are critical parameters for the calculation of volume flows achieved by natural ventilation and the resulting CO2 concentration in the room.

Therefore, such evidence is usually provided indirectly in compliance with the requirements of the standard. So far suitable tools for the development of effective ventilation concepts in the planning phase are missing. This results in a need for corresponding specialist information and a transparent tool for calculation carbon dioxide concentrations in the interior as an approximate planning assessment tool according to sustainable building.

The research project „Entwicklung von Handlungsempfehlungen für praxisgerechte Lüftungskonzepte und Entwicklung eines CO_2-Berechnungstools“[5] presented below is intended to develope instruments for planning the CO_2 concentrations during the phase of use and for verifying the functionality of different ventilation concepts. Furthermore, the possibility of an automated BNB assessment should be created. In detail, the following goals are to be achieved:

a) Identification of opportunities and limitations of natural, hybrid and mechanical ventilation under clearly defined parameters at different use scenarios and under considering all aspects of thermal comfort.

b) Development of a valuation tool through which both the required outside air volume flows and the resulting CO_2 concentrations can be determined especially for window ventilation and in combination with mechanical ventilation according to the respective framework conditions.

c) Drafting of descriptive recommendations for different ventilation concepts and room constellations which can be published within the framework of the BBSR.

3. Concept and method

The possibilities and limitations of natural ventilation in rooms with high occupancy are studied in an experimental test station under laboratory conditions. Through that the numerous factors influencing natural ventilation can be better controlled and logged. The test station simulates a typical classroom situation.The study series includes stationary and transient experiments.

3.1 Experimental test station

The basic structure of the test station (Figure 1) consists of two areas: The climate area 1 simulates the outdoor area and the climate area 2 forms the section of a typical classroom with a need for space of about 2 m²/ child. This area is equipped with rows of tables and people simulators which generate the heat load and CO_2 emissions per person. Both areas are separated by a wall in which the windows to be examined are installed. The selected depth of the test station allows the installation of up to 2 windows allowing experiments with openings of only one or both window axes can be performed.

Adjustable radiators are arranged below the windows. Through a decentralized ventilation system, the climatic area 2 can also be mechanically ventilated. The vertical ventilation system installed on the external wall has two ventilation openings in the parapet area and one exhaust opening in the ceiling area of the facade. Radiators and decentralized ventilation are not shown in Figure 1.

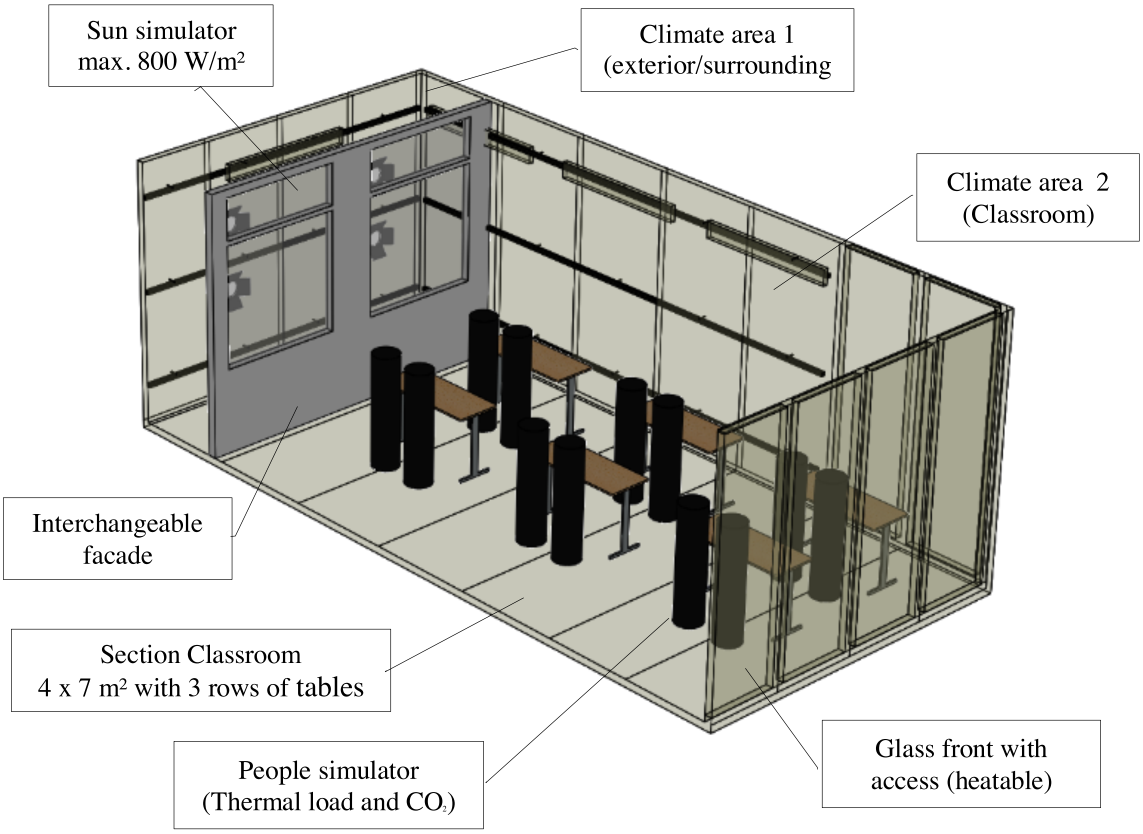

Figure 1. Basic setup of the test station.

The following data are recorded through these measurements:

- Temperature distribution in the classroom distributed up to 27 different points horizontally and vertically
- CO_2 distribution in space at up to 4 positions horizontally and in 2-3 levels at 4-6 positions each
- Thermal comfort at a defined measurement point (operating temperature, air velocity, CO_2)

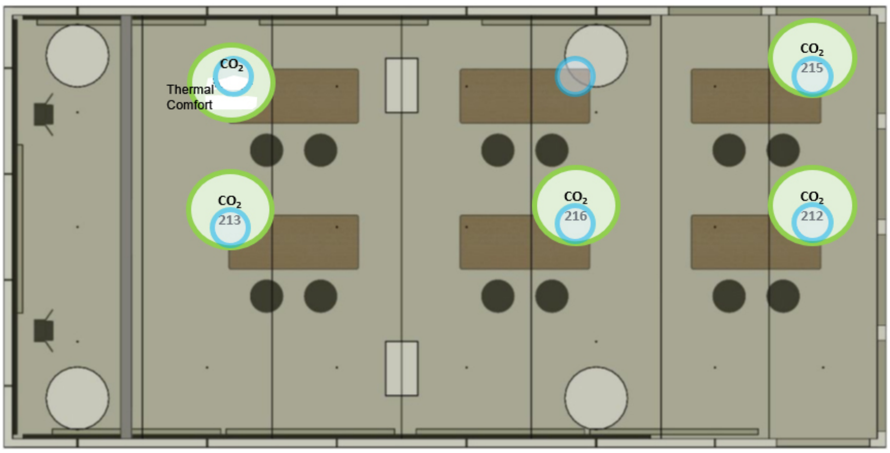

Figure 2. Measurement points ground plan.

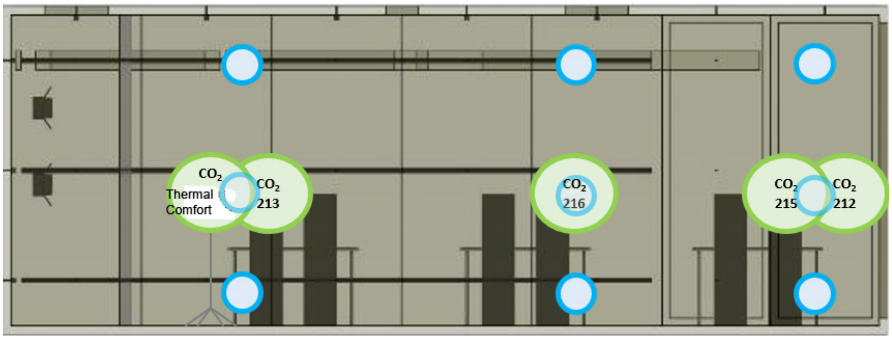

Figure 3. Measurement points sectional drawing.

In the studies on natural ventilation, the resulting volume flows were not measured directly, but indirectly determined by the tracer gas method via the decay of the CO_2 concentration in the indoor air.

3.2 Stationary test

The stationary tests are concerned with the effectiveness of different ventilation scenarios (natural ventilation, mechanical ventilation, hybrid ventilation) under constant conditions to determine the actual outside air volume flows and the resulting CO2-concentrations in the room.

The focus of these studies is initially on windows with turn and tilt wings, as this type of window is the most widespread. As a next step, other types of windows will be examined. In the test series, different boundary conditions vary, such as outside temperature (0 °C, 13 °C, 26 °C), solar heat input (with / without), wind speed (0 m/s, 3 m/s) and window opening positions.

The results for the outside air volume flows in the stationary tests with focus on natural ventilation are the base for the comparison which calculation approach is best suited for the calculation tool. The standards listed below are generally suitable for the calculation of volume flows from natural ventilation:

DIN EN 15242 [6]
DIN EN 16798-7 [7]
DIN SPEC 4108-4 (draft) [8]

Within the BNB assessment the calculation of the volume flow according to DIN EN 15242 [6] is mandatory. For the closer examination of the carbon dioxide concentration in the course of the day with freely selectable parameters no calculation rule has been defined yet in the BNB. For this purpose, prospectively the calculation formula which comes closest to the measurement results should be selected.

3.3 Transients tests

The series of measurements under transient conditions should provide insights about the spatial distribution and development of the CO_2 concentration over a longer period under certain ventilation scenarios and operating conditions. The results of the measurements are also used to evaluate the CO_2 tool which is used to calculate CO_2 developments over longer periods of time. Table 2 shows an example of a corresponding daily profile.

Table 2. Usage profile of a lesson day for a transient test.

Time-Start	Time-End		Presence of Children	Occupancy	Window Position
08:00 am	08:45 am	1. period	yes	100%	all closed
08:45 am	08:50 am	5-min-break	yes	100%	upper part tilted, lower part 140 mm
08:50 am	09:35 am	2. period	yes	100%	all closed
09:35 am	09:55 am	20-min-break	yes	50%	upper part tilted, lower part 140 mm
09:55 am	10:40 am	3. period	yes	100%	all closed
10:40 am	10:45 am	5-min-break	yes	100%	upper part tilted, lower part 140 mm
10:45 am	11:30 am	4. period	yes	100%	all closed
11:30 am	12:00 am	30-min-break	no	0%	upper part tilted, lower part opened 90°
12:00 am	12:45 am	5. period	yes	100%	all closed
12:45 am	12:50 am	5-min-break	yes	100%	upper part tilted, lower part 140 mm
12:50 am	01:35 pm	6. period	yes	100%	all closed
01:35 pm	01:45 pm	10-min-break	yes	50%	upper part tilted, lower part 140 mm
01:45 pm	02:30 pm	7. period	yes	100%	all closed
02:30 pm	03:15 pm	8. period	yes	100%	all closed

The results lead to planning and action recommendations for the creation and implementation of ventilation concepts.

3.4 Tool development

The new CO_2 tool is based on Excel and serves as an instrument through which both the outside air volume flows and the CO_2 concentration in the indoor air can be determined. Particularly the contribution of pure natural ventilation is of interest, but also their contribution in combination with mechanical ventilation according to the respective framework. The tool has two modes:

a) Calculation of the CO_2 concentration according to BNB-criteria 3.1.3 (V2015) under fixed conditions
b) Calculation of the CO_2 concentration during the day under free conditions

Case a) serves to demonstrate the indoor CO2 concentration within a ventilation interval in accordance to the requirements of the corresponding BNB assessment criterion under following conditions.

- Intensive airing for 5 min. once after 60 Min. or during lessons once after 45 Min.
- Temperature difference inside / outside: 7 K
- Outside CO_2 concentration: 400 ppm
- One-sided room ventilation
- Average wind speed 3 m/s

The case of application b) also allows the CO2 concentration profile to be determined via a self-selected daily profile and / or under changed climatic conditions in order to be able to check different usage scenarios under different conditions.

4. Summary of the results

In the studies on the effectiveness of natural ventilation through windows with turn / tilt wings, 28 different configurations of the relevant variables were considered. In addition, 8 hybrid and 2 mechanical ventilation scenarios were examined. The number of experiments with mechanical ventilation could be kept low since the expected decrease in concentration occurred. To ensure result transferability to other types of windows corresponding series of tests are currently in progress.

4.1 Algorithm for the calculation of volume flows in natural ventilation

An essential aim of the studies on natural ventilation was to find out which of the existing calculation rules in the standards best reflects the results of the experiments. Therefore the experimentally determined volume flow of a test series was compared with the calculated volume flows of the three considered standards.

The summarized results in Table 3 show that the use of the calculation regulation from DIN SPEC 4108-8 (draft)[8] gives the smallest deviations from the experimental volume flows. The calculation of this standard is therefore used calculating the air volume flows for window ventilation in the CO_2 tool.

Table 3. Summary of the results with regard to frequency of deviations as well as the absolute and percentage deviation of the measured values from the calculated values.

Standards	Number of lowest Deviation total	Up from that	Down from that	Absolute Average Deviation in m³/h	Relative Average Deviation in %
DIN EN 15242	7	4	3	84	16
DIN EN 16498-7	5	3	2	266	54
DIN SPEC 4108-8 (draft)	16	2	14	20	15

4.2 CO_2 Tool

For natural ventilation, the calculation tool considers the algorithm for determining the volumetric flow chosen in Section 4.1. The volume flows of the mechanical ventilation are entered directly into the tool. The CO_2 concentration of the indoor air can be determined by a pollutant balance of the considered area at any point in time. The tool is separated into three sections:

- **Input section:** In this part all relevant parameters for every room, which has to be considered, are entered (e.g. climate, room geometry, windows, users, usage profile).
- **Calculation section:** The calculation of the respective carbon dioxide concertation curves for all individual rooms occurs after the completed data entry.
- **Result section:** Graphical representations of the carbon dioxide concentration profiles are shown (see Figure 4). In addition the BNB assessment is shown for the use case a).

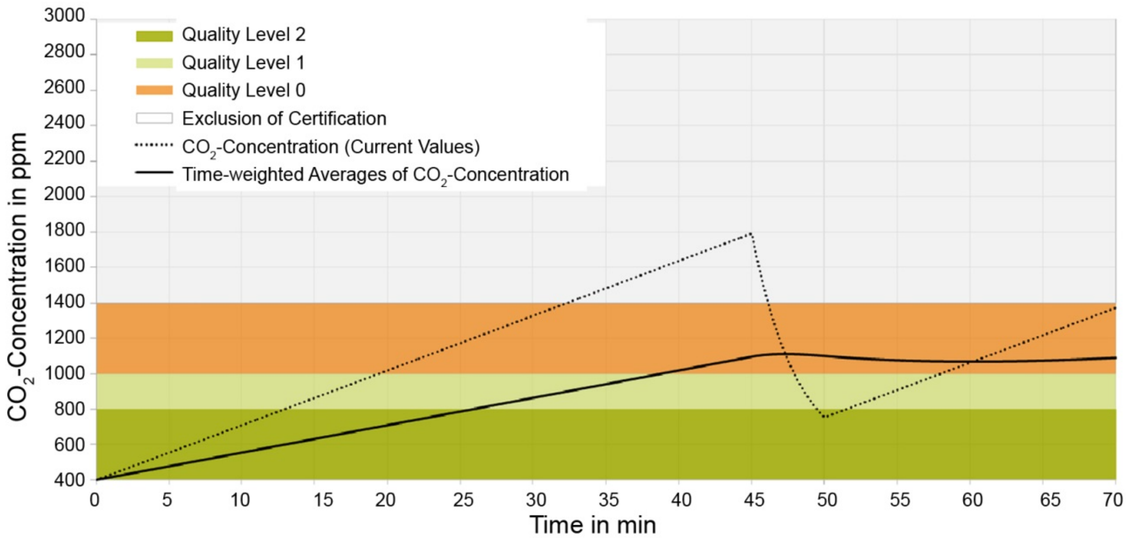

Figure 4. Graphical representation of the carbon dioxide trend and assignment of quality levels according to BNB 3.1.3 version 2015.

4.3 Results of the transient investigations during the course of the day

The CO_2 concentration developments during the day are represented very well based on the different studied usage and ventilation scenarios. Therefor any ventilation concepts can already be modelled in early planning phases and simultaneously its effectiveness is assessable. The exemplified ventilation concept, shown in Figure 5, illustrates that neither ventilation during breaks nor permanently tilted windows – over the entire teaching period – are sufficient to keep the hygienic CO_2 concentrations of max. 1000 ppm on average. Longer periods of intensive airing during lunch break causes a clear subsidence, but this is insufficient for lesson units over several hours.

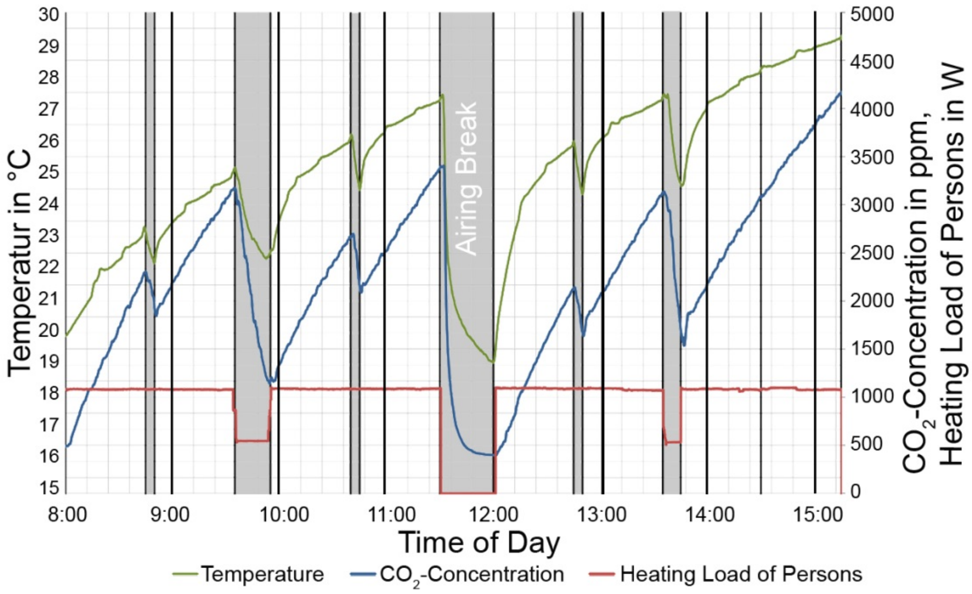

Figure 5. Average temperature and CO_2 concentration curve – transient test at 13 °C outside air temperature (see also Table 3.).

5. Conclusion and outlook

The result of the research project reveals for the first time a tool with user-friendly and intuitive applications, which can already be used during the planning phase and is also suitable for the proof of the expected carbon dioxide content in interiors within the framework of the BNB assessment. The advantage of this procedure of furnishing proof lies in the clarity, comparability and traceability due to its graphic and tabular evaluation. Furthermore, the assessment result is calculated automatically for each individual room and for the entire building at the same time.

All results of the project lead to a manual in the form of a BBSR brochure. Both basics and indicators for functioning ventilation concepts are presented and case studies are used to show which parameters influence the course of the CO2 concentration. Thereby the most problematic spatial constellations with a high occupancy rate are discussed in the example of typical school situations and possible solutions are shown with the help of the tool application.

a.mueller@massivbau.tu-darmstadt.de

Abstract. Climate change and its effects are the reasons for the energy transition in Germany and lead to an increasing exploitation of renewable energy sources. At the same time, energy efficient buildings reduce the heat demand significantly and allow for the operation of electricity based heating systems. With the aid of dynamic CO_2 emission factors, the life-cycle assessment (LCA) for buildings can be adapted to reflect the fluctuating nature of renewable energy sources and the dynamics of heating power demand during the use phase more precisely. A case study using dynamic building simulation and static as well as dynamic emission factors for the year 2017 shows deviations of 3.4 % in the building's GHG emissions. Furthermore, two emission factors for 2030 and 2050, which reflect the national 80 % carbon dioxide reduction target, are developed and applied to the case study. For these emission factors, the overall building's GHG emissions decline drastically, whereas the deviation between the LCA using static or dynamic emission factors increases significantly. It can be seen that the application of a more dynamic approach for LCA adds substantial value to the investigation. However, further investigation on a broader set of dynamic input parameters for the LCA of energy efficient buildings seems to be reasonable.

1. Introduction

Climate change and its effects are threatening the lives of millions of humans globally. Since the beginning of industrialization in the end of the 19th century, an anthropogenic greenhouse effect caused by carbon dioxide and other greenhouse gases has led to an increase of the global mean temperature and a more frequent occurrence of extreme weather phenomena. In order to prevent major impacts on the livelihood of mankind, climate change needs to be limited to a maximum increase of around 1.5 °C compared to pre-industrial ages. [1] This is why the German federal government has set the ambitious target to reduce greenhouse gas emissions about 80 % to 95 % compared to the base year 1990. As the largest part of German greenhouse gas emissions is caused by the combustion of fossil energy carriers in the electricity sector, the German *Energiewende* initially concentrated most of its efforts on increasing the share of electricity generation from technologies based on renewable energy carriers. Today, Germany's energy transition affects the three sectors electricity, heat and mobility, equally. [2, 3] At first glance, Germany has succeeded in enhancing the electricity generation from renewable energy sources significantly. In 2017, more than one third of the national gross electricity consumption was covered by renewable energies. However, the corresponding GHG emission factor for the public electricity supply in Germany reflects this progress only in part. [4] A stronger penetration with renewable energy sources in all sectors and the implementation of innovative, highly efficient cross-sectoral technologies will help to accelerate the reduction of energy-related GHG emissions. Therefore, sector coupling is considered to be a prerequisite for the next phase of energy transition. [5, 6]

Against this background, it is still uncertain which technologies in which sectors may come up with particularly low GHG emissions if the share of volatile renewable energy sources in the German electricity mix increases steadily until 2030 and beyond. To some extent, this uncertainty can be ascribed to the current methods for the evaluation of environmental impacts of products and processes. The common approach to use static emission factor for the electricity mix, which are defined as an average ratio regarding the produced electric energy over the period of one year, does not lead to realistic results as it neglects the real operation of building technology when assessing the annual energy consumption. Moreover, the integration of more flexible innovative technologies for the power and heat supply asks for more dynamic approaches. As a consequence, any future environmental assessment has to consider the dynamics of both energy supply and consumption.

For this reason, the authors developed a methodology to create electricity generation profiles for Germany in a temporal resolution of 15 minutes, which are transformed into a time series of GHG emission factors in a subsequent step. These dynamic emission factors provide the opportunity for realistic evaluations under consideration of real operation. Furthermore, the high temporal resolution is suitable for complex dynamic simulations. [7]

The paper is organised as follows: Chapter 2 starts with a brief description of the life-cycle assessment (LCA) framework and the adaptations necessary to incorporate dynamic emission factors, followed by an overview of the approach mentioned to develop dynamic emission factors based on [7]. In the end of Chapter 2, future scenarios for the public electricity mix in 2030 and 2050 are presented. In Chapter 3, a case study depicts the application of dynamic emission factors in the course of an LCA. The applicability of the dynamic GHG emission factors for building LCA and the benefits are discussed in Chapter 4. Finally, Chapter 5 gives an outlook on how to further develop dynamic building LCA methods.

2. Methodology

The following chapter gives an overview of methods and databases that are the basis for the authors' approach to develop dynamic emission factors for the German electricity mix together with a brief description of the developed technique itself. For further details about the complex methodology to process given electricity generation data and to convert it into emission factors please refer to [7].

2.1. Environmental evaluation of buildings and the built environment

2.1.1. Life-cycle assessment (LCA) and building-related LCA. The methodological basis for the calculation of emission factors for the public electricity supply is the life-cycle assessment (LCA) technique, a well-established methodology to account environmental impacts of products and services along their life-cycle. Common principles of LCAs are the definition of a specific research subject for each assessment as well as the definition of a functional unit to enable a comparison of different products or processes on the basis of their benefit for the user. In the context of fuel combustion related to electricity generation, calculated emission factors either just consider the environmental impact of fossil fuels while burning the fuel or also the upstream chain from fuel extraction and transportation, which corresponds to the LCA approach. [8, 9]

In accordance with the general LCA, building-related LCAs facilitate the evaluation of the environmental impacts during the construction, use, renovation, reutilization and demolition phase of buildings. Amongst others, the German Sustainable Building Council (DGNB) established a methodology for a holistic assessment of the sustainability of buildings, which contains a building-related LCA as major part of the ecological assessment criteria. Therefore, relevant environmental impact categories (e.g. GHG emissions) from building construction, use and reuse, recycling as well as disposal are calculated over a period of 50 years. There exist multiple databases that contain various environmental product declarations (EPDs) for building materials. In addition, numerous data sets feature mean values for a certain category or technology of construction related components like the Sustainable Construction Information Portal ÖKOBAUDAT. [10, 11]

While data sets can easily be used for the calculation of construction, transport and disposal related impacts, the use phase of a building – and in particular the energy supply for heating, domestic hot water and electricity – require additional information, input parameters and demand calculations. Besides information about the technical equipment, e.g. heat generators and storages, the final energy demand for the chosen energy carriers has to be determined. This final energy demand can be calculated according to different energy balance schemes, which in turn serve as a requirement for the issuance of energy performance certificates. [12] Anyway, all of these calculation methods usually deliver the total final energy demand per year as an input to the building-related LCA, which is then converted into a certain environmental impact using the current impact or emission factor for the corresponding energy carrier. The overall impact for the use phase is projected by multiplying the annual impact based on the final energy demand with the duration of the use phase.

2.1.2. Adapted environmental impact analysis for the use phase. In order to incorporate dynamic emission factors with a higher temporal resolution than one year, some adaptations to the described application of the building-related LCA have to be made. First and most important, the established energy demand calculation methods cannot be used any longer. Instead, dynamic building simulations replace traditional energy balance schemes giving the opportunity to simulate profiles for the space heating and the electrical power demand in a higher temporal resolution of 15 minutes. As a basis for this simulation, a building model must be elaborated that reflects the energy related behaviour of the building assessed using the LCA. Afterwards, the multiplication of the energy demand q in each time step i with the corresponding emission factor f_{GHG} leads to a dynamic profile for the environmental impact, e.g. GHG emissions c per time step i (see Eq. 1). The input to the LCA is the sum of all greenhouse gas emissions c_{total} during the period under review which is calculated from the sum of GHG emissions (c_{annual}) for all time steps multiplied by the number of years (n_{years}) of the period reviewed (cf. Eq. 2).

$$c_{\mathrm{GHG},i} = q_i * f_{\mathrm{GHG},i} \tag{1}$$

$$c_{\mathrm{total}} = c_{\mathrm{annual}} * n_{years} = \sum_i (c_{\mathrm{GHG},i}) * n_{\mathrm{years}} \tag{2}$$

2.2. Dynamic emission factors for the German electricity mix

2.2.1. Power generation and energy-related emissions. The basis for the calculation of dynamic emission factors for the public electricity supply in [7] is a set of different data on German electric power generation and consumption. For this reason, aggregated data from the transparency platform of the European Network of Transmission System Operators for Electricity (ENTSO-E) serves as the main input. [13] The data is available in 15 minute time steps and represents a mean value of the power generation from 17 different types of electricity generation. However, the data has to be processed to comply as good as possible with German national energy and emission balances. As a result, a dataset is available which shows the power generation from different types of energy carriers and power plants in the same temporal resolution on the one hand and with the correct sum of produced electricity over one year on the other.

Finally, the electricity generation time series needs to be converted into dynamic GHG emission factors, which is done by using specific environmental impact factors for different types of electricity generation provided by [14]. The resulting dynamic emission factors refer to the total consumed electric power in each of the time steps and, hence, can be used to assess the electricity demand of a building as part of a building-related LCA.

2.2.2. Modelling of future emission factors. The methodology described above is applied to calculate the German public electricity supply on the basis of actual power generation data and assessments of the environmental impact of technologies reflecting the status quo (cf. [7]). To evaluate how an increasing share of electricity generation from renewable energy sources impacts the LCA results and the dynamic approach, in particular, requires the modelling of future emission factors. This modelling is subject to certain simplifications and estimations: *a)* A major simplification is that the LCA results for all power generation technologies are considered to be constant, i.e. the environmental impact of a unit of electricity generated from a certain technology in the future will be the same as it is today. *b)* A scenario for the increasing installed capacity and power generation from renewable energy technologies is used to obtain the annual power generation from these renewable sources as well as from conventional technologies. *c)* The profile of feed-in of electrical power from renewable energies for the future has the same pattern as in 2017. This means, the increased annual power generation in the future leads to a scaling of the respective profile for the year 2017. At the same time, conventional power production is restricted to gas-fired power plants only, which are modelled as combined-cycle power plants capable for base load and gas turbine power plants in order to cover peak loads.

With these simplifications and principles, dynamic emission factors for the years 2030 and 2050 were derived from scenarios developed in [15]. While [15] discusses multiple scenarios, only the scenarios aligned to the German policies on climate change reflecting a 80 % reduction of CO_2 emissions compared to the base year 1990 will be used in this paper. Table 1 summarises some of the key parameters of the model. The GHG emission profiles for 2017, 2030 and 2050 are illustrated for a period of one week in Figure 1.

Table 1. Parameters of the most important energy carriers of the model of dynamic emission factors.

	2017	**2030**	**2050**
Annual power generation (in TWh)			
Net annual production	619.4	578	627.1
Photovoltaics	39.3	70	100
Wind-Onshore	87.6	136	188
Wind-Offshore	17.6	63	208
Biomass	46.7	46.8	36.8
Other renewable	26.3	27.2	27.3
Conventional fossil	401.9	235	67
Consumption weighted annual GHG emission factor for the public electricity supply (in $g_{CO_2\ eq}$ /kWh)			
direct	524.5	340.6	77.6
incl. upstream chains	594.1	401.4	119.6

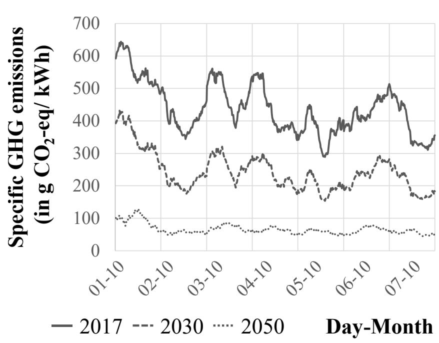

Figure 1. Dynamic GHG emission factors in a temporal resolution of 15 minutes for the years 2017, 2030 and 2050 in the period of 1st October to 7th October.

3. Case study

The following case study shall demonstrate the application of dynamic GHG emission factors on the building-related LCA. Remarks focus on those variations in results that occur from applying dynamic input parameters instead of static emission factors. Furthermore, the sensitivity of the simplified LCA approach becomes evident when comparing the results based on today's public electricity supply with those referring to a scenario with higher shares of renewable energies.

3.1. Building Model and simulation environment

In order to carry out the LCA, the experimental design of this study case is based on a generic building model. Its geometry is derived from [16] and used to set up a simulation model for the dynamic simulation software IDA Indoor Climate and Energy 4.81 [17]. The aim is to simulate the building's final energy demand in a high temporal resolution. Afterwards, the details on the building construction as well as the energy demand profile are used as inputs for the adapted LCA described before. [10] has already proved the general applicability of the chosen generic building models in the course of a profound scenario analysis. For the case study of this paper, a residential single family home will be investigated, which was modelled by [10] in accordance with the minimum requirements of the latest Energy Saving Ordinance (EnEV). In the building model, an air-to-water heat pump covers the building's space heating demand in combination with a floor heating system. Table 2 outlines the most relevant model parameters and boundary conditions of the simulation.

Table 2. Simulation and building model parameters.

Building design	2 floors	
	Net floor area	197 m²
	Gabled roof	
Heat transmission coefficient of the building envelope		*W/(m² K)*
	Wall	0.19
	Roof	0.20
	Floor	0.15
	Windows *(glazing / total)*	0.60 / 0.74
	Thermal bridges	0.05
Sun shading	External sun blinds	
Infiltration		*Air change rate per hour*
	Fixed natural infiltration	0.21
Ventilation	Window opening	
Internal loads	Residents	4 / MET 1.
	Equipment	370.2 W
Location, climate data, simulation year	Potsdam	
	Test reference year 2010	
	2014	
Heat generation	Air-to-water heat pump	
	Nominal power	9.28 kW
	COP / Annual performance ratio	3.5 / 2.95
Heat transfer	Floor heating	
Room temperature	Heating period	min. 20 °C
	Cooling period	max. 26 °C

Among others, the case study in this paper is subject to the following boundary conditions: *a)* First, the simulation model includes both, heating demand for zone conditioning and hot water demand. The latter is implemented as a hot water demand profile for a household of 4 persons calculated with DHWcalc. [18 in 10] *b)* A base load of approximately 370 W reflects the household's internal heat source due to electrical equipment, which leads to an annual electricity consumption of approximately 3,240 kWh. The power demand for lighting is not modelled in detail, but is part of the base load power consumption. *c)* The ecological assessment follows a simplified approach compliant with the DGNB certification system and [19] which comprises the thermal envelope of the building and the technical equipment for heating and ventilation. Building components that do not have any direct influence on the energy performance of the building are left aside for this case study. Furthermore, the impact of doors or other opaque openings is not reflected. *d)* The review period is 50 years. *e)* The environmental impact assessment is based on [11] and focuses on the GHG emissions of the building. Other impact categories are neglected, since the emission factors developed in [7] cover carbon dioxide and GHG emissions only. *f)* The dynamic GHG emission factors used for the assessment of the electrical power consumption include the impact of upstream chains for the electrical power generation.

3.2. Simulation and LCA results

The annual building's energy consumption is about 6,420 kWh. Because of the fact, that the heat generator is an electrically powered heat pump, the only energy carrier consumed is electricity. The overall consumption comprises 3,180 kWh for heating and auxiliary equipment as well as 3,240 kWh for the household's power consumption. Figure 2 depicts the distribution of power consumption for the heat generation and the household's power consumption on a monthly basis. It is obvious, that most of the power consumption for heating occurs from October to April during the heating period.

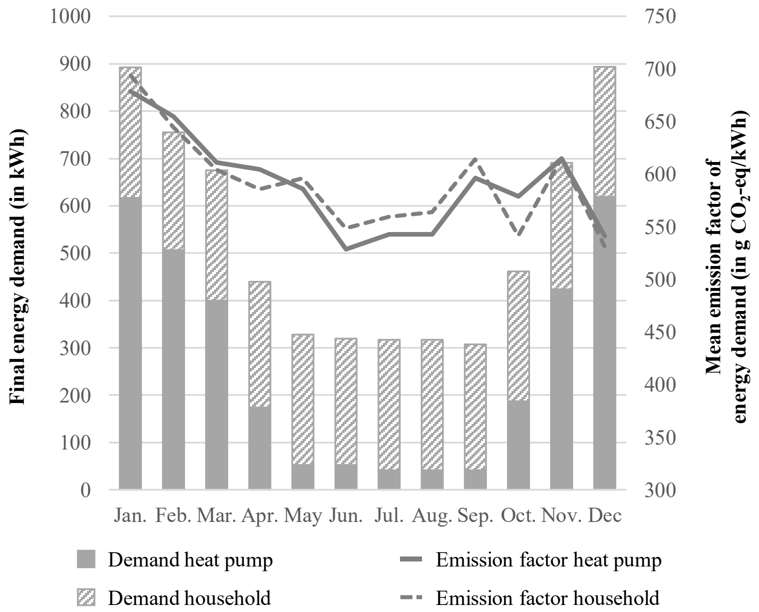

Figure 2. Final energy demand of the building for heating (incl. domestic hot water) and household's power consumption as well as monthly mean emission factors of the demand.

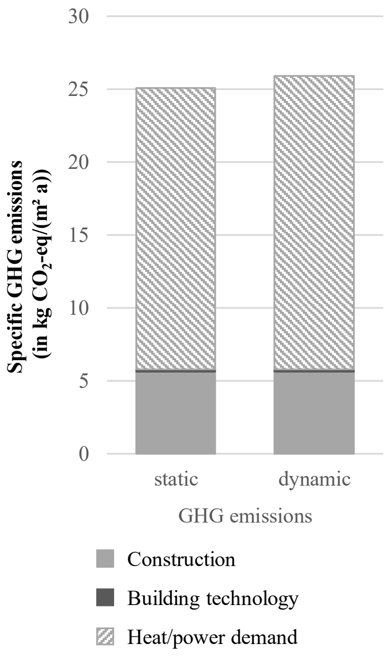

Figure 3. Results of simplified building LCA with static and dynamic GHG emission factors for the energy demand in the use phase.

As shown in Figure 3, the results of the simplified LCA reveal that the construction and disposal of the building causes 5.6 kg CO_2-eq per square meter floor area[1] and annum. At the same time, the consumption of heat and electrical power during the use phase of the building accounts for 20.2 kg CO_2-eq per square meter floor area and annum over a period of 50 years. The heat generator accounts

[1] The reference area is the gross floor area less the area for construction of external walls.

for less than 1 % of the GHG emissions of the building and is not of major importance for the LCA. A comparison of LCA results using the static method against the approach based on dynamic GHG emission factors shows a deviation of the specific emissions of about 3.4 %. This means, the GHG emissions of the energy consumed in the use phase of the building are higher than estimated by the standard calculation method. The reason for this situation is quite clear: While the static emission factor averages the annual emissions from all power generation technologies and renewable energy sources despite their varying seasonal distribution, the electrical power consumed for heating during the heating period lacks a high share of (almost carbon-neutral) photovoltaic power generation. Nevertheless, the deviation is quite small, when taking into account that many of the LCA input data sets reflect average values for components and materials.

3.3. LCA using dynamic emission factors for 2030 and 2050

As already demonstrated for the LCA results with 2017 GHG emission factors, a deviation from the static to the dynamic approach exists. To evaluate how the increasing share of electricity generation from technologies based on renewable energy carriers will impact the adapted LCA of buildings, 2030 and 2050 emission profiles are used for the investigation.

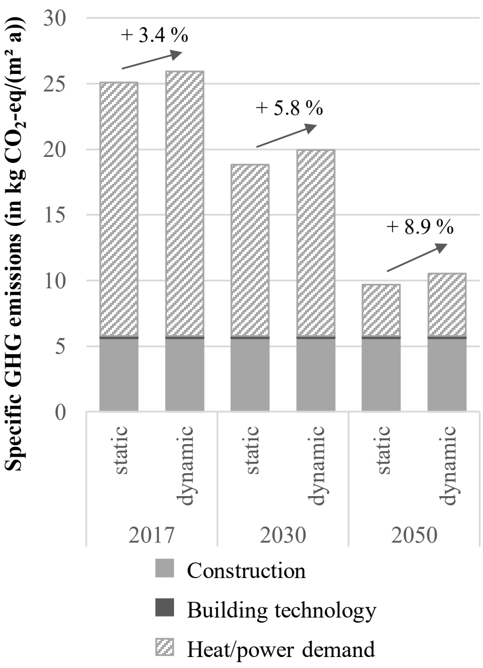

Figure 4. LCA results for GHG emissions profiles of the years 2017, 2030 and 2050

Table 3. Comparison of static vs. dynamic LCA results for scenarios (GHG emissions in $kg_{CO2\text{-}eq}/(m^2\ a)$)

	Construction	Building Technology	Heat/power demand
2017			
static	5.61	0.17	19.31
		Total	**25.09**
dynamic	5.61	0.17	20.15
		Total	**25.93**
		Deviation	*3.4 %*
2030			
static	5.61	0.17	13.05
		Total	**18.83**
dynamic	5.61	0.17	14.14
		Total	**19.92**
		Deviation	*5.8 %*
2050			
static	5.61	0.17	3.89
		Total	**9.67**
dynamic	5.61	0.17	4.74
		Total	**10.52**
		Deviation	*9.8 %*

Very clearly, Figure 4 shows the reduced GHG emissions of the electrical power consumed during the use phase of the building, provided that the share of renewable energies in the public electricity supply increases until 2030 and 2050, respectively. In this case study, the LCA input parameters for the construction and disposal phases are not adapted for the scenarios. Thus, only the electricity demand during the use phase changes according to the calculated dynamic GHG emission factor profiles. For the static LCA approach, the GHG emissions of the use phase decreases from 25.1 kg CO_2-eq to 18.8 kg CO_2-eq in 2030 and 9.7 kg CO_2-eq per square meter floor area and annum in 2050 (Table 3). This corresponds to a 25 % and 61 % reduction of GHG emissions, respectively. The comparison of static and dynamic LCA results shows that the deviation between both calculation methods is increasing with the rising share of power produced from renewable energy sources. While the deviation is 3.4 % with emission factors for the year 2017, it increases to 5.8 % in 2030 and 9.8 % in 2050, respectively (cf. Table 3).

4. Conclusion

In this conference paper, dynamic emission factors for the public electricity supply have been applied in a high temporal resolution to the life-cycle assessment of buildings. The paper shows that a dynamic simulation instead of an energy balance can be used as a methodological adaptation to the LCA. The impact of the adapted LCA approach is demonstrated in a case study, which reveals an increase of LCA results about 3.4 % for the building's life-cycle GHG emissions with a dynamic emission profile for the year 2017. In addition, the calculation of future GHG emission factors for 2030 and 2050 and their application to the LCA shows that although the overall GHG emissions for the use phase of the building decrease, a tripling of the deviation between the static and the dynamic LCA approach occurs. The building model investigated in the case study follows an electricity-only concept. Thus, deviations are higher than for a conventional setting with a non-electric heat generator. However, the combination of an increasing share of houses equipped with heat pumps in Germany along with higher efficiency requirements for buildings to achieve emission targets and the overall need for integrated energy systems underline the necessity that corresponding LCA results should match reality as good as possible. In contrast, the results of the conducted case study show the imperative to improve established assessment methods if LCAs shall help to achieve the emission targets on building level as well as on the level of national and global GHG inventories, respectively.

5. Outlook

Three main aspects regarding a building-related LCA that considers the fluctuating character of electricity from renewable energy sources have not yet been considered in this study. First, other dynamics in the power consumption of households (e.g. power demand for lighting) are not taken into account. German standard load profiles show winter-summer dynamics, which could also lead to higher emissions when incorporating them into a LCA with dynamic emission factors. In addition, the study case does not consider mechanical ventilation and, in particular, cooling in summer time. Most probably, the electrical cooling demand will have a reverse effect on the total GHG emissions compared to the heating loads when using dynamic load and emission profiles. Second, the building-related LCA uses dynamic load and emission profiles to assess the environmental impact of the use phase. However, the LCA is still restricted to multiplying the annual GHG emission in a certain year of investigation with the number of years reviewed (cf. Eq. 2). An approach for a more realistic evaluation of a certain building could be the use of a scenario model, which determines dynamic emission profiles for each year of the review period. Third, the overall impact of energy transition and lower emission factors for the public electricity supply is not reflected in this case study with regard to building components and materials that have a high electricity demand in the production phase. Scenario-specific data sets of LCA input parameters for components and materials, which reflect a decreasing emission factor of the German electricity supply would enable a profound evaluation of environmental impacts of future buildings. In this context, the potential of using dynamic CO_2 and GHG emission factors for reducing the overall environmental impact could be investigated more comprehensive.

Abstract. The IEA EBC Annex 72 focuses on the assessment of the primary energy demand, greenhouse gas emissions and environmental impacts of buildings during production, construction, use (including repair and replacement) and end of life (dismantling), i.e. during the entire life cycle of buildings. In one of its activities, reference buildings (size, materialisation, operational energy demand, etc.) were defined on which the existing national assessment methods are applied using national (if available) databases and (national/regional) approaches. The "be2226" office building in Lustenau, Austria was selected as one of the reference buildings. TU Graz established a BIM model and quantified the amount of building elements as well as construction materials required and the operational energy demand. The building assessment was carried out using the same material and energy demand but applying the LCA approach used in the different countries represented by the participating Annex experts. The results of these assessments are compared in view of identifying major discrepancies. Preliminary findings show that the greenhouse gas emissions per kg of building material differ up to a factor of two and more. Major differences in the building assessments are observed in the transports to the construction site (imports) and the construction activities as well as in the greenhouse gas emissions of the operational energy demand (electricity). The experts document their practical difficulties and how they overcame them. The results of this activity are used to better target harmonisation efforts.

1. Introduction

One major cause of greenhouse gas emissions (GHG), primary energy demand and environmental impacts is the construction of buildings and their operational energy demand for heating and cooling [1-4]. To support decision making in reducing environmental impacts, it is important to quantify the impacts and show opportunities for optimization. Environmental life cycle assessment (LCA) is commonly used to assess the environmental impacts of buildings during production, construction, use (including repair and replacement) and end of life. The LCA approach is standardized in ISO 14040 and 14044 [5, 6]. In addition, there are European standards (EN15978 [7] and EN15804 [8]) for the assessment of environmental performance of buildings and the development of environmental product declarations (EPD) of building products, respectively.

Today, there is disparity in the level of application of LCA on buildings and the existence of LCA databases targeted to the building sector across the world. The international research project IEA EBC Annex 72 focuses on the assessment of the primary energy demand, GHG emissions and environmental impacts of buildings occurring during production, construction, use and end of life. The main objectives of IEA EBC Annex 72 are among others to foster [9]:

- the discussion and harmonisation of methodology guidelines;
- the use of environmental information in an early design stage;
- the development and use of benchmarks;
- the development of national databases targeted to the construction sector.

To be able to establish harmonized methodology guidelines and identify areas of disagreement existing national methods are compared. Reference buildings are defined for that purpose on which the national LCA methods are applied. If available, national databases are used to quantify the primary energy demand, GHG emissions and environmental impacts.

2. Reference building

The "be2226" office building, located in Lustenau, Austria, is used as a reference building to evaluate existing national LCA methods. The building was designed by the architects Baumschlager Eberle architekten and built in 2013. It is a massive construction and can be seen as a low-tech building. The primary structure consists of pre-stressed and prefabricated concrete ceilings with overlay concrete and 76 cm thick exterior walls in composite masonry. The exterior walls consist of two layers of hollow perforated bricks, whereby the outer bricks are optimised for the insulating effect and the inner bricks bear the loads. The façades are covered on the outside as well as on the inside with lime plaster.

Due to its compact building shape, small and cleverly situated windows and thick exterior walls with a high thermal capacity, neither additional thermal insulation nor active heating and air-conditioning is required. The building is "heated" exclusively by the internal loads from devices and the lighting in combination with the heat dissipation of the people[27,28]. A Building Information Model (BIM) of the building was established by TU Graz. Based on this model the amount of building elements and materials required is quantified. The energy reference area of the building is 2421 m^2. All results shown in this paper are quantified against the energy reference area. The electricity demand for lighting and operating equipment is 196 MJ/m^2a.

3. Methods and databases

3.1. Used national methods including study period and databases

The assessment of the building was carried out by 22 different institutions using the same material and energy demand but applying different LCA approaches. Within the different approaches the primary energy demand, GHG emissions and environmental impacts were assessed. The focus in this paper is on the GHG emissions. In total 21 different national or regional LCA approaches were applied. The assessments of the be2226 building were carried out by the national experts, and results were reported in a uniform template that allowed for comparison between the countries. The applied methods are mainly used as part of a sustainability assessment and for certification schemes of buildings, design aid and in research activities in the respective countries.

The methods apply different reference study periods. 15 methods use a reference study period of 50 years for this case study[29]and six methods use 60 years. Denmark uses 80 years as reference study period (see Table 1). The reference study period has an influence on the relative importance of the GHG emissions of manufacture, construction, replacements and end of life stages on one hand, and the operational GHG emissions on the other. Furthermore, the methods differ in the used service life of building elements/components and the modelling of the end of life treatment of the materials. In cases the service life of a building element exceeds the reference study period, the reference study period is applied.

[28] It could be argued that the internal loads from devices are a free heating source (waste heat) and that their electricity consumption shall not be attributed to the building's operational energy demand. However, for the purpose of this paper (comparing national assessment methods) electricity demand of devices is considered part of the operational energy demand.

[29] France is one of them, but usually uses 80 years.

Mostly different versions of the ecoinvent database (i.e. [10-12, 14, 18, 19, 24, 26]) were used to assess the environmental impacts of the building. Some institutions applied country specific databases (see Table 1). The life cycle stages included in the respective approaches are shown in Table 2.

3.2. GHG emissions of construction materials

A preliminary contribution analysis of the different building elements to the total GHG emissions showed that bricks, concrete, windows and reinforcing steel are important. In Figure 1 the GHG emissions of brick along the life cycle stages (Modules A-D) as defined in EN 15804:2012 [8] are presented. Hong-Kong and the Netherlands did not report the emissions according to the life cycle stages. In all countries, which reported the emissions according to the life cycle stages, most of the GHG emissions of bricks are emitted in the product stage. While the GHG emissions in the product stage (A1-A3) of bricks are similar in all countries, differences are observed in the construction process stage (A4-A5). New Zealand reported a substantially higher impact in this life cycle stage than the other countries, mainly due to the large import distances of bricks from Australia to New Zealand (no domestic production). In the end of life stage (modules C1-C4) differences in the results are based on different assumptions on recycling shares, waste processing and final disposal scenarios. Germany reported negative GHG emissions in the end of life stage of bricks. According to the LCA data they use, the treatment in the decomposition phase leads to a complete carbonation of the free alkali- and alkaline earth oxides, which is accounted for as a credit. China assumed a high recycling potential for bricks and therefore reported high negative GHG emissions in the end of life stage. The highest GHG emissions of bricks are reported by Hong-Kong. Over all life cycle stages (i.e. without Module D) and excluding New Zealand and Hong-Kong the GHG emissions of bricks reported by the countries differ by a factor of 1.6.

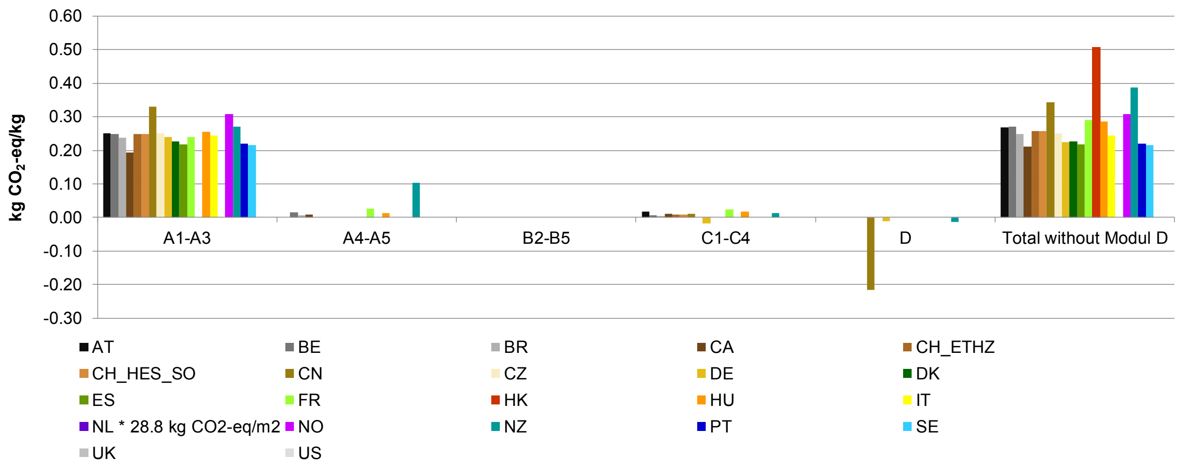

Figure 1. GHG emissions of bricks caused in the different life cycle stages in kg CO_2-eq/kg assessed according the national LCA approaches from the countries listed.

In Figure 2, the GHG emissions in kg CO_2-eq/kg of concrete are presented. Most of the GHG emissions of concrete are emitted in the product stage. The emissions differ up to a factor of 2.2 between the countries. The main reasons are different energy mixes in clinker production (share of traditional and secondary fossil fuels such as hard coal, lignite, fuel oil and natural gas or used tires), different average shares of clinker in 1 kg cement and different cement contents in 1 m^3 concrete.

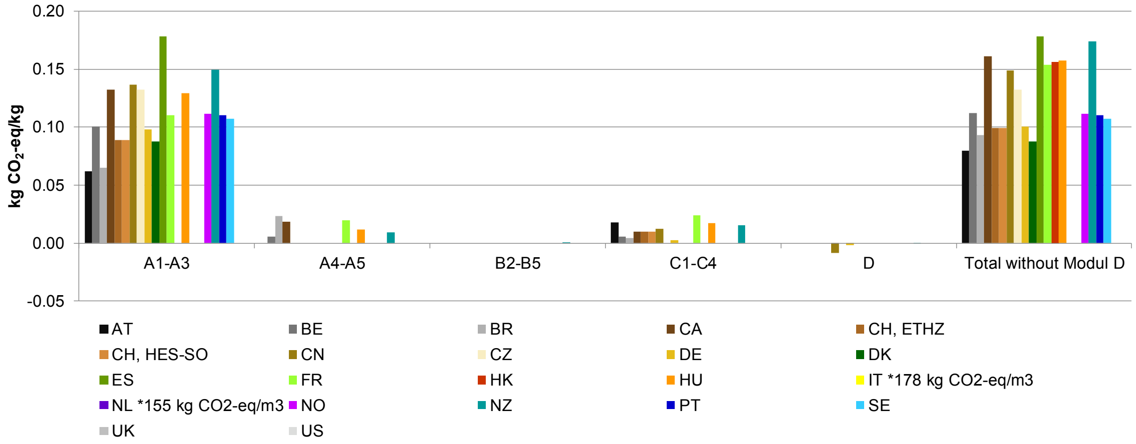

Figure 2. GHG emissions of concrete during different life cycle stages in kg CO_2-eq/kg assessed according the national LCA approaches from the countries listed.

The GHG emissions in kg CO_2-eq/kg reinforcing steel are shown in Figure 3. In all country assessments the product stage of reinforcing steel contributes most to the GHG emissions. The highest reported emissions are around 6 times higher than the lowest ones. The main reason is the share of recycled content in the reinforcing steel. The approaches applied in China, France and New Zealand report the net benefits and loads beyond the system boundaries. In China the net benefit is 53 % of the total GHG emissions of reinforcing steel reported for A1-C4. In France, the net benefit amounts to 57 % of the A1-C4 emissions and in New Zealand 8 %.

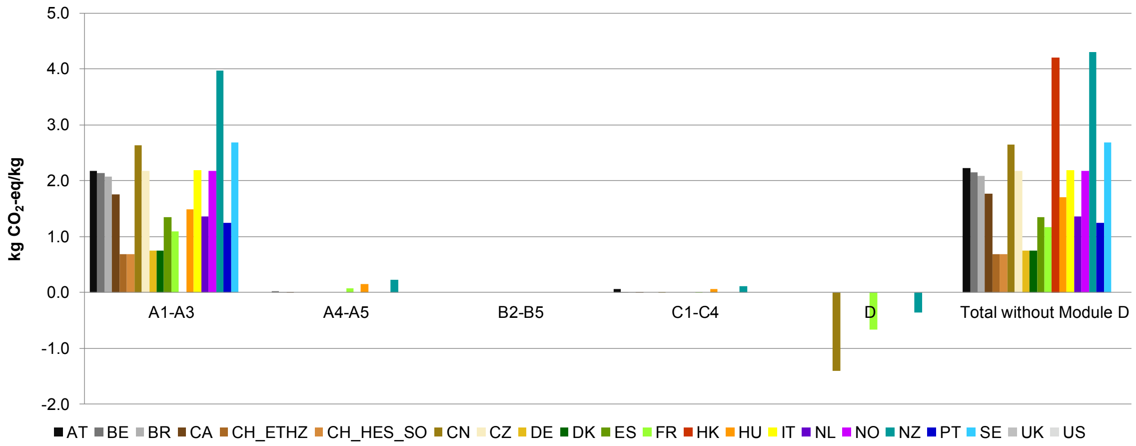

Figure 3. GHG emissions of reinforcing steel during different life cycle stages in kg CO_2-eq/kg assessed according the national LCA approaches from the countries listed.

3.3. GHG emissions of electricity mixes

The GHG emissions of the electricity used in operation reported by the different countries differ substantially (see Figure 4). While Denmark, Norway and France report low GHG emissions of their electricity mix, China, Czech Republic, Hong-Kong, Hungary and the Netherlands report comparatively high GHG emissions. The highest reported emissions are 30 times higher than the lowest reported emissions. These differences in GHG emission from electricity reflect the real existing differences in the national electricity supply. Denmark is the only country reporting a future average mix based on renewable energies only.

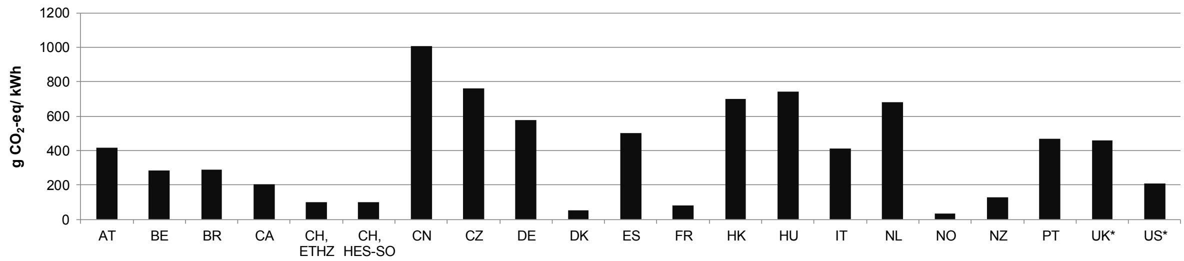

Figure 4. GHG emissions of the electricity mixes applied in the assessment of the operational electricity demand (module B6) of the reference building in g CO2-eq/kWh.
*: value back-calculated from the GHG emissions of B6

3.4. Issues encountered during the assessment

During the assessment of the reference building the authors of this paper encountered several issues with the provided data. Most of the issues were related to missing life cycle inventory data for specific materials, such as “vacuum insulation panels” and different aggregation stages in the information provided and the data available. The issue encountered with the aggregation level concerned the product level (e.g. reinforced concrete, instead of having separate LCI data on concrete and reinforcing steel) and the life cycle stages (e.g. data only available for the whole life cycle and not for Modules A, B and C separately). Furthermore, differences in the units of the building data and the available LCA data occurred (e.g. pieces vs. m^3 of stairs). To overcome the limitations of lacking LCI data for materials the authors used proxies, EPDs or did not consider the material and building elements at all (e.g. elevator).

4. Preliminary results: greenhouse gas emissions caused by the be2226 building

The preliminary results of the assessment of the GHG emissions caused by the manufacturing, construction, use and end of life of the reference building “be2226” are presented in Figure 5. The total GHG emissions reported are between 10 and 71 kg CO_2-eq/m^2a depending on the national approach used.

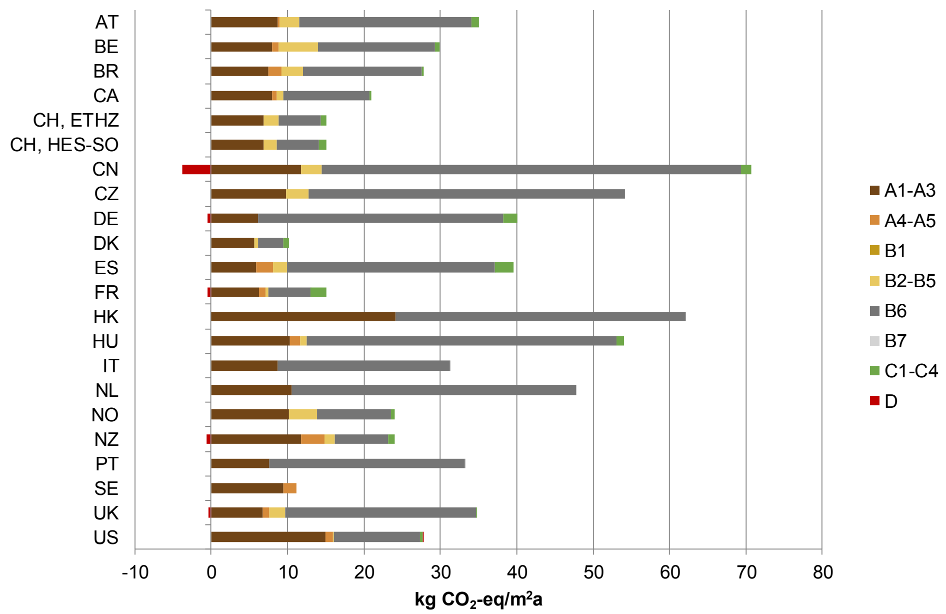

Figure 5. Greenhouse gas emissions in kg CO_2-eq per m^2 and year of the reference building **“be2226”** assessed according to the national/regional approaches of the countries listed (preliminary results).

Different life cycle stages were taken into account depending on the national approaches (see Table 2). Most of the countries were able to report the GHG emissions according to the life cycle stages defined in EN 15804:2012 [8] and EN 15978:2011 [7]. Hong-Kong and the Netherlands reported the emissions of modules A4, A5, B, C and D all together in the product stage (modules A1-A3) except the operational energy use (B6)[30]. The product stage was assessed by all countries and varies between 5.7 and 15 kg CO_2-eq/m^{2}a. Within the product stage the GHG emissions vary by a factor of 2.6 (excluding Hong-Kong). The transport to site and the construction and installation process (construction process stage A4 and A5) was addressed by 13 approaches. Over all countries those life cycle stages vary between 0.3 and 3.1 kg CO_2-eq/m^{2}a.

All national approaches, except Portugal and Sweden took the replacement (B4) of materials and building elements into account. However, only few approaches consider the maintenance (B2), repair (B3) and refurbishment (B5). Overall, the use stage (B2-B5) varies between 0.1 and 5.2 kg CO_2-eq/m^{2}a. A very high variability can be seen in the contribution of the operational energy use stage. It directly reflects the differences in GHG emissions of the electricity mixes (see Section 3.3) because electricity is the only energy carrier used in operation. The end of life stages (C1-C4) vary between 0.2 and 2.4 kg CO_2-eq/m^{2}a. This variation is not linked to the scope of end of life stage modules considered. Net benefits and loads beyond the system boundary were reported by six approaches out of 21. The approach applied in the Netherlands includes energy recovery from waste incineration and product reuse or recycling. However, the net benefits are not reported separately in the Dutch assessment. Where reported separately, the benefits are between 0.1 and 3.7 kg CO_2-eq/m^{2}a.

5. Discussion

In all assessments, most GHG emissions occurred either in the product stage or during the operational energy use. The differences in the operational energy use are due to the substantial difference in the GHG-intensity of the national electricity mixes. The variance of the GHG emissions occurring in the product stage is due to the different GHG emissions of the construction materials (see Section 3.2) and to the differences in the reference study period applied.

The Danish assessment shows the lowest GHG emissions per m^2 and year. Firstly, a reference study period of 80 years leads to lower annual emissions from the product stage (A1-A5) compared to the reference study period of 50 or 60 years. Secondly, the electricity mix applied during operation is a future national mix based on renewable energies with comparatively low GHG emissions per MJ.

The annual specific GHG emissions of this building are mainly influenced by the GHG intensity of the electricity mix used during operation. The GHG intensity of the construction materials used (Modules A1-A5) as well as the difference in reference study period cause additional differences in the annual specific GHG emissions of the "be2226" reference building. The contributions from the end of life stage are minor. The building hardly uses plastics and plastics-based insulation materials which would give rise for substantial GHG emissions when incinerated. On the building level, the potential loads and benefits beyond the system boundary are hardly visible.

The different applied approaches result in a wide range of the total GHG emissions of the "be2226" building. The differences in the results of the assessments of the "be2226" building are due to the substantially different CO_2-footprints of the energy carriers and the construction materials rather than methodological differences between the approaches applied. Hence, the relatively large differences are no cause for concern. Depending on the national context low carbon footprint buildings are achieved using different concepts. It is crucial however, that environmental benchmarks for buildings in a country are based on the LCA approaches and LCA databases used in that particular country.

[30] For reasons of confidentiality the Dutch National LCA database comprises only aggregated emissions data for the stages A, B, C and D together, in case of producer-specific LCA data.

6. Outlook

The comparison of all the national LCA approaches applied will be used to better target harmonization efforts and identify areas of disagreement. Furthermore, a second reference building, a Chinese high-rise building will be assessed by the IEA EBC Annex 72 participants to get a deeper understanding of the different approaches applied on a more complex building. The insights gained from both comparative exercises will be used along with other results of the international research project IEA EBC Annex 72 to develop and extend the methodology guideline on LCA of buildings and life cycle related environmental benchmarks.

Acknowledgments

The authors would like to thank the IEA for its organizational support and the colleagues involved in the project (Members: Australia, Austria, Belgium, Canada, Czech Republic, P.R. China, Denmark, Finland, France, Germany, Italy, R. Korea, the Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, United Kingdom, United States of America, Observers: Brazil, Hungary, India, Slovenia) for their cooperation. Additionally, they would like to thank the organizations and institutions in the participating countries for their financial support.

New Portfolio-Rating-System based on LEVEL(S)

Bernegger H J
ZHAW Zurich University of Applied Sciences, IFM Institute for Facility Management
8820 Wädenswil - Switzerland

heinz.bernegger@zhaw.ch

Abstract. In Switzerland, there are currently no instruments for the holistic and easily applicable assessment of the sustainability of existing buildings, which can also be applied to larger real estate portfolios and which are structurally based on Swiss or European sustainability standards. The instrument, developed as part of a ZHAW R&D project for the City of Zurich, Public Real Estate Management, is based on the already existing LEVEL(S) criteria structure. As distinguished from LEVEL(S), it can be applied to all types of buildings, including mixed buildings, and also scalable to larger portfolios of cities, banks, insurances or real estate investment funds. LEVEL(S) is a voluntary reporting framework to improve the sustainability of buildings. Using existing standards, LEVEL(S) provides a common EU approach to the assessment of environmental performance in the built environment. In the current Version LEVEL(S) is suitable for new office and residential buildings and existing buildings at the time of a major refurbishment. The paper shows, how the rating structures of Agenda2030/SDG's/GAPFRAME, ESCI City Rating System, DGNB and LEVEL(S) can be combined into a holistic evaluation system. If required, the developed portfolio analysis instrument can be coupled - with a more detailed building analysis as an intermediate step - directly with a DGNB renovation certification. It will show how sustaining property owners can be supported in this holistic way. Finally, the first findings from the practical application are explained. It will be shown how it is possible to support sustainably acting portfolio holders in this holistic way.

1. Introduction

Currently, the Swiss building park consists of approx. 2.5 million buildings with a total value of over EUR 2 trillion and approx. 1 billion m2 of floor space. Of these, approx. 1.7 million buildings are residential properties (approx. 1/5 of professional or institutional investors) and approx. 600,000 office und commercial properties (approx. 1/3 of professional or institutional investors). The annual building construction expenditure in Switzerland amounts to more than 50 billion EUR [1]. At present, professional or in particular institutional investors are becoming increasingly interested in being able to invest in new buildings and in refurbishing existing ones, while also taking sustainability into account.

From the perspective of Swiss portfolio holders, the first thing to do is to gain an overview of the sustainability of one's own real estate portfolio. This allows the portfolio to be broken down into sub-segments for which specific restructuring or investment strategies can then be developed and implemented.

The instruments currently used to assess the sustainability of real estate portfolios in Switzerland are usually only "one-dimensional" or relate to very few criteria. In the case of the economic dimension, for example, the parameters taken into account refer only to the structural condition of the buildings or, in the case of the ecological dimension, only to the specific and consumption-dependent environmental parameters (energy consumption). In many cases, social parameters, especially those relating to user satisfaction, are not collected, and if only unsystematically or incompletely.

In Switzerland, there are currently no instruments for the holistic and easily applicable assessment of the sustainability of existing buildings, which can also be applied to larger real estate portfolios and which are structurally based on Swiss or European sustainability standards. In the specific area of listed real estate properties, GRESB is used as an international ESG benchmarking tool. But, GRESB focuses primarily on the organization and the management processes and considers the single building limited to a few KPI's (LEED based). A holistic performance assessment as well as the derivation of concrete optimization measures at the level of individual buildings is therefore not possible.

Many of the major Swiss portfolio holders are also feeling the pressure at management level for greater sustainability transparency, driven on the one hand by an ever-increasing public debate on sustainability and on the other by increasingly stringent and detailed CSR guidelines and the associated requirements for company-specific sustainability reporting. At present, it is primarily a question of the transparency resulting from an evaluation and the possibility of better supporting decisions on necessary investments. Large-scale certification of the company's own real estate is generally not considered necessary immediately. However, it is expected that this will become necessary in the medium or longer term. In this respect, the interest in an appropriate evaluation instrument also corresponds to the need to find a way of gradually preparing for future CSR-requirements.

Based on these findings, the overriding problem or question that arises is how a future portfolio rating instrument should be designed which, on the one hand, is able to meet the general requirements of Swiss portfolio holders and, on the other hand, has the highest possible connectivity to all relevant national and international sustainability instruments.

The needs of the interviewed portfolio holder can be clustered into the following sub-requirements groups:

General requirements for the instrument:

1. Simple, effective and cost-effective applicability (time expenditure)
2. Flexible applicability due to the heterogeneity of the objects
3. Holistic assessment on all three dimensions of sustainability
4. General applicability (for public and private portfolio holders)
5. Focus on relevant aspects, central consideration of the climate topic
6. Performance-oriented definition of the criteria
7. Scientifically referenced criteria and indicators
8. Compatibility with international rating standards

General requirements for the structure of the instrument

1. Coordination with Agenda 2030 [2] and SNE (Sustainable Development Strategy for Switzerland) [3]
   in order to be able to support corresponding reporting requirements in the future.
2. Consideration of the structural condition under
   a) Alignment with national frameworks on sustainability
   b) Coordination with international frameworks with relevance for Switzerland
3. Adequate consideration of operational aspects

In summary, the main reasons to applicate a portfolio-rating-system can be derived from the following three core benefits:

- The benefits of continuous transparency through reporting in the CSR or Agenda 2030 context as well as with reference to risk management the identification of "risk objects" in the portfolio
- The benefits of hedging investments in new construction and renovation resp. the direct derivation of measures or at least as a basis for this and
- The benefit of optimizing building operations

2. Methodology

The structure of the research project is divided into three phases

1. Basic analysis, system development and definition of criteria
2. Development of the evaluation tool, pilot application
3. Monitoring and scientific evaluation

Only the results of the first phase are presented in more detail in this paper.

2.1 Basic analysis

The basic analysis comprised the evaluation of all national and international instruments existing in Switzerland with regard to their suitability relating to the evaluated requirements of the Swiss portfolio holders. This formed the basis for the selection of instruments which were used as a basis for the development of the new system architecture and criteria structure.

2.2 System development

During system development, the comparison was first made between the respective superstructures and the criteria of the selected instruments. In a further step, those criteria were evaluated which essentially form the intersection of the various sets of criteria analyzed. When selecting the criteria, however, not only the number of mentions was decisive, but also the relevance of the respective instruments (norm compatibility).

2.3 Definition of criteria and indicators

In a final sub-work package, adequate indicator definitions were sought in order to make the selected criteria assessable at portfolio level as well. On the one hand, these should be geared to the central theme of the criterion and at the same time permit simple evaluation at portfolio level.

The structure of the criteria descriptions is divided into four sub-areas:

1_Criterion_Name
2_Dimension:
3_Subject area:
4_Percentage of total evaluation:

5_Contribution to sustainable development:
6_Objective:
7_Explanation/benefit:
8_Added value (ecological/economic/sociocultural)

9_Method:
10_System limit (delimitation/inclusion)
11_Valuation (a) qualitative:
12_Evaluation (b) quantitative:

13_Type of evaluation:
14_Measured variables & characteristic values:
15_Referencing (National & International Instruments)
16_Further sources (literature, standards, guidelines, etc.)

3. Theoretical background

Switzerland has a large number of instruments for optimizing the sustainability of real estate.

The following aspects were selected as criteria for consideration in the context of instrument development:

- Comprehensive set of criteria in all three dimensions of sustainability
  - ➢ This excludes e.g. Minergie, GEAK, Energiestadt, GI, Stratus
- Public accessibility and usability
  - ➢ This excludes e.g. NRI, GeNaB, iCD, CS Green Property
- Relevance resp. distribution
  - ➢ This excludes e.g. ESI / NUWEL, INrate, SAM, BREEAM IN USE
- Relation to the local market and local norms (Switzerland, European Union)
  - ➢ This excludes e.g. LEED, WELL
- Relation to the use for individual buildings and aggregation on a portfolio scale
  - ➢ This excludes e.g. GRESB

Based on these “negative” selection criteria, 15 existing instruments were selected for detailed analysis. The aim of the analysis was, on the one hand, to find a set of criteria that is limited to the essential aspects of the sustainability of existing buildings in order to remain applicable to larger portfolios. On the other hand, all sustainability resp. performance dimensions should be considered equal and the structure should be compatible with as many instruments as possible. The instruments selected for the detailed analysis can also be assigned to the general requirements of the surveyed Swiss portfolio holders, as shown below:

3.1. Coordination with Agenda 2030 and SNE (Sustainable Development Strategy Switzerland)

- ➢ Inclusion of the Agenda 2030 at the level of sub-goals and inclusion of the gap frame instrument, as this is the only instrument known in Switzerland to provide an adequate translation resp. specification of SDG targets at company level, which also applies to building portfolios.
- ➢ Inclusion of the "Circle Indicateurs" instrument [5], as this is an instrument for the sustainability rating of Swiss cities that is aligned with the objectives of the SNE
- ➢ Inclusion of the Swiss «2000 Watt Area» Certification System [5]

3.2. Consideration of the structural condition

a) Matching national sustainability frameworks

- ➢ Inclusion of the SNBS - Standard Sustainable Building Switzerland [6]
- ➢ Inclusion of the SIA112/1 standard [7]: Sustainable construction - Building construction - Communication standard for SIA 112
- ➢ Inclusion of the KBOB/IPB guideline for sustainable real estate management of public and private clients [8]

b) Voting on international frameworks relevant to Switzerland

- ➢ Inclusion of the SIA 490 [9] as Swiss adaptation of the European Sustainability Standard CEN/TC350, which also operationalized at the detailed level via the DGNB/SGNI system
- ➢ Inclusion of the LEVEL(S) system [10], as the first EU-wide reporting tool for the sustainability performance of buildings.

3.3. Adequate consideration of operational aspects

- ➢ Inclusion of the GEFMA 160 classification [11], since requirements from the point of view Facility Management in the European area are most detailed in this instrument.
- ➢ Inclusion of the GiB instrument (Building in use) [12] in the context of the DGNB classification

In addition to these directly derivable instruments, the following two instruments were also considered:

- Inclusion of the SMEO system [13], as it is already used at the portfolio level, but is primarily used in French-speaking Switzerland
- Inclusion of the European ESCI City Rating System (Emerging and Sustainable Cities Initiative) [14], as it contains a detailed criteria and indicator structure that is also applicable to Swiss cities

4. Results

The overall structure is divided into the classic three performance dimensions of sustainability, each of which is equally weighted at 33.3%, and each of which is divided into three subject areas. This upper structure is the result of a comprehensive structural comparison of the 15 instruments examined and shows optimal compatibility based on the relevance of the instruments (norm compatibility).

Environment	**Society**	**Economy**
U1_Climate protection & energy	G1_Health & Wellbeing	W1_Building performance
U2_Material cycles	G2_Safety & Accessibility	W2_Building attractiveness
U3_Nature & Landscape	G3_Quality of spaces & communication	W3_Building resilience

Parallel to the analysis of the superordinate structures, the criteria of the selected 15 instruments were also compared in more detail, with the DGNB system [15] forming the reference structure. As a result of this time-consuming comparison, 23 criteria resulted, which essentially form the intersection of the different sets of criteria analyzed, limited to the performance-related criteria from the three dimensions of environment, society and economy of sustainable development.

As a result, the developed set of criteria is in good agreement with LEVEL(S) but is designed for existing buildings rather than new buildings or existing buildings at the point of major renovation and complements the European LEVEL(S) system with the following criteria:

- Inclusion of mobility in the life cycle assessment
- Inclusion of biodiversity issues
- Security & Accessibility
- Quality of stay & communication
- Building condition analysis
- Identity & (Building) Cultural Value

In comparison with GRESB (LEED based), the main KPIs of energy, greenhouse gas emissions, water consumption and waste are also calculated quantitatively.

In comparison to the existing DGNB usage profiles for new buildings and buildings in operation, the portfolio analysis tool developed concentrates on the actual performance dimensions. Only a few references are made to criteria from the process and technical quality dimensions. Nevertheless, the instrument developed has a consistent system for DGNB building analysis and DGNB refurbishment certification.

In the portfolio evaluation, the weighting shares of the other criteria to be "served" from the process and technical quality dimension are equally distributed among all evaluated portfolio criteria, resulting in 33.3% for each dimension. When switching from the portfolio to the more detailed building analysis view, these criteria then regain their original weighting. In project phase 2, the significance of the weighting mechanism will be checked in practical tests and, if necessary, adjusted on the basis of the results.

5. Discussion

The criteria structure developed shows for the considered topics an almost complete coverage ratio for "LEVEL(S)" and the "SGNI/DGNB system" (environment/society/economy dimensions). It is also very high for the two instruments "SNBS" and "KBOB Factsheets" (70-80%) and structurally very well compatible. In principle, a high coverage ratio with these instruments is a major advantage of the system developed. The strong link to the established European and international sustainability standards (LEVEL(S) & DGNB) promotes a high international and national reputation, makes the system compatible with international and European developments and future-proof, and makes it easier to communicate. A high degree of coverage of the national planning instruments "SNBS" and "KBOB Factsheets" is important insofar as it enables continuity and uniform consideration of issues during the planning phase and subsequently during operation or over the entire life cycle. Indirectly, the effectiveness of sustainable planning and its effects in operation can also be better assessed and plausibility checked.

In project phase 2, the significance of the weighting mechanism will be checked in practical tests and, if necessary, adjusted on the basis of the results.

The coordination to instruments such as the "cercle indicateurs" or the "2000-Watt Area Certification" is somewhat less high, as these have a broader focus that goes beyond the building itself. The "Cercle indicateurs" was developed to cover the whole range of sustainable development issues. Many of these themes cannot be influenced by buildings, or only indirectly. However, those that can be influenced by buildings are also supported to a large extent. The same applies to the "2000-Watt Areas" system, which considers an entire area or neighbourhood. However, many criteria (e.g. participation, urban development, diversity of use, etc.) are geared to planning here and can only be influenced to a very limited extent in existing buildings.

The relationship to strongly planning-oriented instruments such as "SIA112-1" and "SMEO" is also somewhat less good. On the one hand, this is due to the fact that in the case of "SIA112-1" it is difficult to make a concrete allocation due to the fact that the existing thematic structure (e.g. solidarity, balance, consolidation, innovation) is only superordinate. With "SMEO", on the other hand, direct assignment is made more difficult by the phase-based structuring as well as by many purely planning-oriented criteria (e.g. location & architecture, development, construction site management, etc.).

With the operation process-oriented instruments such as "GEFMA160" or "SGNI-GiB Building in Use" many topics are considered process-oriented but not performance-oriented. For example, the "GEFMA160" has many process-related special requirements from pure management, which have no relevance at portfolio level or only indirectly influence the actual performance criteria (e.g. document & knowledge management, CAFM, etc.).

A comparison with the goals of "Agenda 2030" shows that a considerable number of subgoals can be directly or indirectly supported to varying degrees. This is likely to become increasingly important, especially in the future, when it comes to showing and reporting the sustainability impact of these instruments in more detail.

6. Conclusion

The developed portfolio rating instrument can offer a solution on how individual existing buildings can be holistically evaluated with regard to sustainability. Analogous to the same system as DGNB for buildings in operation, entire portfolios can be assessed with little effort. For each criterion, all buildings that have comparable basic conditions or characteristics are grouped into clusters for the evaluation.

A unique selling point is the combination of high standards compatibility with SIA 490 (CEN/TC 350), SIA 112/1 and SNBS in combination with high connectivity to international assessment instruments such as LEVEL(S) and the DGNB system.

Whether the system is also easy to apply, highly effective in its evaluation methodology and highly informative in terms of the evaluation and meaningfulness of derived measures will be seen in the next phase with pilot application.

The first application tests are currently only allowing provisional conclusions to be drawn in this respect. The first clear challenges are thus emerging at portfolio level. On the one hand, it is very difficult to distinguish many properties by specific criteria. On the other hand, due to the range of criteria, the required information must be gathered from a relatively large number of different data sources. In this respect, it is only possible to estimate how much initial effort can generally be expected on the basis of the pilot application.

Experience has shown, however, that this effort decreases considerably with a cyclically repeated evaluation.

The portfolio analysis instrument developed is designed in such a way that it can be coupled optionally or, if required, directly via a more detailed DGNB-based building analysis as an intermediate step to a final DGNB remediation certification. Here, too, it will only become apparent through effective application whether the chosen approach of deriving the weighting factors from the respective new building usage profile will in reality help to derive suitable conversion and refurbishment measures.

However, the first application results for simpler objects already show that the criteria are generally well applicable and also yield meaningful results. It can therefore be expected that in the future it will be possible in this way to use the developed portfolio rating instrument to provide holistic support to portfolio holders who act sustainably.

The BNK Assessment Tool for the sustainability performance of small residential buildings in Germany – Lessons learnt

Essig N

Munich University of Applied Science, Faculty of Architecture, Karlstrasse 6, 80333 Munich, Germany

natalie.essig@hm.edu

Abstract. Several instruments for the assessment of the sustainable building performance such as BREEAM (Great Britain), LEED (USA) and DGNB or BNB (Germany) have been developed in the last years. These methodologies have the same intent - advancement of the sustainable building performance. These systems focus mostly on commercial buildings. However the sustainability assessment of the residential sector is getting more important. Giving that around 115,000 owner-occupied detached houses are built up per year in Germany, a new assessment method (BNK system) for small residential houses was developed on behalf of the Federal Ministry for the Interior, Building and Community (BMI) in 2015. To ensure the suitability of the assessment system, the BNK method was tested in a pilot phase and from 2016 on it is available for general use and the assessment is financially supported by public funds (KfW Banking Group). To date more than 100 of small residential buildings have been certified with BNK. This paper will show the development and experience with the sustainability assessment of buildings in Germany in general, as well as the intents, indicators and real case projects of the BNK-Tool for small residential buildings (up to five dwelling units) and its further development.

1. Introduction

If future generations are to have a quality of life comparable to the one we enjoy at present, then we need to act sustainably towards our environment. This applies to everyone, including the construction industry. Up until now, the term "sustainable construction" has been associated mainly with efforts to reduce the impact a construction project has on the environment, and to improve its energy efficiency. In fact, however, this is only part of what sustainability means [2].

At least in relation to the construction industry, sustainability is actually much more complex than that. Sociocultural, functional and economic aspects, and the building's technical and process and location specific characteristics, are also important. To build sustainably, it is therefore not enough just to follow a rigid set of guidelines.

Special concepts, solutions, alternatives and measures need to be developed, all tailored to the construction project in question. Sustainability quality labels are important as a tool for achieving and assessing sustainability in a building: they ensure that all of the above aspects are given equal attention during the planning process, and they take into account all stages of the building's life cycle. In recent years, numerous labels and certificates of this kind have been developed around the world, all designed to allow a building to be assessed as a complete system. They draw on existing planning tools and aspects of sustainable construction, and complement existing national standards and legislation. They give planners and clients an assessment of their project during its very early stages, which can be used in drawing up sustainable planning objectives and improving the building's sustainability credentials right from the planning stage. Building certificates are additionally an easy-to-understand way for users and operators of finished projects to obtain information on the building's level of sustainability. Certification systems do not only assess the sustainability of the building as it stands, but it also provides added quality assurance by requiring the compilation of suitable building documentation [2] [3].

2. Sustainability Assessment Methods for Buildings

2.1. Methods for Assessing Sustainability – International

The established international methods for assessing the sustainability of buildings are the British system BREEAM (BRE Environmental Assessment Method), the American method LEED (Leadership in Energy and Environmental Design) and the German DGNB certificate. BREEAM and LEED were both developed in the 1990s. In 2009 two systems were launched in Germany – the Sustainable Construction Evaluation System (BNB) of the Federal Ministry for the Environment, Nature Conservation, Building and Nuclear Safety (BMUB), and the DGNB certificate of the German Sustainable Building Council (DGNB), that, unlike previous methods, did not focus solely on the building's environment-friendliness and energy efficiency, but instead considered its entire life cycle [2].

Thanks to their successful marketing strategy aimed at promoting the "green building" concept, the American LEED and the British BREEAM system are currently the best-known certification systems worldwide. This is shown also in the number of certifications, like 100,100 LEED and 18,800 BREEAM certified buildings [4] [5]. BREEAM owes this success also to the fact that the British government has enshrined sustainability standards for the UK construction industry in law [6]. Notable documents are the 2006 "Sustainable Procurement Action Plan", according to which all new and refurbished government buildings must achieve the "BREEAM Excellent" standard, and the "Code for Sustainable Homes", which since May 2008 has required that all new residential buildings be built according to specific sustainability standards, and subsequently rated [6].

2.2. Methods for Assessing Sustainability – in Germany

In 2007, the German Sustainable Building Council (DGNB) was set up with the aim of developing a German quality label for assessing the sustainability of buildings. At the same time, the Federal Ministry of the Interior, Building and Community (BMI, former BMVBS Federal Ministry of the Interior, Building and Community) started work on a method for the evaluation of sustainable buildings. The DGNB and the former BMVBS soon decided to join forces and worked together in this area. In 2009, on the basis of past experience, international and European standards for sustainable construction such as the international standard ISO TC 59 SC 17 (Sustainability in building construction) and the European standard CEN/TC 350 (Sustainability of construction works), and the results of the "Round Table on Sustainable Construction" and "Guideline for Sustainable Building" of the BMI, the first list of criteria for the "German Certification Method for Sustainable Building" was published [2] [7].

There are now two systems in Germany based on that original joint list of criteria: firstly the DGNB certificate, which is mainly for commercial buildings in the private sector. The DGNB itself is responsible for promoting the system internationally. Over 1,500 buildings have been certified to date under this system [7]. The BNB system from the former BMVBS (now BMI), on the other hand, is for all buildings that are of significant relevance to the general public, for example federal buildings. So far 25 buildings have been certified under this system [8].

3. Sustainability Assessment Method for Small Residential Buildings in Germany – the BNK System

3.1. Why detached and semi-detached houses?

Up until now, it has been almost exclusively buildings such as office buildings, schools, industrial buildings and large residential buildings (i.e. those containing six or more dwelling units) that have been assessed for sustainability in Germany. Insufficient attention has been given to smaller residential buildings ranging from detached houses to apartment blocks with up to five flats, even though these buildings represent a large share of total residential new build – up to 60 percent [9]. The former BMUB has tackled this problem, together with Munich University of Applied Sciences (MUAS) and other building experts and researchers, by developing a list of criteria specifically for these smaller residential buildings. A wide range of industry players were subsequently called upon to fine-tune this list, which was then subjected to pilot test to test its suitability for the market. These included housing construction industry associations, architects, engineers, and the prefabricated house industry [1].

Outside Germany, residential buildings have long since been assessed against sustainability criteria. Some 1,700 residential buildings (more than 426,000 dwellings) have so far been assessed under the BREEAM "Code for Sustainable Homes" system, for example. This is thanks to the UK government's decision in 2008 to enshrine in law the sustainability assessment of buildings [5] [10]. More buildings are being assessed with other systems as well, under the LEED quality label 28,900 single and multifamily homes and under the Swiss Minergie label (21,800 detached and semi-detached houses as well as 20,900 multifamily houses) [4] [11].

In Germany, the Sustainable Housing Construction Quality Label (NaWoh) and individual system variants of the DGNB certificate are available for assessing residential buildings, although the formers are only available for structures containing six or more dwellings [7] [12]. However, the list of criteria of both systems is very complicated and costly to implement. With an average of 120,000 new detached and semi-detached houses being built each year in Germany, a cost-effective, lean, simple assessment system for residential buildings that all clients can apply, and that is designed to encourage sustainability in small residential buildings, is essential [13]. Therefor the BNK system was developed and is available on the market since 2015 [1].

Figure 1. Sustainability qualities of BNK [1]

3.2. BNK-System: Criteria for sustainable small residential buildings

The list of criteria for sustainable small residential buildings is divided up into the four categories

- Sociocultural and functional quality
- Economic quality
- Environmental quality
- Process quality

broken down into a total of 19 criteria [1]. Figure 1 shows a summary of the qualities for small residential buildings, Figure 2 the 19 BNK sustainability criteria.

The system is based on the Sustainable Construction Evaluation System (BNB). However, due to the importance of the social aspects in determining the sustainability of small residential buildings, the category of “Sociocultural and functional quality” comes first in the list of criteria for detached and semi-detached houses, rather than environmental quality, which is the top category for the other building types. Each of the four categories accounts for 25 % of the overall result [14].

3.2.1. Sociocultural and functional quality. Social aspects are particularly important in determining the sustainability of small residential buildings. In the category of “Sociocultural and functional quality” the aspects of quality of life, comfort, safety, security and adaptability are assessed. The level of comfort is determined by measuring the characteristics of the building from the building physics point of view. This is based on a number of calculations regarding thermal, acoustic and visual comfort and by assessing the inherent level of air hygiene inside the building. Because the system takes into account the aspects of safety and security, accessibility, and the user-friendliness of the building services, it helps to enhance residents’ quality of life.

3.2.2. Economic quality. The goal of the “Economic quality” category is to determine selected costs incurred during the building’s life cycle, and to assess its long-term viability. The calculation of life cycle costs is based on the standard DIN 276 (Building costs – Building construction). Long-term viability is based on the assessment results for various criteria such as accessibility and thermal insulation in summer, and the extent to which the building’s energy efficiency figures exceed those demanded by the German Energy Saving Regulation, the degree to which the rooms are designed in a neutral way to allow for alternative uses, and the extent to which the client has been briefed to enable them to maintain the building’s value over time.

3.2.3. Environmental quality. The environmental quality of a detached or semi-detached house is assessed by carrying out a life cycle assessment (LCA). The LCA is prepared using the online tool “eLCA” provided by the BMI and the BBSR (German Federal Institute for Research on Building, Urban Affairs and Spatial Development) [15]. The LCA looks at the building’s entire life cycle, this include the building fabric and the building services. The most important indicators used are Primary Energy Consumption and Global Warming Potential. Other aspects such as recyclability, the use of local or certified wood, measures taken to reduce drinking water consumption, and the efficient use of space in order to minimize soil sealing are considered.

3.2.4. Process quality. The main aim of the “Process quality” category in relation to residential buildings with up to five dwellings is to ensure the quality of planning, construction and documentation, and to provide a building dossier including a user manual. The building dossier includes the latest plans, energy performance certificates, measurement records, safety certificates, data sheets, care instructions, and all documents relevant to the operation and maintenance of the building. Process quality also includes having the quality of construction verified by an external assessor.

3.3. BNK-System: Assessment Methodology and Certification Authority

For each criterion there is a description of the assessment method and indicators, general information, an assessment scale, and the documents required as evidence of adherence to that criterion. The result of the assessment is represented by a score between 1 to 5, and its percentage. The scores and percentages relate to one another as follows [1] [14]:

- 80 % or more: score of 1.5 or better
- 65 % or more: score of 2.0 or better
- 50 % or more: score of 3.0 or better

The building owner will receive the BNK certificate, in case one point in each criterion is achieved. The certificate will be proved and over given by BiRN (Bauinstitut für Ressourceneffizientes und Nachhaltiges Bauen GmbH). BiRN is the official certification authority for the BNK system and is accredited by the BMI. Furthermore BiRN is responsible for the training of BNK auditors and for the development of the BNK system [16].

Figure 2 List of BNK criteria [1]

3.4. BNK System: Further development

To ensure the practicability and user-friendliness of the sustainability assessment of small residential buildings in the long term the intents, the standards, methodologies and benchmarks referring to the BNK system are updated and developed at regular intervals.

In 2018 the results of the research project "Further development of the criteria indoor air hygiene, pollutant emissions, dismantling and dismantling friendliness and resilience of the BNK system“ was published by BiRN. This research project was developed by BiRN in close collaboration with building experts from all over Germany [17]. It was funded by the research initiative "Zukunft Bau" of the Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR). In addition to the revision of already existing criteria, new aspects of sustainability were taken up.

These criteria have been proofed in real case studies involving building owners, developers, project managers, architects and engineers. A pilot study was carried out in order to check the suitability of the new and overworked criteria on real detached and semi-detached houses. Around ten single family housing have taken part. In the following the four new developed criteria will be shown:

- Criteria “Indoor hygiene and risk-based emissions of construction products”:
  New assessment processes and methodologies were added to the existing criterion. Further on benchmarks of the existing indicator were revised. Originally the listing of used construction products was sufficient for assessing small residential buildings. In the new version

benchmarks and parameters for "Volatile Organic Compounds" (VOCs) and other risk-based substances were defined and added. For this purpose, different digital tools have been developed to implement the new assessment methodology in a simple and practicable way.
- Criteria “Consultation, agreeing objectives and risk assessment against natural hazards”: The methodology for assessing the risks for natural hazards has been newly integrated into this criterion. Natural hazards, like wind, heavy rain, hail, lightning, snow load, flood, radon and earthquake will be considered now. The assessment was divided into three risks classes "low", "medium" and "high" risk.
- Criteria “Building dossier including user manual, demolition and dismantling-friendliness”: The topic of deconstruction, separation and the re-use of buildings product was taken into account. Aspects for resource-efficiency and waste-minimizing of buildings were extensively overworked. A new process for the preparation and evaluation of dismantling concepts was integrated into the criteria. Therefor a component catalogue with dismantling and separation option was developed that includes the mass balance of building products coming out from Life Cycle Analyses (LCA).
- Criteria “Quality assurance in planning, construction and use”: In addition to an editorial revision, the benchmarks were adjusted in this criterion during the research project.

4. Outlook and Benefits of Assessing Building Sustainability

Since April 2015 the BNK system is available for general use as a simple and cost-effective assessment system for small residential buildings. Assessments are carried out by “Sustainability Coordinators” who hold a specialist qualification in sustainable building by BiRN and who monitor the project during planning and construction. To ensure that all certificates are of a suitably high quality, the assessments are checked furthermore by BiRN [16]. From 2016 the KfW Banking Group is providing financial support to help projects achieve the sustainability certificate for houses with one to five dwellings, similar to the support it offers for those seeking to achieve the Efficiency House standard.

Based on the results of the research project the new criteria will be integrated in the BNK system in a new version at the end of 2019. Furthermore the system will be extended to cover residential buildings with up to five dwellings; in future it is conceivable that it will also allow the assessment of refurbishment work on existing residential buildings.

Summarizing the abstract - the advantages of applying sustainability tools and criteria for small residential housing are the follows [2] [3]:
- benchmarks help to reduce and monitor the building’s impact on the environment,
- allows quality of different buildings to be compared,
- helps in setting sustainable planning objectives (e.g. checklists),
- improves the transparency of planning and construction work,
- provides a project management tool for ensuring that sustainability is achieved,
- better building documentation (e.g. building passport),
- more competitive at all stages of life cycle.

A stakeholder- and function-based planning method for space-efficient buildings

Von Both P[1]

[1] Department Building Lifecycle Management, Karlsruhe Institute for Technology, Karlsruhe, DE

petra.both@kit.edu

Abstract. Space efficiency has proved to be one of the basic parameters for achieving a high level of sustainability of buildings. By optimizing the required space to fulfil functional requirements, high potential savings can be achieved in terms of space, material and energy consumption. This presupposes, however, that – following the principles of an integrated design process - the use-related functional requirements of buildings have been determined in the early planning phases and that architects take these functional requirements into account accordingly - also with regard to possible organizational, logistic and process-related options. So, interdependencies and (temporal) overlays can be reflected and the topological structure can be transferred into space-efficient spatial structures. But adequate tools and methods are currently missing that support this process of user-based functional demand planning in the sense of an integrated participatory process. This contribution introduces a methodology for early planning phases, which is based on a stakeholder analysis and helps to specify process-related user functions as well as qualified functional correlations. The functional relationships can be described, for example, spatiotemporally or in relation to the flow of materials and can be mapped in an adjacency matrix. The planner is thus actively encouraged to think about area- and space-related optimization potentials and can transfer the topological structure of functions into an space-efficient floor plan concept. Also a prototypical implementation of this method will be presented as a web-based tool that supports a participatory user and stakeholder-related planning process.

1. Introduction

To implement sustainability strategies in the construction sector holistically, a rethinking of pure technical (eco)-efficiency strategies is necessary that includes also social and user-related considerations and sufficiency strategies [2, 3, 4]. Only after the analysis and reflection of the real functional demands of building users, we can answer the question of 'how much and what kind of resources are used for achieving the desired purpose', needs and functions' and offer a quality response to these needs [1]. Boulanger [3] speaks about the 'Satisfaction/Service ratio' with the superordinate goals of well-being, happiness or needs satisfaction.

In the construction sector, an important starting point is the fundamental question about the construction volume or space that is necessary to fulfill the relevant user functions and to enable an adequate execution of processes. Thus, space efficiency is one of the key factors for achieving a high level of sustainability of buildings. By optimizing the required space to fulfill functional requirements, high potential savings can be achieved in terms of space, material and energy consumption.

This is particularly evident in the field of residential buildings. Housing is currently one of the most important and much-debated topics of architectural design in Europe. Due to current political and sociological changes such as migration growth, demographic change and urban-rural movements, the demand for affordable and sustainable living space is growing. The latest changes in legal framework conditions for the densification of existing urban structures in Germany exemplify the urgency of the problem [4].

The topic of space- and thus resource and cost-efficient construction gets a special meaning here. However, space efficiency can only be achieved, if the implementation of the functional requirements is taken into account in a systemic manner to create adequate and sustainable building structures and typologies.

A look at the available planning literature and construction practice, however, shows that standard solutions and traditional typologies are used without any reflection. They represent current energy-saving regulations but are hardly capable of dealing with the current sociological changes in the resident respectively family structures and also in the living behaviour.

Standard literature such as floor plan compendia for dwelling houses (for example the German ‘Grundrissatlas Wohnungsbau’ [6]) focus mainly on the subject of single-family dwellings and floor plan typologies, which originate from the 1950s and thus serve primarily family structures such as the classical nuclear family and a very traditional understanding of roles. These are in today's time, however, from a sociological point of view, hardly available and desirable. Unfortunately, there are hardly any planning aids and generalized examples of new approaches such as residential communities, intergenerational living or cooperative housing. The ever more popular approach of minimal and often modularized Tiny Houses [7] provides first good approaches to space efficiency, but focuses – often combined with concepts of ressources self-sufficiency - on very specific target groups and can therefore hardly be generalized.

Niklas Maak - Chief editor of the culture department of the Frankfurter Allgemeine Zeitung and a well-known architecture critic - for example, in his book "Baukomplex" [8] calls for a fundamental rethinking of current planning practice and explains the need for the development of new user-related typologies that can adequately serve today's functional and structural needs of different user groups.

This presupposes, however, that – following the principles of an integrated design process - the use-related functional requirements of buildings are determined in the early planning phases and that architects take these functional requirements into account accordingly - also with regard to possible organizational, logistic and process-related options. So, interdependencies and (temporal) overlays can be reflected and the topological structure can be transferred into space-efficient spatial structures.
But adequate tools and methods are currently missing that support this process of user-based functional demand planning in the sense of an integrated participatory process.

This article introduces a methodology and planning means for the early planning phases, which begins with a stakeholder analysis and helps to specify process-related user processes and functions and which supports their transfer into topological concepts and floor plans. The function-based methodology for architectural design has been applied, evaluated and enhanced in teaching design projects for over 3 years now and will be presented with students’ design examples in the following.

Application context of these teaching projects has been housing projects as well as hybride buildings that should cover the design principles of mixed-use, flexibility and space efficiency. But the principles of the methodology are generalizable and not limited to a specific typology of buildings.

2. Methodical Conception

One important prerequisite for successful design projects is the existence of a holistic target system that makes the impact of planning activities assessable with regard to the entire life cycle of the planning object or system. Taking into account its interactions with the superordinate systems and stakeholders [9]. From the objectives of this superordinate system, the purpose and utility of buildings and thus the specific object-related objectives and functional requirements (including functional performance) of the planning subject can be deduced. Here, it is important to analyse the value systems, consumer behaviour and development strategies of the clients and also later building users [10], if possible by a participatory process.

If the customer is also the future user, the application of target planning methods and tools [11] can support the direct interaction. In the case of, for example, investor projects or the design of rental properties, in which the future user is not yet (concretely) known, the (functional) needs can be generalized at the level of target groups by means of marketing methods, such as the persona method

[12]. An important mean for the identification of value systems and consumer behavior are socio-scientific approaches of life-world studies [13] like the sinus milieu data [14].

The methodical approach, that bases on this system of objectives, supports the design process on two levels (see figure 1): At the structural level, the development of spatial-functional topologies and spatial structures takes place, basing on the relevant user processes and their interactions.

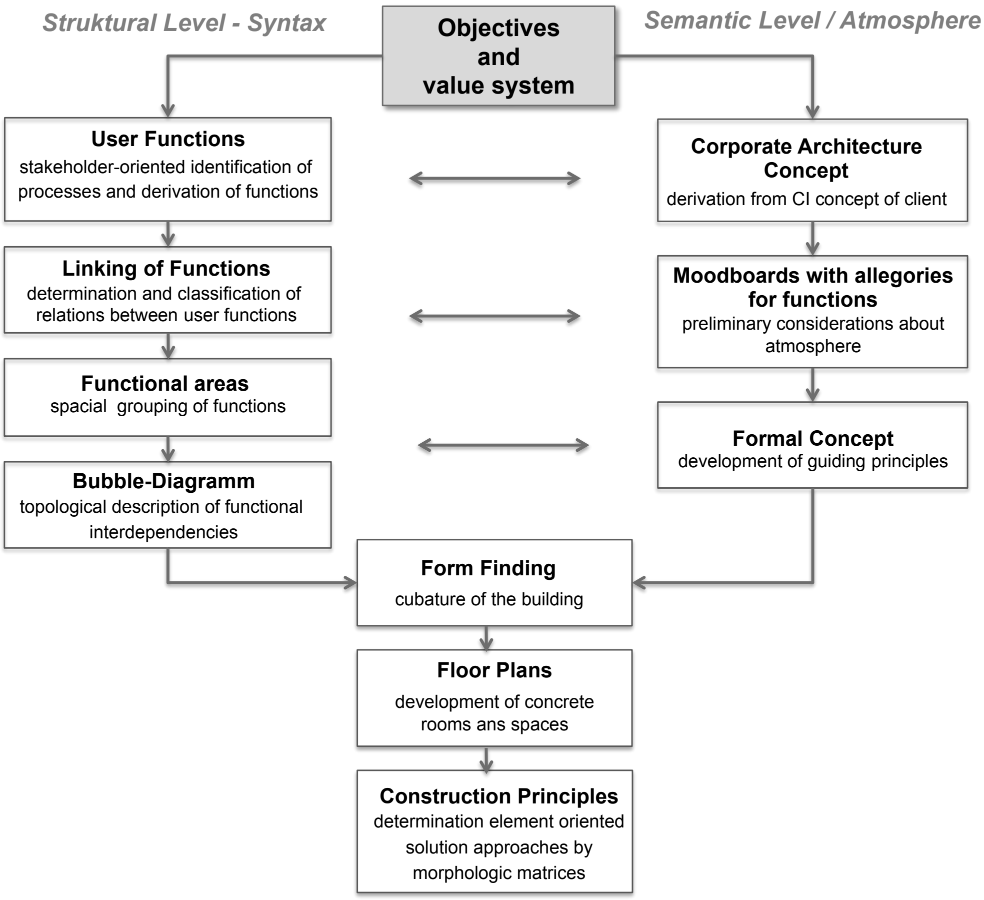

Figure 1: Process-logic of the Function-based Methodology

This process starts with a stakeholder and user analysis and is supported by a so called „structure matrix' - an adjacency matrix, which helps to analyse, qualitatively specify and formalize process-related user functions for the different stakeholders (see figure 2), that should be developed in interaction with the functional requirements in the target system. The analysis and overlay of daily and annual routines of the different users can reveal first relevant correlations. Here, it is very important to specify the functions qualitatively, because it has different spatial consequences.

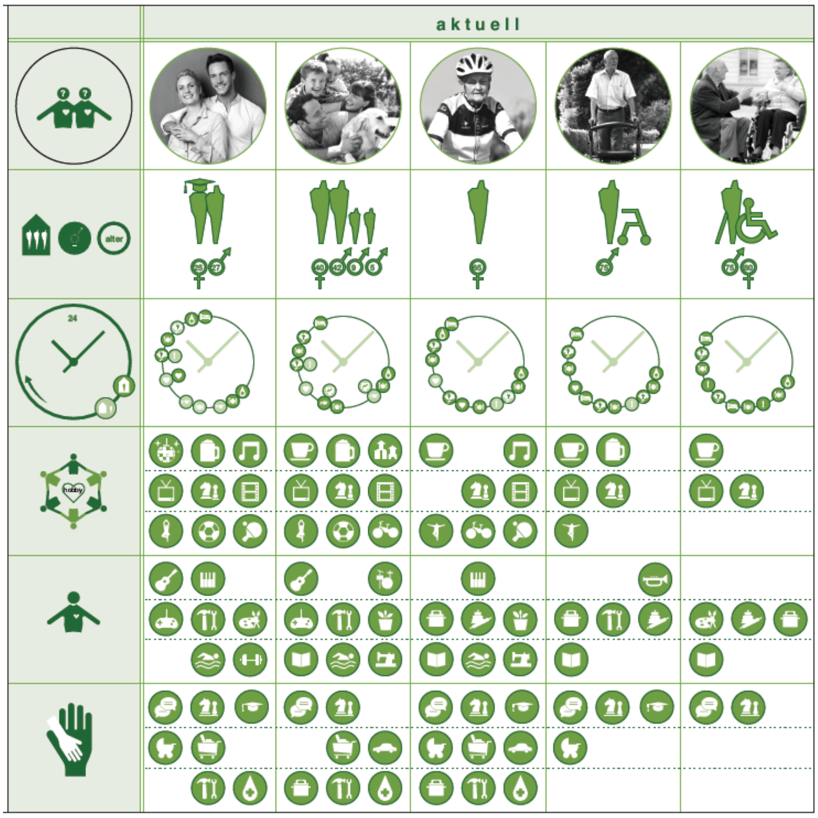

Figure 2: Comparison of Daily Routines of Different Stakeholders, student example of a mixed-used housing project: 'Marketplace of Generations', Noel Rabuffetti 2017 [15]

Currently a student's master project deals with the analysis of the possibilities to apply the methods in the area of healthcare and hospital buildings, which have a very high complexity concerning the logistics. Here the DIN 13080:2016-06 - Division of hospitals into functional areas and functional sections - can serve as a kind of check-list to choose the relevant user functions for the structure-matrix [16].

The next step is the analysis and survey of qualified functional correlations. The use-related functional relationships can be described, for example, spatiotemporally or in relation to the flow of materials or persons (logistics) and can be mapped in the adjacency matrix (see Figure 3). Here, the challenge is to identify possibilities for (temporal) spatial overlaps and mixed-use spaces.

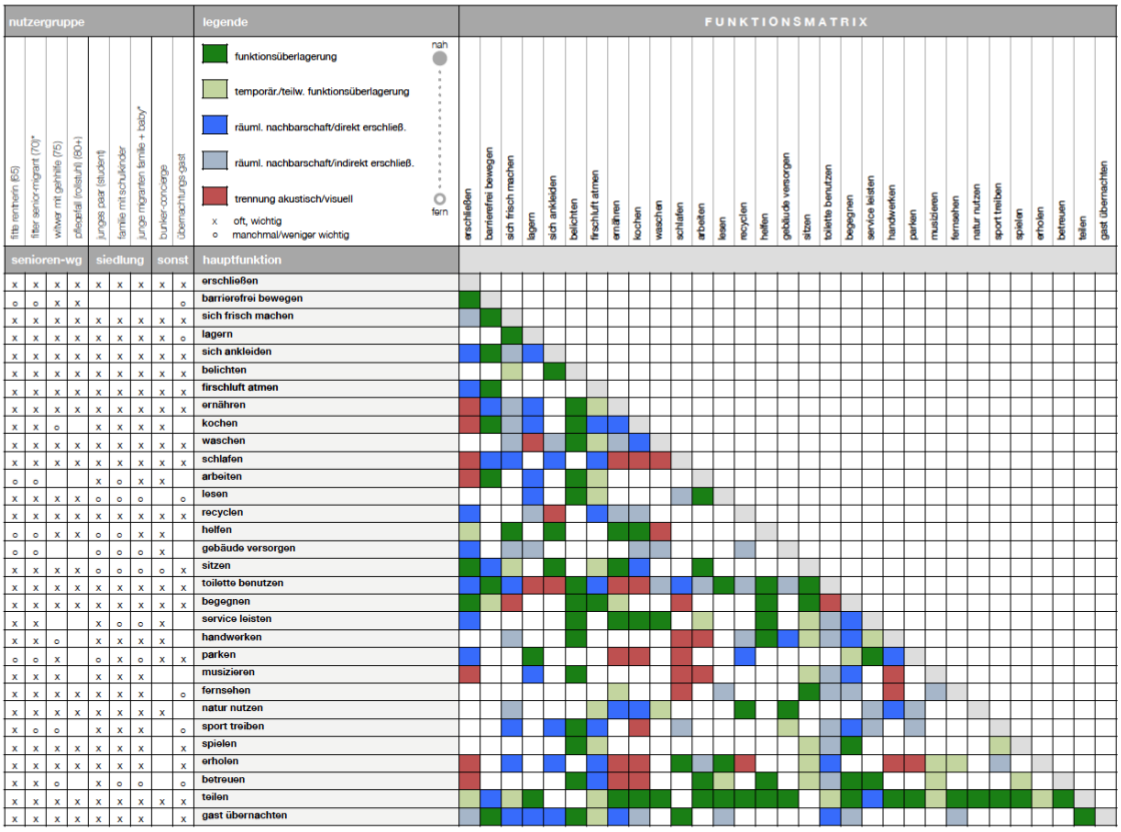

Figure 3: Structure-Matrix for the Analysis of Functional Correlations; student example of a mixed-used housing project, Noel Rabuffetti, 2017 [15]

Considerations about the required technical and physical conditions as well as emissions of the functions with regard to lighting, air conditioning, acoustics and other aspects, describe additional preconditions for the structural formation process in the sense of a systemic approach. An assessment (e.g. by using ranges from one to five) of functional output and required or permitted Input of the system dimensions serves as complementary base for the mapping and structuring (see figure 4).

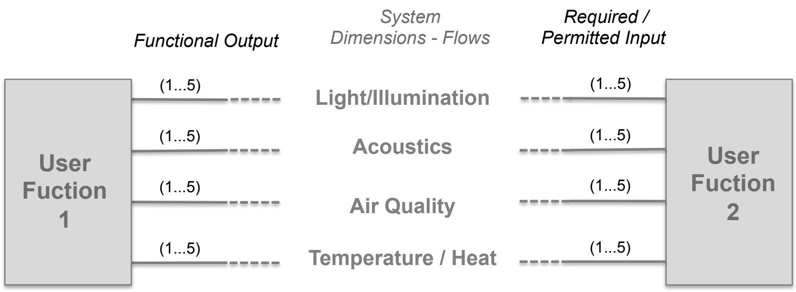

Figure 4: Mapping of Functions with Regard to System Flows

Based on these identified relations and functional conditions, first arrangements of functional groups and areas and for the spatial positioning of functions in the system ‚building' can be made in a reflected way as a first step toward the following space-formation. Here, the functional mapping supports the identification of overlay and flexibility options, which can later be realized, for example, via so-called cluster-flats, a combination of minimized apartments and shared living area and kitchen or so-called joker rooms, which could be assigned to different housing units temporarily.

The planner is, thus, actively encouraged to think about area- and space-related optimization potentials and can transfer the topological structure of functions into a space-efficient floor plan concept. Sustainability assessment systems here also speak about functional equivalence.

A feedback loop with the stakeholder-oriented processes and time-schedules can help to evaluate the logistic quality of the floor-plans.

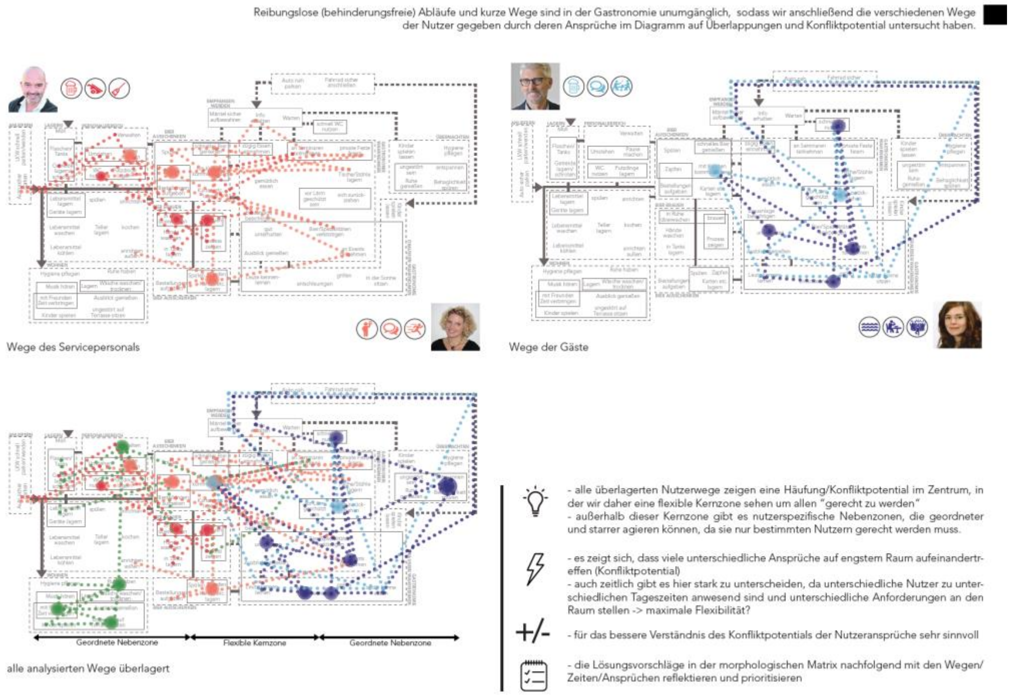

Figure 5: Example of a Students Project: Evaluation of the Floorplan by Overlaying the User Processes, K.Grötsch und Th. Müller 2017, design project ' Brewery at the lake' [17]

To avoid a pure technocratic approach, the building conception in the early planning stages also takes place on a semantic level, in which the designer deals with corporate architecture and questions about the required atmosphere of the functional areas as a basis of later form-finding and spatial design. Here the analysed value systems of the customer helps to develop a specific customer and user oriented architectural statement and semantic.

So, an important step is the elaboration of suitable guiding principles and atmospheric concepts for the identified functions. Working with mood boards, ideographs and symbols for the functions and functional areas supports an abstract and thus more experimental approach, which has been seen to be able to expand the range of solutions consciously. The Maggie's Centre in Glasgow, a hospital for people with cancer, designed by Rem Koolhaas is a very good example for the creation of a surprising atypical and cosy atmosphere that is conducive to the healing process [18].

The merging of structural and semantic level leads to the reflexive conception of the cubature of the building. Input workshops about form finding methods [19] can enhance the quality of results noticeable. Under consideration of the cubature and the functional topology, now the floor plans can be elaborated. Supported by morphological matrices also first ideas about constructive and design principles can be elaborated. Also on level of the building elements the elaborated strategies for the flexibilisation of spaced shall be implemented by appropriate constructive solutions.

3. Technical Implementation as IT-based Tool

To facilitate the application of the method, a web-based tool, the 'functionsTool', has been prototypically implementation of this method will be presented as a web-based tool that facilitates a participatory stakeholder-related design process. The so-called 'functionsTool' supports the user oriented development, structuring and grouping of user functions. Based on this, a qualified allocation of the functions and their spatial-temporal interdependencies can be done. Based on these interdependencies, the tool generates automatically a structural bubble-diagram– an abstract topological graph schema – from the entries and qualified relations in the adjacency matrix. Figure 6 shows a screenshot of the functionsTool with a students' design project - functional conception of a Digital Detox Camp (DDC) using the functionsTool.

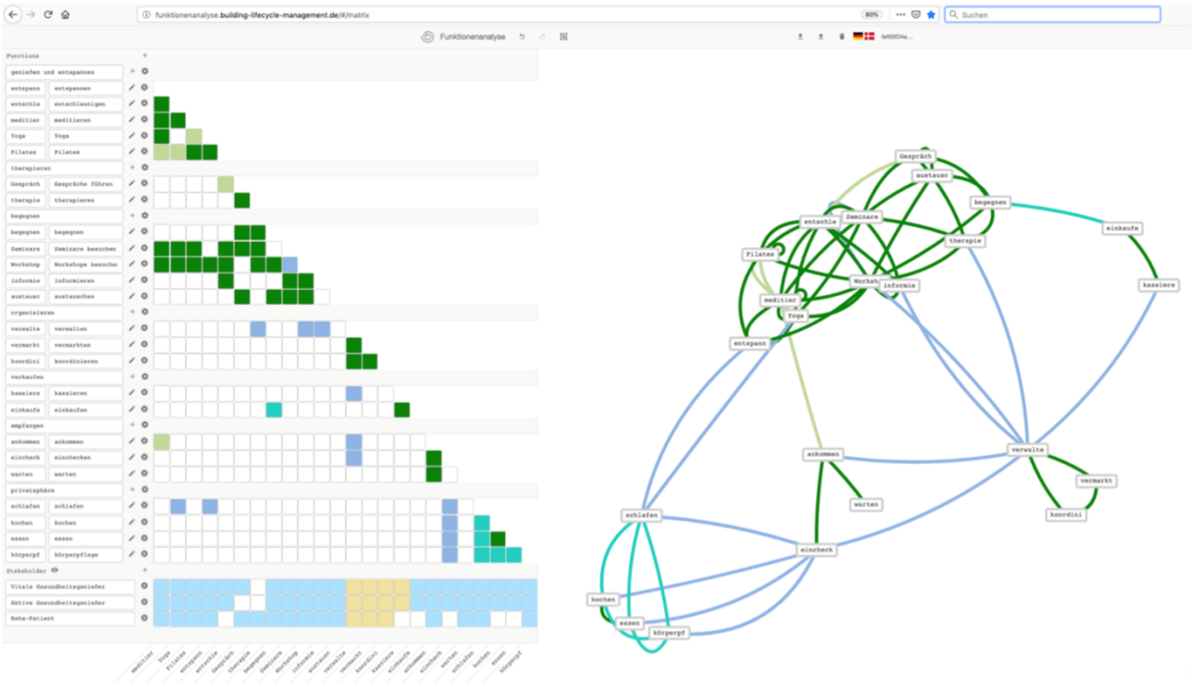

Figure 6: Screenshot of the 'functionsTool' that shows the Structure Matrix and the Automatically Generated Bubble Diagram, (C.Conway and S. Djokic, 2018) [20]

Also, graphics and ideographs can be stored and provided. So, the functional and topological structure of the building can be presented and edited in a transparent and ergonomic way. Here, differentiations in colour allow an easier comprehension and, depending on the quality of the relations, different spatial distances between the functions facilitate the pre-structuring and grouping of functions as base for the next step, the spatial location of functional areas and the geometric room generation.

In a next step, also the specification and representation of system dimensions and their flows as output and input (see figure 4) shall be implemented in the tool. Thus, also the qualified system flows can influence the attraction forces of the functional bubbles and the finally the topology of functional areas.

Sustainability assessment of a Flemish office building with Level(s): a Level 1 assessment

Ramon D, Pironnet C, Allacker K

Department of Architecture, Faculty of Engineering Science, KU Leuven, Leuven, Belgium

delphine.ramon@kuleuven.be

Abstract. Recently, Level(s) has been developed by the European Commission as a common EU framework to assess sustainability of buildings with the intention to provide a consistent and comparable framework across national boundaries. It aims at providing a general language for sustainability for buildings and to promote life cycle thinking. This paper describes the application and results of a Level 1 assessment for the design stage of a Flemish office building. Level 1 is a common performance assessment which aims to be used amongst others by building professionals. Common standards and simplified methods are used for the indicators. The paper focusses on the experiences of testing the method by evaluating the user-friendliness of the assessment method for architects considering the information and calculations needed. The added value of applying the methodology in the design stage is furthermore discussed. Based on the test phase, further improvement is recommended by aligning current national tools for data gathering and by providing default values. A Level 1 assessment allows to gain insights in various performances of a building but does not aim to evaluate the "sustainability" level. A level 2 assessment is probably more useful for practitioners to make well-founded choices between different design options.

1. Introduction

The building industry, being one of the biggest waste creators and energy consumers, started to pay significantly more attention to sustainable buildings during the past decades. Since the first mentioning of sustainable development in 1987 in 'Our Common Future', the assessment of sustainable development in the building sector has gone through an evolution [1]. Different stakeholders have to make informed decisions in order to meet sustainability goals [2]. Hence, sustainable building had to become 'measurable'. John Elkington defined the three fundaments of the Brundtland report as 'triple P' (People, Planet and Profit) in 1994 [3], but without defining the importance of each the three pillars. Based on personal interests and views on society, different attitudes towards sustainable development have appeared, reflected in a proliferation of sustainability assessment methods for buildings [4].

Worldwide, more than 600 sustainability tools are available for products and buildings [2]. The United Kingdom developed the first one for buildings, called BREEAM, in 1990. After that, western Europe (e.g. HQE) and North America (e.g. LEED) followed in the 1990's, Asia (e.g. CASBEE) in the 2000's and finally South America (e.g. Processo AQUA) in 2008 [2]. At first, single indicator metrics were developed in order to assess for example CO_2 emissions or construction waste [4]. Gradually, the evaluation methods and related tools became more complex and evolved to more holistic and comprehensive approaches. Eventually, the idea of life cycle analysis was introduced to prevent burden shifting between different domains and life cycle phases [4]. The nature of the different tools can be categorized into two groups: quantitative and qualitative tools. However, due to a lack of international regulations, different national assessment frameworks have been developed with each their own focus, amongst others Active House (Denmark 2017), DGNB (Germany 2007), Milojöbyggnad (Sweden 2005) and GRO (Belgium 2017) [2,5].

To respond to the concern of the proliferation of assessment methods in Europe, the Level(s) framework for environmental impact assessments was developed by the Joint Research Centre (JRC) in close co-operation with industry stakeholders [6]. The EC aimed for a consistent and comparable framework across national boundaries as well as for promoting life cycle thinking. Level(s) features three different assessment levels: the common performance assessment (Level 1), the comparative performance assessment (Level 2), and the optimized performance assessment (Level 3). Level(s) can be used during different phases in the design process as well as for the post-occupancy phase. The framework is launched in 2018 and is currently going through a two-year test phase to get insights in cost, application and time implications.

This paper discusses the application of a Level 1 assessment for the design stage of a Flemish office building and describes the experiences of testing the method by evaluating its user-friendliness for building practitioners. The added value of applying the methodology in the design stage is furthermore discussed by showing how the results might influence decision taking. The scope of the paper is limited to the indicators which are closely related to life cycle assessment and life cycle costing. Further, only the most relevant results are shown due to the limited pages available.

2. Methodology

2.1. Level(s) framework

The Level(s) framework comprises assessment criteria related to six macro-objectives (see Table 1) of the EC in the field of sustainable building: (1) reduction of greenhouse gas emissions along the building life cycle, (2) increased resource efficiency and circular material life cycles, (3) increased efficient use of water resources, (4) provide healthy and comfortable spaces, (5) adaptation and resilience to climate change, and (6) optimized life cycle cost and value. The six macro-objectives can be linked to the three previously mentioned pillars of sustainability as indicated in Table 1. Indicator 2.4 'Cradle to cradle life cycle assessment (LCA) is an overarching assessment method which covers the first three macro-objectives [7].

Table 1. Overview of the Level(s) macro-objectives and indicators to be assessed.

Pillar	Macro-objective	Indicator	
PLANET	1 Greenhouse gas emission along a building life cycle	1.1 Use stage energy performance	2.4 Cradle to cradle life cycle assessment (LCA) (overarching assessment method)
		1.2 Life cycle global warming potential	
	2 Resource efficient and circular material life cycles	2.1 Building bill of materials	
		2.2 Scenarios (3) for lifespan, adaptability and deconstruction	
		2.3 Construction & demolition waste and materials	
	3 Efficient use of water resources	3.1 Use stage water consumption	
PEOPLE	4 Health and comfortable spaces	4.1 Indoor air quality	
		4.2 Time out of thermal comfort range	
		Potential future aspects: 4.3 Lighting and visual comfort 4.4 Acoustics and protection against noise	
PROFIT	5 Adaptation and resilience to climate change	5.1 Scenarios for projected future climatic conditions	
		Potential future aspects: 5.2 Increased risk of extreme weather events 5.3 Increased risk of flood events	
	6 Optimized life cycle cost and value	6.1 Life cycle cost	
		6.2 Value creation and risk factors	

Most of the indicators are further divided in sub-indicators, which are described more detailed in section 3. As this paper focusses on the indicators which are closely related to life cycle assessment and life cycle costing, the indicators belonging to macro-objective 4 and 5 are not further discussed. A reporting excel file is available and used (version Beta v1.1) for this Level 1 assessment.

In addition to the sustainability indicators, also a data quality indicator is included in Level(s), entitled "reliability rating of the performance assessment" [8]. This indicator must be evaluated for each of the sustainability indicators assessed, but is not further elaborated in this paper.

2.2. Case study building - BelOrta

The BelOrta office building is located in Sint-Katelijne-Waver in Flanders (Belgium) and has a net floor surface of approximately 3000m². The office is designed by the architectural office ar-te and is finished in 2014. The building is an extension to the existing auction hall of the BelOrta company. The two-floor building has a compact layout with an inner courtyard and consists of landscape and cellular offices, and meeting rooms. It is seen as a representative Flemish office building regarding building typology, energy performance and technologies. For the Level(s) assessment, the scope was limited to the building itself excluding external works. This case study was selected because of previous analysis. Hence, al lot of the building data was already inventoried based on a BIM-model, bill of materials, performance documents and technical information sheets. It moreover allows to compare the results of the Level(s) testing with results obtained using other assessment methods such as the Belgian method GRO and the EC PEF (Product Environmental Footprint) method. A detailed description of the case is not included in the paper but can be found in [9] and [10]. Although the building is already in use, the design stage documents are used for the assessment as an assessment during the design stage is focussed on.

2.3. MMG+_KULeuven tool

As shown in table 1, the Level(s) framework requires to perform a cradle to cradle environmental life cycle assessment (criterion 2.4) and financial life cycle costing (criterion 6.1) of the building. National tools in line with EN 15978 [11] and EN 15804 [12] can be used for this assessment. For the cradle to cradle life cycle assessment and life cycle costing the excel-based MMG_+KU Leuven tool has been used. The latter uses the Belgian LCA method for buildings, called the MMG method ("Environmental profile of building elements") [13] and allows to calculate financial life cycle costs too. The MMG method is in line with the European standards EN 15804 and EN 15978, but considers ten additional impact categories (in line with the recommendations of the International reference Life Cycle Data (ILCD) Handbook). For the life cycle inventory, the Ecoinvent database (version 2.2) is used. The life cycle stage of module D (as referred to in the EN15978 standard) is currently not considered in the MMG method [13]. The life cycle cost calculation in the MMG_+KU Leuven tool includes material and labour costs based on data from the ASPEN database [14] and the British Spon's Price Books External Works and Landscape Price Book [15], with 2015 as reference year. The financial cost is calculated as the sum of the present values of all costs occurring during the life cycle of the building.

3. Application

This section describes the application of the different indicators for the Level 1 assessment. An overview is given of the requirements to perform this assessment and the repercussions for architectural firms.

3.1. Indicator 1.1: Use stage energy performance

The use stage energy performance requires information about the primary and delivered energy demands for spatial heating, cooling, ventilation, production of hot water and lighting. In case the energy calculation method used is able to calculate unregulated energy uses (e.g. electricity use for appliances, elevators …), a section with 'small power' and 'other uses' is provided.

For the Belgian case, the energy performance is calculated based on the NBN EN 15603 with the EPB software Flanders version 1.8.5. Such calculation is required in Belgium during the design stage and was hence provided by the architectural firm. For the primary energy demands, the EPB calculations suffice to fill in the required data for Level(s) (see Table 2) but some small additional calculations are needed (e.g. breakdown of auxiliary energy use). Further, the delivered energy demand differentiated between the different energy sources used is asked for (e.g. renewable and non-renewable electricity use, fuels used).

Table 2. Primary energy data of the BelOrta building (design stage) as required by Level(s)

		Total ($kWh/m^2/yr$)	**Energy uses ($kWh/m_2/yr$)**				
			Heating	**Cooling**	**Ventilation**	**Hot water**	**Lighting**
1.1.1 Use stage primary energy demand							
Total primary energy demand		116.8	57.9	21.1	11.4	0.0	26.4
Non-renewable primary energy demand		116.8	57.9	21.1	11.4	0.0	26.4
Renewable primary energy demand		0.0	0.0	0.0	0.0	0.0	0.0
Exported energy generated		0.0	0.0	0.0	0.0	0.0	0.0
1.1.2 Use stage delivered energy demand							
Fuels	Natural Gas	57.2	57.2	0.0	0.0	0.0	0.0
Electricity	Non renewable	15.9	0.0	8.4	4.5	0.0	2.9

3.2. Indicator 1.2: Life Cycle global warming potential (GWP)

For the evaluation of the GWP of the building, Level(s) differentiates fossil carbon, biogenic carbon and biogenic carbon related to land occupation and land transformation. A simplified assessment is possible for Level 1 including the product stage (A1-3) and use stage (B4-5, B6) called an "incomplete life cycle". A building service life of 60 years is assumed, which is in line with the Belgian MMG method.

The MMG+_KULeuven tool was used to calculate the GWP of the building. As this tool does not include module D, the simplified reporting option was chosen. The Belgian MMG method furthermore does not include biogenic carbon, hence only GWP due to fossil carbon has been assessed (see Table 4 in section 3.6). Further, only the building elements of the shell are assessed defined as minimum building scope for a Level 1 assessment.

A material inventory of the building is needed to calculate the GWP. In general, architects do not have such a detailed list readily available and hence this is a time-consuming activity. If an inventory exists, it often has a different focus (e.g. cost sheet) and is mostly not as detailed as required for an LCA. It is hence recommended to provide a list of predefined elements per country with pre-calculated GWP values. As mentioned in Röck et al. [16] harmonization between the existing LCA and BIM standardization could help to facilitate LCA studies and improve the accuracy of the life cycle inventory.

3.3. Indicator 2.1: Building bill of materials

With this indicator an overview of the total mass of the building materials is provided, categorised into four material types defined by Eurostat (i.e. metal, non-metallic mineral, biomass and fossil energy) [7]. 99% of the total building mass should be covered and at least encompass the shell, core and external work elements [7]. For this assessment, the external works were not included in the scope and left out.

The data inventory for this indicator was taken from a BIM model provided by the architects, complemented with extra information found in technical information sheets, building construction plans, tender document. Such inventory is time consuming, but was already available (in a different format than the one required by Level(s)) from a previous LCA study of the same building. Although the format was different, the bill of materials was already structured per building element. Such detailed bill of materials is however not standard practice in architectural offices and hence will require additional efforts from architects assessing their building design with Level(s) [16]. It is furthermore important to note that the table format as required by Level(s) does not provide sufficient information for a hotspot analysis and hence will be of limited value for architects to improve their design in a time-efficient way.

3.4. *Indicator 2.2 Scenarios for lifespan, adaptability and deconstruction*

3.4.1. S1: Scenarios for life span. For every building element defined in indicator 2.1 the expected life span and corresponding data source should be provided. Four possible data sources can be used: 1) typical life spans based on reported averages, 2) life span estimate calculated by building professional, 3) life span estimate provided by building element manufacturer; or 4) life span estimate obtained from field experience. In this assessment, the default life spans of the materials and building components according to the Belgian MMG method were used.

3.4.2. S2: Scenarios for adaptability. Firstly, an overview of the addressed design aspects related to adaptability and refurbishment is required (e.g. column grid span, flexible cabling patterns, …). For office buildings three focus areas are brought forward: 1) changes in user space requirements; 2) changes to building servicing; and 3) changes to building structure. A description of the design solutions should be added for each of these (see Table 3). Secondly, it is asked whether a property market check is carried out or not, which was not the case in this project. To retrieve the needed information, additional interviews with the architects were required in addition to the available building documentation.

Table 3. Design aspects considering adaptability of the building design

Aspects addressed			Description of design solution(s)
Building Type	**Focus area**	**Design aspect**	
Office	Change in user space requirements	Internal wall system	System walls that can be (re)moved.
Office	Change in user space requirements	Column grid spans	Possibility to convert the landscape office to office rooms on both sides of a corridor.
Office	Changes to building servicing	Flexible cabling patterns	There horizontal and vertical cable trays everywhere. Lowered ceiling
Office	Change to building structure	Future-proofing of load bearing capacity	Structure allows adding an extra storey later.

3.4.3. S3: Scenarios for deconstruction. Firstly, the availability of building inventories and a deconstruction plan is quested. The specific deconstruction, reuse and recycling characteristics of the building have to be described. For each topic a series of design aspects are presented, such as “mechanical and reversible connections” or “constituent materials can be easily separated” Similar to the previous, an additional interview with the architects was required.

3.5. *Indicator 2.3: Construction and demolition waste*

The waste indicator aims at gathering information about the total amount of waste and the types of waste (hazardous or non-hazardous) during construction and at the end of life. Pre-estimates or actual data can be used as source. Further, possibilities for reuse and recycling and for recovery during specific life cycle stages (i.e. A3, A5, C1/3 and module D) are asked for.

As for the BelOrta building, no special attention was given by the architects to end of life recycling or reuse, the default end-of-life scenarios of the Belgian MMG method for each of the materials were assumed. The MMG method does not include information about waste being hazardous or not. This hence had to be inventoried which is time intensive if a detailed material list is not available.

3.6. *Indicator 2.4: Cradle to cradle life cycle assessment*

The Level(s) framework has selected a set of nine environmental indicators to be evaluated with a corresponding measurement unit in line with EN 15978 and EN15804. With exception of use of renewable primary energy sources used as raw material and use of non-metallic mineral resources all indicators are listed in Table 4. The indicators have to be assessed separately for the five different modules (life cycle stages) defined in EN 15978.

Similar as for indicator 1.2 (life cycle GWP), the MMG+_KULeuven tool was used to assess the various environmental impact categories required (this would not have been the case if a carbon foot printing calculation tool was used). The same simplified reporting option and building scope are used for this indicator as discussed above. Similar challenges were faced as for indicator 1.2. Results can be found in Table 4.

Table 4. Environmental impacts per life cycle stage and environmental indicator

Global Warming Potential for each life cycle stage					
Indicator	**Unit**	**Product (A1-3)**	**Construction process (A4-5)**	**Use stage (B1-7)**	**End of life (C1-4)**
Global Warming Potential (GWP)	kg CO_2 eq	982958	117775	5429271	115390
Depletion potential of the stratospheric ozone layer (ODP)	kg CFC11 eq	0.3	0.0	0.7	0.0
Acidification Potential of land and water (AP)	kg SO_2 eq	2926	516	11024	391
Eutrophication Potential (EP)	kg $(PO_4)_3$ eq	419	102	2632	88
Formation potential of tropospheric ozone photochemical oxidants (POCP)	kg C_2H_4 eq	230	23	682	11
ADP elements	kg Sb eq	1.8	0.3	7.7	0.1
ADP fossil fuels	MJ (LHV)	11709810	1612427	92140796	878090

3.7. Indicator 3.1: Use stage water consumption

Indicator 3.1 deals with the operational water use of the building, expressed in litres per occupant per year. An extra calculation file is provided to calculate the water use based on various inputs. First, the country and river basin of the case study are asked for to generate the water exploitation index[1] and ranking. Second, based on the entered occupancy conditions (i.e. gender distribution, building use factor and occupants behaviour) the volume of water per occupant per day is calculated (see Table 5). If the building is located in an area with water stress, which is not the case for the case study, extra reporting on the division of water consumption into potable and non-potable water is required. As no detailed information was available (except the absence of showers), the provided default values file were used.

In general, this default values simplified the needed calculations for this indicator and the availability of these default values could also be of interest for other indicators.

Table 5. Water consumption (litre) per occupant per day

Male occupants	0.5	Female occupants	0.5	Sum of occupants	1.0		
Building use factor	250	days/annum					
Sanitary fittings	Consumption rates		Usage factor		Daily consumption per occupant		
Toilet (full flush)	7.5	L/full flush	1	flushes/o/day	7.5	L/o/d	
Toilet (small flush)	4	L/small-flush	2	flushes/o/day	4	L/o/d	
Urinal	3	L/flush	2	flushes/o/day	3	L/o/d	
Bathroom tap	4	L/minute	45	seconds/o/day	3	L/o/d	
Shower	0	L/minute	30	seconds/o/day	0	L/o/d	
Kitchenette tap	12	L/minute	30	seconds/o/day	6	L/o/d	
Total					**23.50**	**L/o/d**	

3.8. Indicator 6.1: Life cycle cost

This indicator evaluates the different costs occurring during the building service life. Various types of costs are distinguished according to their recurrence: the one-off costs, annual costs and periodical non-annual costs. Both the annual as periodic non-annual costs are based on the sum of the present values of

[1] "*The mean annual total abstraction of fresh water divided by the long-term average freshwater resources. It describes how the total water abstraction puts pressure on water resources.*" [7, p. 106]

those future costs [7,17]. The costs are subdivided according to the same life cycle stages as for the life cycle assessment (see Table 6).

A combination of data sources was used for the assessment of this indicator. The building tender gave information about the construction and production costs while the MMG+_KULeuven tool gave an estimate for the costs of the use stage and EoL stage. As there was not a concrete maintenance plan nor a plan for element replacements, default scenarios from the MMG method were used.

Table 6. Life Cycle costs of BelOrta building

Type of costs	Cost by life cycle stage (€/m²/yr)		
	Product and Construction stages	**Use stage**	**End of life stage**
One off costs	74.54	0.00	4.41
Annual recurrent costs	-	17.44 (Energy)	-
	-	1.68 (Water use)	-
	-	37.78 (Cleaning)	-
Projected non-annual costs	-	32.41 (Maintenance, repair and replacement)	-
Total costs	74.54	89.30	4.41

4. Discussion

Firstly, some of the main results of the assessment are discussed followed by the main lessons learned in terms of time effort, actors needed, required information, relevance of the different indicators and added value for the practitioners.

4.1. Results

Based on the assessment results, it is clear that the use phase has an important contribution to the buildings environmental impact (see Table 4) and financial costs (see Table 6). Likely the importance for the environmental impact is mainly caused by the energy use for heating (see Table 1), while for the financial cost, cleaning and maintenance are important. Further, the construction phase as well has a big influence on the costs and impacts. Lastly, it has to be recognised that multiple aspects considering future adaptability of the building to changing user needs are implemented in the building design as discussed section 3.4.2. However, based on these results, it is not possible to highlight the importance of the different building elements and to get insights about opportunities to improve the sustainability of the building. This would be an added value for practitioners as now a Level 1 assessment is limited to reporting only.

4.2. Time effort

The testing of the Level(s) to BelOrta revealed that for many of the indicators detailed life cycle inventory data is needed which cannot be directly retrieved from the architectural plans or documents. A complete assessment of all the indicators on a Level 1 requires a lot of time. The reporting itself is not time consuming due to the excel files provided. To reduce the time efforts, it is recommended to establish or improve the links with national tools (e.g. current link with EPB-software for indicator 1.1). Default values are seen as a second way to reduce time efforts (especially in the design stage) as was experienced for the water consumption indicator. Default values could for example be provided for cleaning costs for typical elements, for EoL scenarios of construction products and for life spans of building products. In addition to the above, it is important to mention that the documentation provided by the JRC revealed to be sufficiently complete and comprehensive, but sometimes confusing.

4.3. Actors needed

As a team of actors are typically involved in the design of buildings, it became clear that the data and knowledge required for Level(s) is spread over these different actors. For example, the EPB-document for indicator 1.1 was drafted by the collaborating engineer firm, the design strategies for indicators 2.2.S2-3 require interaction with a designer of the building, while the LCA and cost analysis were now performed by an academic institution. In order to work efficiently, it might be recommended that various actors are responsible for parts of the Level(s) reporting. Although this is probably more time efficient, a good overall coordination will then be required to ensure that the same assumptions are taken for the multiple calculations required. Linking as much as possible with available tools and interfaces (e.g. BIM-model) could enhance uniformity across different assessments and actors.

4.4. Required information

The testing revealed that most of the indicators are linked to assessment methods that require data structuring that is different than in architectural practice to date. This is for example the case for the LCA study: even if a BIM model is available, this model may provide information about the general composition of building elements and their amounts but information on sub-element composition is lacking, such as for example the kg of brick per m² wall or the kg of cement mortar per m² wall. Default element compositions and related amount of materials could help practitioners. Further alignment between different tools could moreover improve this information flow.

4.5. Relevance indicators

The scope of the Level(s) framework is office buildings and residential buildings [8]. However it was found that some parts of indicators are more relevant for office buildings than for residential and conversely. Water consumption is for example more relevant for residential buildings though not unimportant for office buildings neither. While the relevance of the cleaning cost could be questioned in case of residential buildings.

4.6. Added value for practitioners

The objective of the Level 1 assessment is "*to provide a common reference point for the performance assessment of buildings across Europe*" [8]. The testing phase is interesting for architects to become familiar with the assessment methodology, requirements and challenges. The assessment moreover provides general insights in the various environmental impacts, waste streams and costs their design is causing. However, it does not allow to evaluate the 'sustainability' level of their project as reference values are not available to compare with and detailed hotspot analysis is not possible. In order to increase the added value of the assessment for practitioners it is recommended to integrate such reference values (benchmarks) or more detailed reporting in future. To use Level(s) to date during a design phase, the authors would rather recommend to use a level 2 assessment to be able to compare various design options.

5. Conclusion

This paper discusses a Level(s) Level 1 application on an office building in Belgium. The assessment of the indicators related to the macro-objectives (1) Greenhouse gas emissions along a building life cycle; (2) Resource efficient and circular material life cycles; (3) Efficient use of water resources; and (6) Optimised life cycle cost and value have been presented. The study showed the implications of performing a Level 1 assessment for building practitioners in terms of information, time and experience needed. It was found that the assessment requires information and experience from practitioners which is not commonly available in current practice. Further improvement is recommended by aligning current national tools for data gathering and by providing default values. The testing furthermore revealed that Level 1 assessment allows to gain general insights in various performances of a building (e.g. waste streams, impacts across different indicators …) but does not allow to evaluate the "sustainability" level of the design as reference values are lacking as basis of comparison. As long as such reference values are not available, a level 2 assessment is probably more useful to make well-founded choices between different design options.

Acknowledgements
The authors want to acknowledge DG Environment for the necessary documentation and support during the Level(s) test phase, the architectural firm ar-te for providing the necessary information about the case study. This paper is part of (1) an SBO PhD fellowship 'Towards future-proof buildings in Flanders: Climate and Life Cycle modelling for resilient office buildings' (1S97418N) funded by Research Foundation Flanders (FWO) and (2) a thesis written in partial fulfilment of the requirements for the degree of Master in Engineering Science: Architecture at the department of Architecture of KU Leuven.

Abstract. Investment decisions for buildings made today largely determine their environmental impacts over many future decades due to their long lifetimes. Such decisions involve a trade-off between additional investments today and potential savings during use and at end of life - in terms of economic costs, primary energy consumption, greenhouse gas emissions and other environmental impacts. Life cycle assessment (LCA) is suited to identify measures and action to increase the resource efficiency and the environmental performance of buildings and construction. This paper gives an overview of an ongoing international research project within the IEA EBC with the overall aim to harmonise LCA approaches on buildings and foster life cycle thinking in the real estate and construction sectors. The objectives of the project are i) to establish a common methodology guideline to assess the life cycle based environmental impacts caused by buildings, ii) to establish methods for the development of specific environmental benchmarks for different types of buildings, iii) to derive regionally differentiated guidelines and tools for the use of LCA in building design and tools such as BIM, and iv) to improve data availability by developing national or regional databases with regionally differentiated LCA data tailored to the construction sector. To ensure practical solutions a number of case studies will be used to test and illustrate the consensus approaches and research issues.

1. Introduction

In response to concerns about climate change, energy security and social equity, countries around the world are either planning to substantially reduce energy demand and greenhouse gas emissions or in the case of emerging economies to develop in less energy intensive ways. The construction as well as heating and cooling of buildings is one major cause of primary energy demand, greenhouse gas emissions and environmental impacts of developed and emerging economies [1-4]. Buildings have a long lifetime of between some decades to more than 100 years. The replacement rates in Europe for instance suggest that the average lifetime of residential buildings is well above 60 years. Thus, investment decisions on buildings today determine by and large the environmental impacts during several future decades. Furthermore, such decisions can involve a trade-off between additional investments today and potential savings during use and end of life (both in terms of economic costs on one hand and primary energy demand, greenhouse gas emissions and environmental impacts on the other). Today, natural resources such as clean air, clean water, biodiversity or natural resources are free and their use as a sink is hardly charged to those polluting them. The current price system does not (systematically) account for such external environmental effects (market failure) which leads to an inefficient (over)use of natural resources. That is why, environmental assessments of human activities are necessary to highlight the inefficient use of natural resources and to take measures and action to increase the resource efficiency of buildings and construction by substantially reduce consumption and pollution of natural resources.

The life cycle assessment (LCA) approach as standardised by ISO 14040 and 14044 [5, 6] is suited to quantify the environmental impacts of buildings based on the principles of ISO 15392 [7]. The assessments performed using the LCA approach are very much in line with an economic assessment which follows a life cycle costing approach. Hence, LCA is suited to complement economic information on buildings with information on their environmental impacts (see also Figure 1). Important developments on the topic in recent years have been the many international (such as ISO 21930 [8] and ISO 21931 [9]) and European (such as EN15978 [10] and EN15804 [11]) standards for the development of environmental product declarations of building products and the environmental performance assessment of construction works as well as the recently published report by the European Commission on resource efficiency and resource consumption mitigation opportunities in the building sector [12].

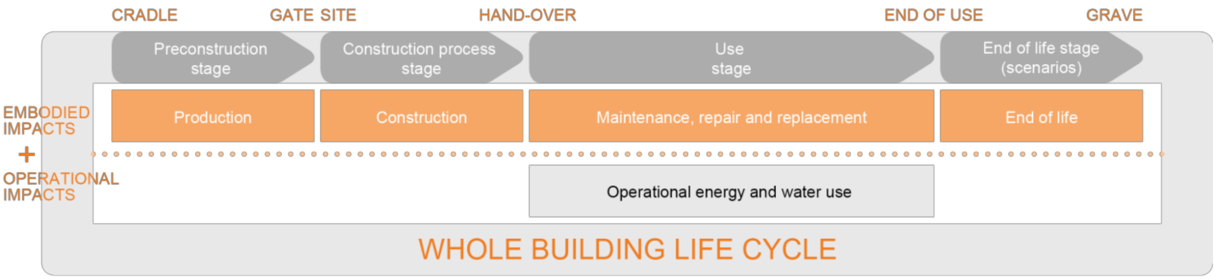

Figure 1. The different stages in the Life Cycle of buildings and the distinction between embodied and operational environmental impacts.

The environmental assessment of buildings using life cycle assessment approaches entails several research issues and issues which call for harmonisation and consensus, while respecting national and regional traditions. The following list of issues illustrates the kind of topics discussed in the international research project IEA EBC Annex 72, building on results of the former IEA EBC Annexes 31 [13] and 57 [14]:

- Environmental "optimisation": When considering the entire life cycle of buildings, efforts can be either focused on reducing embodied or operational impacts. With current discounting practices, the use and end of life phases are economically less important. This situation gives rise to the following questions: Where is the environmental optimum between gross zero operational energy buildings on one hand and minimised embodied impacts buildings on the other? Is it sensible to try to reduce energy consumption for heating and cooling close to zero or do the environmental impacts of the additional material and equipment overcompensate the reduced environmental impacts during operation?
- Net zero energy buildings: More and more buildings integrate on-site renewable energy systems to compensate their operational energy demand e.g., for the heating, ventilation, lighting and appliances uses or even to additionally compensate their embodied energy. The energy produced onsite can either be self-consumed or fed into the grid depending on the level of production and the simultaneity between production and the building energy demand. Previous LCA studies (e.g. in IEA EBC Annex 56 project, see e.g. [15]) have used an annual balance for estimating the building energy demand and production. Other approaches have

assessed the life cycle related impacts based on an hourly balance. Is there one particular preferable approach and if so, which one should be recommended? How should life cycle net zero impact buildings be defined, including rules for balancing and communication?

- Integration of environmental assessment in design process using tools such as building information modelling (BIM): For the aforementioned goal of an environmental optimisation of buildings during their lifecycle it seems necessary to include the environmental assessment in the early design stages to have a higher influence on the final outcome (see "McLeamy effort curve" [16] and potential shift through BIM). Current digital design tools and especially BIM provide the potential to include various kinds of assessment information and simulations (embodied and operational energy, daylighting, et cetera) in early design stages. Issues related to this integration in digital design tools are the different levels of modelling within the tools as well as the accuracy and reliability of information during the different stages of the design process. As this information is only gradually defined, assessment tools need to use constantly refined values and presumptions throughout the planning process. Can approved level of detail (LOD) definitions in design tools such as BIM and defined stages within the building design process be used to mark steps in which to incrementally assess and optimise the environmental performance of the building design? Which values and presumptions should be taken for the assessment at the different design stages? Which variability and safety factors have to be considered to achieve significant and complete assessment results?
- Service life: Some standards prescribe or suggest service lifetimes of building components and technical systems. However, observed lifetimes can be significantly different from the lifetimes prescribed or suggested in national standards. Buildings are long-living investments but office and industrial buildings in particular may have relatively short service lives. Some experts claim that environmental impacts caused by construction (and material supply) today should be balanced within one to maximum two generations, i.e. 30 to 60 years. What service life or reference study period should be chosen with such long-living investments like buildings? Should the reference study period be defined based on observed or default lifetimes or based on an argumentation based on intergenerational equity?
- Technology development: Buildings are expected to be used during 50 to 100 years or even longer. During this period, economy and in particular building elements, building technologies and energy supply systems (fuel oil, natural gas, coal, electricity, wood, biogas) will develop (see e.g. [17]). The following questions related to future scenario will be discussed in the IEA EBC Annex 72: Should technology developments and changes in the mixes related to electricity, heating, cooling and waste management be considered when assessing the environmental impacts of the use and end of life phases? How to deal with new building products and with technology developments of existing ones? How to deal with potential change in type and pattern of use of buildings?
- Aggregation and assessment of current and future emissions: A substantial part of the energy use, greenhouse gas emissions and environmental impacts occur several decades in the future. This raises the question of how to aggregate emissions occurring today (during production and construction stages) and emissions occurring during the use stage and in particular during the end of life stage and whether or not to apply any discounting approach (see e.g. [18]).

2. Objectives of IEA EBC Annex 72

The work of the IEA EBC Annex 72 is organized in five Subtasks which are closely interlinked.

The research work of the IEA EBC Annex 72 aims to achieve the following objectives:

- Establish a harmonised methodology guideline to assess the life cycle based primary energy demand, greenhouse gas emissions and environmental impacts caused by buildings.
- Establish methods for the development of specific environmental benchmarks for different types of buildings to help designing buildings with a minimum life cycle based primary energy demand, greenhouse gas emissions and environmental impacts.

- Derive guidelines on tools (building design tools, BIM and others) and workflows for design decision makers.
- Establish a number of case studies, focused to allow for answering some of the research issues described above and for deriving empirical benchmarks.
- Develop national/regional databases with regionally differentiated life cycle assessment data tailored to the construction sector, covering material production, building technology manufacture, energy supply, transport services and waste management services; share experiences with the setup and update of such databases.

3. Methods

3.1. Surveys

Surveys for LCA experts and for designers were established to learn more about the current situation of LCA in the building sector: One part of the survey is on the methodologies applied to assess the environmental impacts of buildings with regard to modelling aspects, system boundaries and environmental indicators. In addition, the degree of dissemination of the applied methodologies, the frequency of use among designers and their demand for assessment results is investigated. A second part is on national practices of workflows and planning tools, methods, data formats etc. used by LCA experts and design decision makers in the participating countries. Lastly, the surveys include a section on national/regional LCA databases and are exploring the national needs (data gaps) and the driving forces for the demand on LCA data and databases.

3.2. Round robin test and harmonised methodology

A round robin test to assess the greenhouse gas emissions, primary energy demand and other environmental impacts of two reference buildings are performed to identify the differences in national building assessment approaches [19].

The insights gained from the surveys and the round robin test will be used to develop and extend the methodology guideline on LCA of buildings and benchmarks. The guidelines and approaches agreed within IEA EBC Annex 57 [14, 20] serve as starting point. The guidelines will be extended to the full life cycle of buildings and will include:

- operational impacts,
- modelling aspects such as allocation and recycling,
- modelling onsite electricity production,
- reference service life / reference study period,
- technology development (e.g. in the electricity mix supplied to the building during its use phase)
- recommendations on environmental indicators.

A clear distinction is made between modelling practices on one hand and data and databases on the other. In addition the areas of disagreement will also be highlighted by offering at least two alternative approaches in such cases. Regional and national traditions will be captured to the extent feasible and necessary.

3.3. Work flows and data interfaces

The results of the survey on national practices of workflows (see Section 3.1) and semi-structured interviews with selected experts help to identify the current state and potentials of implementing the assessment of life cycle related environmental impacts of buildings during the design process. Besides the survey a systematic literature review is performed to identify the requirements for the implementation of life cycle related aspects in different stages of the design process. As a result, implementation strategies in view of internationally compatible solutions of design tools and formats (e.g. BIM) of life cycle information (e.g. following existing structures of a cost calculation approach) are proposed.

Based on building case studies (see Section 3.4.) an analysis on how differences in building models (completeness and detailing) can be considered throughout the planning process (e.g. application of correction factors) is performed. The aim is to establish guidelines for measuring the completeness of a building model and to indicate how it can be used for life cycle assessment of buildings. Furthermore, guidelines for design decision makers on how to use available information to assess the life cycle-related environmental performance of buildings during the design process for their improvement will be developed.

3.4. Case Studies

A substantial set of building case studies are analysed for which the life cycle based environmental impacts are quantified using either national/regional assessment practice or the methodology agreed in IEA EBC Annex 72 (see Section 3.2.). The buildings selected should be representative to the country/region. The set of case studies include different building types and different decision-making situations. A harmonized documentation of these case studies is developed, including the information on the use (covering e.g. use profiles) of the buildings analysed as well as the climatic zone.

These case studies are helpful in establishing empirical benchmarks based on the methodology developed in the IEA EBC Annex 72 (see Section 3.2.). To develop these benchmarks different reference units (functional equivalence, i.e. impacts per m^2 and year basis, impacts per person etc.) are analysed. The benchmarks shall apply on the entire life cycle of buildings and be subdivided into embodied environmental impacts (production of materials and technical systems, construction, use and end of life) and operational impacts during the use phase. The established benchmarks related to the primary energy demand, greenhouse gas emissions and environmental impacts of buildings are regionally differentiated and tied to different building types such as residential, office, or school buildings. It is explored whether or not a typology of climatic regions can be established to allow empirically derived benchmarks being applied across the participating nations.

Furthermore the case studies will serve as basis to classify and characterize different approaches to optimizing life cycle primary energy demand and greenhouse gas emissions performance of new buildings and renovation projects. The potential to reduce environmental impacts of different types of optimization strategies are assessed in order to develop guidelines for building design and decision-making.

The planning and design workflow have an impact on the whole life primary energy demand/greenhouse gas emissions of the building. Many decisions are taken with no thought of primary energy demand nor greenhouse gas emissions – for instance the choice of structural frame may be based on architectural layout and on construction industry standards for that country, while facade material may depend on local planning requirements, etc. The aim is therefore to further analyse the case studies focusing on the decisions in the planning and design workflow. As a result of this analysis examples and in-depth knowledge on process aspects promoting or hindering a relevant application of environmental life cycle thinking in building design are given.

3.5. LCA databases for the construction sector

The results of the section on national LCA databases in the surveys are used to document national databases used in the construction sector and provide recommendations in view of further improving the situation regarding data availability and suitability. The documentation includes a standardised description of existing database contents. The information gained in the survey on existing national databases helps to develop guidelines and practical hints on how to establish a publicly available LCA database suited for the building sector. It mainly addresses countries with a current lack of a reliable, country specific LCA database. The guidelines include considerations and information related to:

- the need of national databases,
- the contents of such databases,

- organisational aspects (e.g., on how to organise data collection and funding, how to organise updates, etc.).

In a next step the developed guidelines are implemented in country case studies. The aim is to compile a default set of publicly available national environmental indicator results of construction materials, building technology, energy supply, transport services and waste management. The default set of results shall be suited to be used in the preliminary design stage or in case of lack of more specific information.

4. Planned working steps and intermediate Results

4.1. Methodology guidelines (Subtask 1)

Subtask 1 (ST1) takes up the methodological foundations developed in IEA EBC Annex 57 [21] for the determination, assessment and influencing of embodied impacts and further develops them into a complete life cycle approach. Currently, ST1 discusses the following topics (among others): (a) how to avoid physical discounting in the GWP [22] on the one hand, and, at the same time, make possible the consideration of the time factor through the inclusion of external costs (here the damage costs of greenhouse gas emissions - see, inter alia, [23]). In this case, according to the social discounting rate approach [24] the lowest possible interest rate should be selected; (b) the possibilities of considering technical progress for different use cases in a specific way. For the analysis of scenarios this topic may be considered, but for the deterministic models [25] in the context of a sustainability assessment this should be excluded; (c) that although when reusing an existing building structure in the next life cycle the already consumed energy and resulting GHG emissions for the old structure are accounted for as zero (since they can no longer be influenced), the further maintenance, later replacement and the EoL must be taken into account.

Additionally, ST1 deals with the development and use of environmental benchmarks on the basis of the current standardization activities [26]. This standard aims to develop a typology of reference levels, to improve the transparency and traceability of published benchmarks and to describe typical application cases. Some of the authors are directly involved in the latter standardization process. One example of alignment with the ongoing standardization activity is that also Annex 72 adopts the system of limit, reference and target values. Own contributions under the ST1 focus on the basic principles of developing benchmarks for specific types of buildings and uses in different climate zones. However, it is also discussed how, on the basis of scientifically recognized needs and politically formulated goals, target values for the maximum greenhouse gas emissions caused by a building can be defined in a top-down approach, which correspond to a budget and contribute to a uniform net-zero emission approach.

4.2. Work flows and data interfaces (Subtask 2)

Thus far, the activities of Subtask 2 (ST2) have been closely coordinated with ST1 with respect to the establishment and execution of the global survey amongst design professionals. The public survey has been translated by Annex experts in 9 languages and is currently conducted in more than 20 countries.

On ST2 specific topics of LCA workflows and design integration, the work has been structured according to the following tasks:

a) Definition of design phases and milestones,
b) Building decomposition and element method,
c) Strategies for handling design variability and LCA uncertainty,
d) Sample cases for digital building models,
e) Definition of LCA exchange requirements,
f) Options for communication of LCA results.

The ST2 experts have been in regular exchange and have already shown their contributions in various publications on these topics: Yang et al. [27] analysed the environmental impacts in the Chinese context, highlighting the potential to reduce impacts during the design process.

Röck et al. [28] discussed the general challenges of coupling LCA and BIM based on case study implementation. Lupíšek et al. [29] shared their specific findings on the potential for interconnection of tools for cost estimation and life cycle assessment in the Czech context. Peuportier et al. [30] presented building life cycle assessment tools developed for the French context. In the aim of mainstreaming LCA in the building design process, the research of Szalay et al. [31] contributes by showcasing a modular methodology for life cycle assessment of buildings and building stocks. Contributing to both ST1 and ST2 topics, García-Martínez et al. [32] presented their BIM-based LCA approach for obtaining environmental benchmarks for the life cycle of buildings.

The Annex specific research thus has shown the challenges as well as great potential for integrating LCA in the building design process. At this point, ST2 is aiming to coordinate efforts and identify the common requirements for integrating the environmental assessment in different design stages. For this matter, the ST2 experts are elaborating their activities focusing on several key topics in order to: i) identify a common understanding of building decomposition based on existing systems (e.g. for cost estimation); ii) map LCA databases used along the design process in order to identify requirements for both LCA datasets as well as digital building models, as well as; iii) develop common strategies for the handling of variability and uncertainty in design-integrated LCA workflows.

In order to advance the discussion on the ST2 topics, a special session on 'Building assessment workflows' will be held in the framework of the SBE19 DACH conference in Graz, Austria.

4.3. Case studies (Subtask 3)

Experience with analysing a bulk of building cases from different countries in the Annex 57 project demonstrated how building LCA show large variations in assumptions and methodological choices resulting in large variation of numerical results, and which makes them impossible to be compared [33]. Therefore, understanding of methodology and work on harmonisation has had first priority. The first part of the work with case studies, which is in its beginning phase, will focus on collection of case studies displaying and evaluating the consequences of different methodological choices, such as use of dynamic energy modeling, the length of the reference study period, the functional unit and circular economy strategies. Moreover, the work with case studies will focus on displaying different national benchmarks which are already in use based on different methodology and assumptions. The results of this evaluation work can contribute to the development of suggestions for harmonised methods. Later in the project, case studies applying a harmonised method will be collected.

For the subtask on workflows and data interfaces, focus has been on gathering information across countries before collecting case studies. Case studies can be used to analyse how differences in building models (completeness and detailing) can be taken into account throughout the planning process (e.g. application of correction factors).

4.4. LCA databases for the construction sector (Subtask 4)

A preliminary screening about the types of databases used among the IEA EBC Annex 72 participating countries was performed. The participating countries were asked whether an own national database was developed and is being used and if so, by whom the database is developed and maintained. Further, they were asked, what type of data (generic or product specific) is used within their database. Generic data is usually data gathered from different sources of information; whereas product specific data is gathered from one or several producers for a specific construction product. Specific producer data can as well be published in the form of an environmental product declaration.

In total 23 countries filled in the questionnaire. Among the IEA EBC Annex 72 participants, 9 countries have developed their own databases, 10 countries use adapted datasets from foreign databases for their purpose and three countries did not develop or adapt own datasets. In two countries, the national database is developed and maintained by a public organisation. Several entities develop the databases but the database is maintained by the public sector in three countries. In 4 countries any organization can develop and maintain a database. To perform a building LCA, in 7 countries mainly generic datasets are used. 15 countries use both generic and specific datasets. In one country generic datasets are used in an early design stage and specific data in detailed design.

5. Outlook / Deliverables

The results of IEA EBC Annex 72 will help fostering the use of environmental information in the design and decision making process of buildings and thus lead to more resource efficient, environmentally sustainable buildings in the future. The deliverables will promote the importance and best practices of environmental life cycle assessment of buildings and will include a series of reports and national datasets:

- Report on harmonised guidelines on the environmental performance assessment of buildings, based on results of LCA;
- Report on establishing environmental benchmarks for buildings, including case study examples;
- Report on national LCA databases used in the construction sector, including a standardised characterisation of LCA databases relevant to the construction sector;
- Report on design decision maker's guidelines on optimization using building assessment workflows and tools, including case study examples;
- Report on building case studies (using a standardised template), including guidelines with good examples on the application of LCA in different stages of the design process;
- Report on how to establish national/regional LCA databases targeted to the construction sector, including recommendations for data exchange;
- Default publicly available, national data set(s) of LCA based environmental indicators.

The work of the IEA EBC Annex 72 will be finished by 2021 (http://annex72.iea-ebc.org/about).

Acknowledgments

The authors would like to thank the IEA for its organizational support and the colleagues involved in the project (Australia, Austria, Belgium, Canada, Czech Republic, P.R. China, Denmark, Finland, France, Germany, Italy, R. Korea, the Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, United Kingdom, United States of America, Observers: Brazil, Hungary, India, Slovenia) for their cooperation. Additionally, they would like to thank the organizations and institutions in the participating countries that financially support the project.

A special thanks goes to Maria Balouktsi, Martin Röck, Freja Nygaard Rasmussen and Livia Ramseier for helping with the creation of the present paper.

BIM based iterative simulation - efficient building design: a case study

Tallberg M, Bohne R

Norwegian University of Science and Technology

martita@stud.ntnu.no

Abstract. The aim of this case study was to evaluate the energy performance of utilizing different external materials reaching sustainable targets. Buildings are responsible for 40 percent of energy consumption and energy performance of buildings is a key element to achieving the European Unions goals. The EU has pledged to cut its consumption by 20 percent by 2020.
The main objective of this research was to explore the suitability of BIM for sustainabil-ity analysis at the conceptual design process. The procedure included analysis and discussion of the results for the lowest energy performance of materials. It was shown that changing the building envelope had a signi cant e ect on the annual energy performance of the case building. The limitations of the study was the limitations in the software. For further research, the paper nds it expedient to perform a even more detailed simuation analysis on the building design with other energy supply systems.
The value of the paper is to highlight the utilization of BIM to evaluate the material solutions to reach sustainable construction in the future, focusing on the need for lowering the energy consumption of tomorrows buildings.

1. Introduction

In 2015, the residential- and building sector counted for almost 40 percent of the energy con-sumption and 40 percent of the material use in Norway [4]. The energy- and environmental challenges make it necessarily to build with quality and aim for regular renewal of the existing building stock [3]. Sustainable quality in private homes, buildings, and built environments re-duces environmental impacts and improves quality of life for future generations [4]

In the context of the European Union e orts to reduce the growing energy expenditure, it is widely recognized that the building sector has an important role [1]. Directive on the En-ergy Performance of Building (EPBD) imposes the adoption of measures to improve energy e ciency in buildings, in order to reach the objective of all new buildings to be nearly Zero Energy Building (nZEB) by 2020 [1]. It is obvious that the design of a zero-energy building is not yet pro table in terms of costs [2]. The cost of materials and energy consumption will di er from each country and regional areas, the age of the building and it occupancy use.

The present article will present the results of the BIM based iterative energy performing simulations performed in IDA-ICE, with aim to establish a procedure for techno-economic opti mization. Hence, the aim of this paper was to evaluate the energy performance of a traditional apartment building designed for the norwegian TEK-17 standard, compared to the recommended thermal properties compiled by the reseach center on zero emission buildings. The building was designed using Autodesk Revit 2018 edition and exported as a IFC- le to IDA-ICE 4.8.

2. Theoretical framework

The design of low energy buildings involves two strategies minimizing the need for energy use in buildings through energy-e cient measures (EEM) and adopting renewable energy and other technologies (RET) [5]. RET represents photo voltaic (PV) or building-integrated photo voltaic (BIPV), wind turbines, solar thermal (solar water heaters) and heat pumps. EEMs include building services systems, internal conditions and building envelopes. These include life-cycle cost and environmental impacts, climate change and social policy issues [5, 6].

The consecration- rst approach to high performance building starts with advanced building envelope [3]. Guided by physics and building science, advanced building envelopes combine a simple suite of components to manage heat, air, and moisture and deliver superior e ciency, durability, comfort, and occupant health [2]. By controlling the movement of air across building assemblies, stabilizes the temperature and comfort in the building. The vapor barrier should be wrapped continuously, unbroken to prevent heat and moisture owing into the insulation materials. High-performance buildings employ a ventilated rain screen, a gap between the cladding and wall assembly that not only provides a channel for bulk water to drain away, but also generates air movement across the face of the assembly to dramatically increase drying [2]. A highly thermally resistant wall will have less drying capacity than a conventional wall, so the air movement provided by the ventilated rain screen helps ensure the resilience and durability of high performance wall assemblies [2].

3. Methodology

The envelope design was made as simplistic as possible, by improving the building envelope, simulating a air-to-air heat pump in combination with electric oor heating. For reducing the U-values in each occupant room and space, all the external walls were designed as both TEK-17 standard, and the nZEB standard classi cation. As glass surfaces are highly important for ex-ternal energy gains, it was important to evaluate the performance of the di erent window and door types. The baseline model was designed with a commercially available window frame and glazing unit with a U-value of 0.8 W/m2K. For internal heat, the heat gains from occupants, equipment and lightning were had the same default settings for both of the design scenarios. Figure 1 shows the building facades of the designed building using Autodesk Revit 2018 edition. Figure 2 shows the apartment design facades of the designed building using IDA-ICE 4.8 edition.

4. Case building

This chapter describes the designed case building in question and how it has been calibrated. This includes a description of the building envelope, model set up and calibration in Revit 2018 and IDA-ICE 4.8.

The investigated building was a conceptual low energy building which passive parameters are optimized and validated according to TEK-17 and ZEB standardization. The model was a residential building composed of four similar oor levels. Each oor level was divided into two apartments. The buildings net area (excluding balconies and non-conditioned spaces) was 464 m^2. All building rooms was modelled in the IDA-ICE-zone model. The thermo-physical

Figure 1. Building facades (Revit 2018)

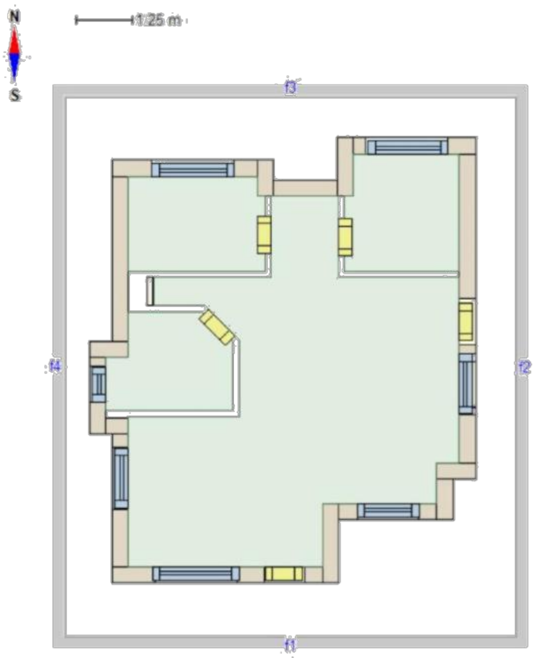

Figure 2. Room and space allocation (IDA-ICE 4.8)

characteristics of the buildings envelope are represented in Table 1.

From the Norwegian TEK.17 standard, heat loss through thermal bridges can be considered satisfactory if the normalized thermal bridge value calculated does not exceed 0.03 W/m^2K for single-family houses. In this case, the study assumes that this value was durable for the apartment building. For the nZEB case, normalized thermal bridge value was set to 0.015 W/m^2K.

Room boundaries and spaces were required in order to simulate the impact of the variation of each parameter in IDA-ICE. The volume computation for space was based on its room- bounding components and was calculated as the area of its base multiplied by the height of the space. The height was set to 2.6 meters, in accordance with the requirements for minimum height (TEK-17).

5. Results

This chapter discusses the simulated results for each simulation and compares the energy consumption. The results was based on the energy balance and delivered energy to the building to reach acceptable temperatures and indoor climate. For the sustainable design, photo voltaic electricity generation on-site was also included in the results. The photo voltaic production was simulated using PVGIS.

Initially, the reference scenario was modelled and analyzed. Secondly, di erent parameters were changed in the system design for mapping the impact on the annual energy use. Lastly, the economic break even for the photo voltaic systems were described. Sensitivity analysis, with respect to the electricity escalation, was carried out based on the simulated annual energy use in the building. The results show the sensible heat balance for the living room and kitchen main area and the total annual energy consumption for the one apartment. The data is presented in

Table 1. Building design envelope

ment (kitchen and living room). The maximum temperatures occur in the bathroom, due to the equipment loads in combination with the solar heat gain through the E/W facing windows. The solution to reducing the overheating in this area was to schedule the windows with an hourly opening in the summer months, to allow fresh air into the zones in combination with the HVAC-system.

The oor heating was based on traditional under oor electrical heating, with an emitted power of 70 W/m^2 in the living room, 60 W/m^2 in the bathroom and 40 W/m^2 in the bed-rooms. Due to overheating and thermal comfort, and the size of the building, the only supply heat was placed in the living room area. It consists of an air-to-air heat pump. The total heat power was 6.0kW w/ COP=3.2.

6. Discussion and conclusion

In this study, four electricity price escalations was be considered. The base case scenario (2.8 %) re ects the EU energy price projections to 2030 and was used as a baseline scenario for the present study. Low scenarios (1.3% an.) are often used in the German national context, including by the Federal Government in the elaboration of energy strategies. The high energy prices scenario (4.3% an. assumes a high energy price rise in the future, similar to the latest years observed rises. Due to resent research, there has been a 5% an. real increase in electricity

Figure 7. Design temperatures in main area (electric heating)

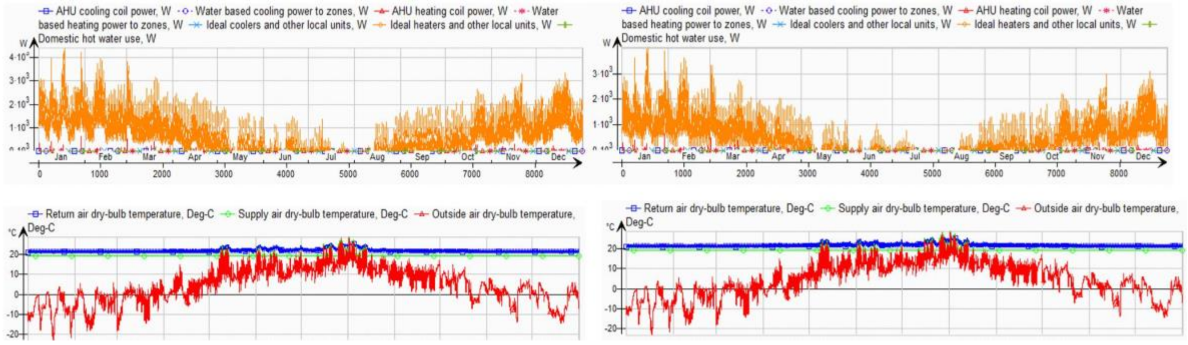

Table 5. Break even (PVGIS)

	PVGIS											
Efficiency	16%				18%				20%			
Escalation	1.30%	2.80%	4.30%	5.00%	1.30%	2.80%	4.30%	5.00%	1.30%	2.80%	4.30%	5.00%
Break even	26	22.8	20.2	19	24.6	21.2	19	18.2	22.9	20	17.9	17

price from 2000-2010. Hence, this optimistic prediction was also presented in the study.

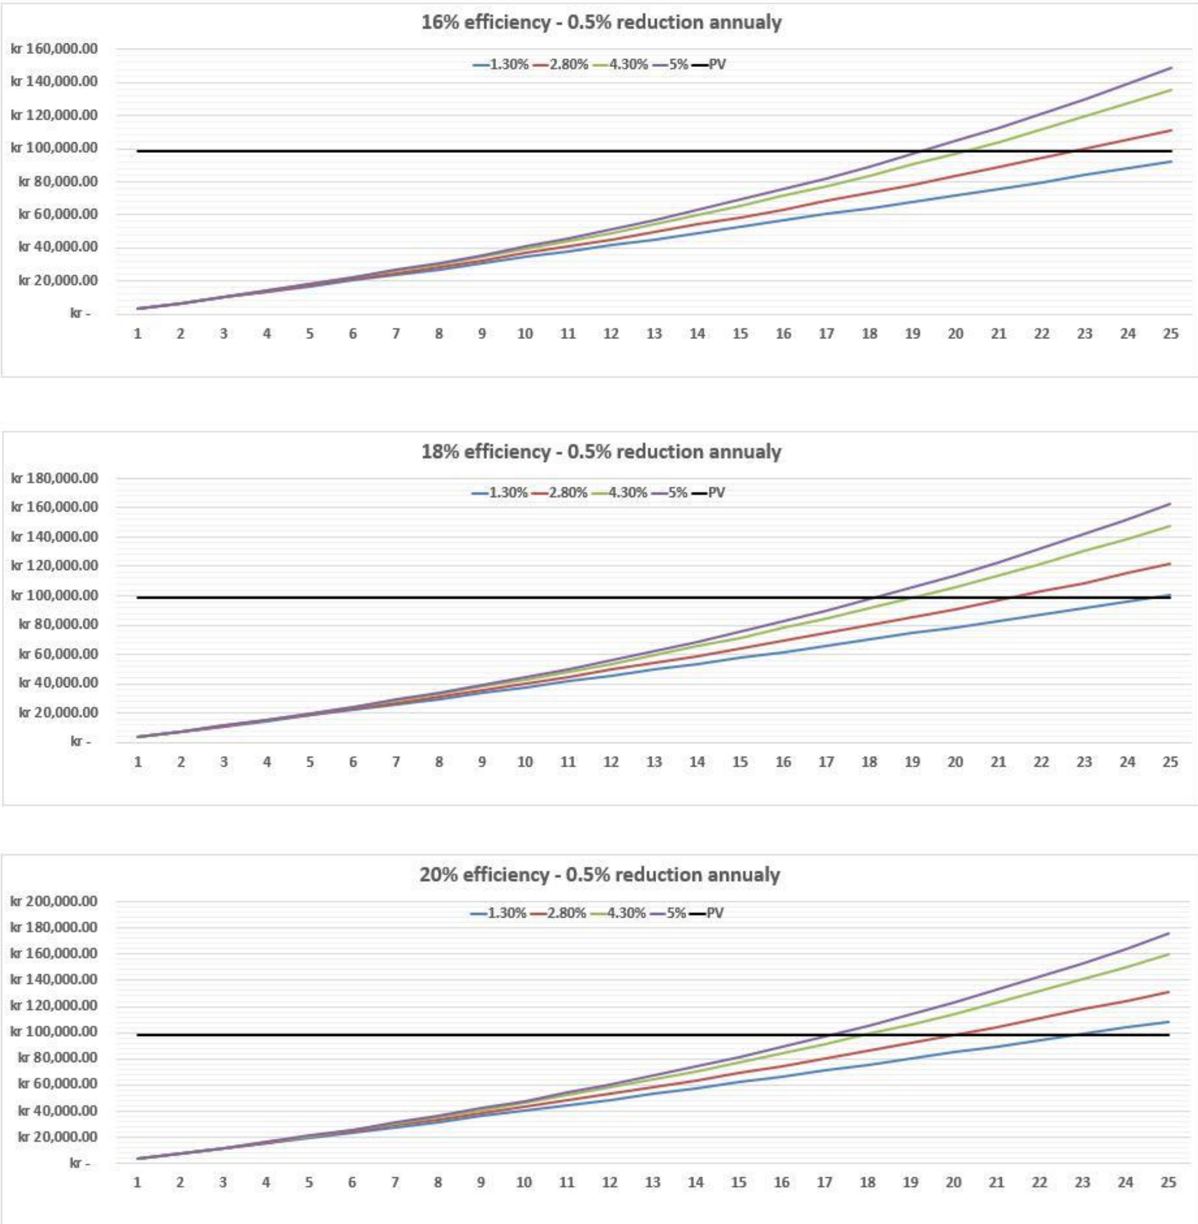
Energy efficiency technologies such as daylight control, thermal insulation, low-emissivity windows and on-site production of energy can be used to decrease energy use in new commercial buildings. Although the increased energy e ciency usually increases the upfront construction costs of a building, the energy savings over the service life of the building often o set these initial higher costs. The results gave a signi cant reduction in energy demend, from 84.1 65.5 kWh/m^2. When considering the displacement from traditional buildings to ZEB, the building type, climate, and study period impact the nancial bene ts from energy e ciency improvements. The longer the study period, the greater the energy savings for the building.

Furthermore, the adaptation of early stage BIM simulation is not a trivial task. This paper nds it prudent to investigate other software tools to evaluate the energy performance of dif-ferent building components. Further research is needed in the areas of software tool integration and selection for establishment of integrated design procedures and optimal criteria.

The results shows that by investing photo voltaic panels in addition to improved building envelope, the building performance reached high levels of performance. However, for the Nor-wegian climate, it is clear that the cost of 22.8 years payback is a high initial investment cost, which was the break even point from the simulations in PVGIS (assuming a 2.8% electricity price escalation). Based on the assumption of escalating electricity prices, specially in Norway, the paper did not nd it recommended from a economical point of view.

Based on the case study and simulations in IDA-ICE, several conclusions can be drawn. The design option with the lowest energy demand was found to be the optional concept building with electric oor heating and a air-to-air heat pump designed according to the ZEB speci cations. By retro tting the design from TEK-17 standard to nZEB, the energy demand reduction was found to be 22%. The cost of retro tting was found to be neglect able, compared to the cost of energy e cient measures, like the photo voltaic system. Furthermore, experimental veri cation of the demonstrated energy demand potential is recommended.

Figure 8. Photo voltaic payback time (PVGIS)



In conclusion, this was a case study of a digital case study building. The work done attempted to establish a fast and precise procedure for optimization of the building envelope using building performance software, which could be applied to di erent case-studies. For further research, this papers nds it necessary to scale the study quantity of di erent building types to be considered in terms of sensitivity analysis based on variation of climatic locations, electricity cost escalation and product costs.

Application of RecyclingGraphs for the Optimisation of the Recyclability in Building Information Modelling

Schwede D

Institute for Building Energetics, Thermotechnology and Energy Storage (IGTE), University of Stuttgart, Pfaffenwaldring 35, 70569 Stuttgart, Germany

dirk.schwede@igte.uni-stuttgart.de

Abstract. This publication discusses the application of RecyclingGraphs and ConnectionMatrixes in Building Information Modelling (BIM) for the assessment of the ability of structures to be decomposed and their components to be recycled. The assessment of recyclability of designed building parts is a data-rich task which requires expert knowledge and detailed analysis on a small scale, if complete recycling of the material content is desired. Today often only the main content of buildings, such as concrete and steel structures, are recaptured, while components of smaller quantities are lost or in the worst case, if they cannot be separated, lead to deterioration of the main material flows. BIM models will be connected to relevant databases and used in future to support the optimization of building parts for complete recycling through assisted design or even in automated analysis runs and workflows. Structural compositions are described by RecyclingGraphs and ConnectionMatrixes, which's components represent on the one hand material elements and on the other hand the connections between them. Materials are classified in terms of various characteristics, such as their recyclability, their ability to be incinerated and the harmfulness of their deposition. The connections are evaluated regarding their ability to be disassembled and the compatibility of the materials connected. The structures are translated into ConnectionMatrixes and the aspects of the evaluation are assessed individually and in combination. The translation of BIM models of four wall structures into RecyclingGraphs and ConnectionMatrix representations is analysed and potentials of such representations in new BIM-based workflows are discussed.

1. Introduction

The principles of design for recycling have been known for a long time and the stakeholders in the design and construction industry are increasingly aware of the need to preserve resources. In future, resource efficiency of buildings will be required as a necessary quality of building designs, like energy-efficient building today [1]. However, up to now there are still no applicable tools and assessment methods that enables engineers and architects to systematically translate these objectives into constructible designs.

Although there are methods for the evaluation of recyclability, these are often limited to the assessment of the individual material elements in a building structure. If at all, joining techniques and the ability to disassemble are only included in the assessment qualitatively. In product design however methods for the development of recyclable products are now widely applied, also because recycling is more straightforward here due to longer design cycles, higher quantities and more controlled production conditions. With the increasing use of digital planning methods and prefabrication, the development of recyclability is becoming also more feasible in the construction industry. Especially the object-oriented approach in Building Information Modelling (BIM) will give rise to the application of pre-designed elements stored in catalogues of design templates optimized for resource-efficiency, recycling and low life cycle impact. Common to these three new design aspects is that their assessment are highly data-rich tasks that required detailed consideration and a large degree of expertise which is not in the core competence of architects and engineers today. Such new requirements will overwhelm design professionals if not supported by databases and computational tools. The approach presented in this paper will allow the evaluation of resource-efficiency, recyclability and life-cycle impact of structural elements represented in BIM template databases.

As the European Construction Product Regulation (EU-CPR) demands that all new building and building products can be recycled already today, an applicable method for such assessment is needed. Beside the technical, economic and ecological considerations also the assessment of the ability for recycling is required in the development of new materials and structural elements [1].

Akinade, et al. [2] conducted a survey among construction industry stakeholders in the UK how BIM methods can support recycling and resource-efficient design, however most of these approaches address the reduction of construction waste on site ("designing out waste") and the prediction and management of material flows. The authors identified seven key BIM functionalities to be leveraged for design for recycling [3]. These are "Improved stakeholders' collaboration", "Visualization of the deconstruction process", "Identification of recoverable materials", "Deconstruction plan development", "Performance analysis and simulation of end-of-life alternatives", "Improved building whole life management" and "Interoperability with existing BIM software". The utilization of pre-designed and optimized design templates in the object-oriented structure of a BIM model is not listed although such applications will effectively support the introduction of structures optimized for deconstruction and recycling into design practice.

2. Building Information Modelling (BIM)

The term "Building Information Modelling" (BIM) refers to an object-oriented and parametric representation of design objects in the field of building design, construction and building operation. Design elements are represented in digital models as geometric, volumetric objects, which are augmented with relevant numerical and textual parameters. As an object-oriented approach BIM allows nested representations with adapted levels of detail. Through a common modelling standard and aligned workflows BIM facilitates the cooperation of the various disciplines in the design process and between the relevant lifecycle phases. BIM is used for coordination between architectural design, structural engineering and mechanical design. In the building's lifecycle information is passed from design to construction and to facility management.

In the field of resource efficient design BIM models are used for the generation of simulation models for thermal building simulation, load calculations and structural engineering from one common representation. In the context of recycling the application of BIM is often discussed for resource flow management, volumetric waste volume estimation and the prediction of transport and processing requirements [4].

While the main benefit of BIM is often seen in its ability to provide coordination between the disciplines in the design flow, the capacity of the nested object orientation to develop detailed design solutions bottom-up and then to plug them into the top-down design model is not yet utilized for deep analysis of design solutions. Although suppliers of technical installations, such as shading systems or ventilation units, already provide augmented BIM representations of their products to reference to the central BIM model, the detailed representation of for example wall structures with all their constructive and building physical elements and layers is not common today. BIM models are developed to limited level of geometry (LoG) and a limited level of information (LoI) and detailed design information is attached in form of 2D plans and textual descriptions [5,6]. This is partly to reduce the workload of the specialized engineers, who are still reluctant to design, specify and to enter such detailed information into the model [7]. It is also to maintain a workable size of the model since data rich representations become heavy even with today's computer infrastructure [7].

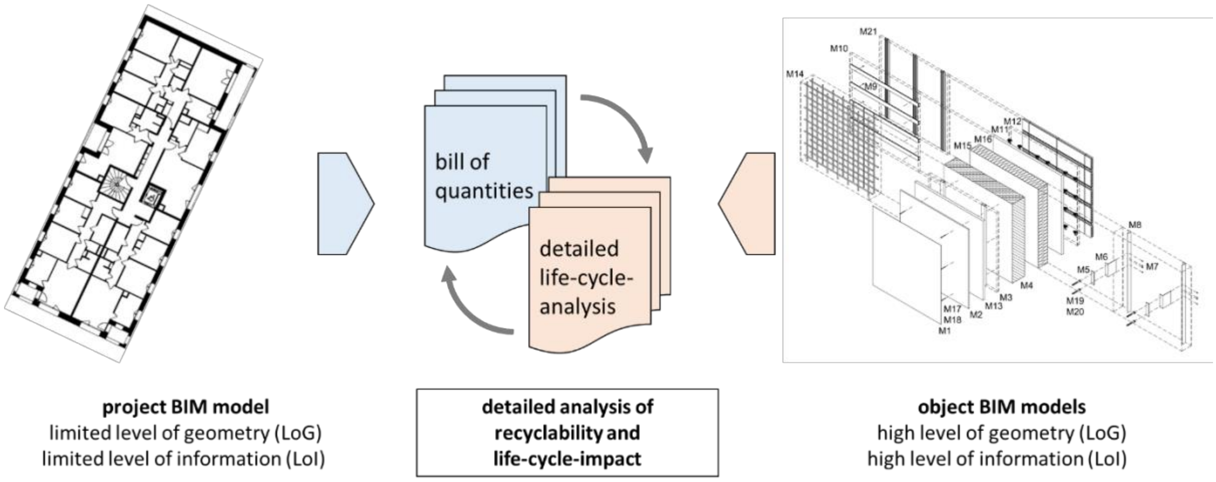

Figure 1. aggregation of detailed analysis results on building level.

3. Description of the method

BIM models contain geometric and volumetric information about the objects in the design. Additional parameters can be attached to these objects, such as material names and properties. However, information on their relationship is usually not included other than through their geometric coordinates and their shape.

Through automatic geometric analysis of the element's geometry and their placing in the model it is possible to identify adjacent elements and to plot a simple recycling graph and connection matrix [8,9] (moving from A to B in Figure 2). Pairs of adjacent elements are then listed as connection datasets. In a next step (moving from B to C in Figure 2) these connections are qualified with relevant parameters indicating the type of connection and other characteristics of the connection such as the ability to be separated and the compatibility of the connected materials [9]. This qualification can be performed by hand or supported by a database of common connection properties of material pairs. However, such information is not yet available in a structured form and will need to be developed to support future design for recycling [10].

Obviously, also the objects in the design can be specified with relevant information on the recyclability and the path of disposal, as well as of other relevant properties for life-cycle assessment and for environmental and economic evaluation. Such information can be retrieved from the available databases and connected to the material elements.

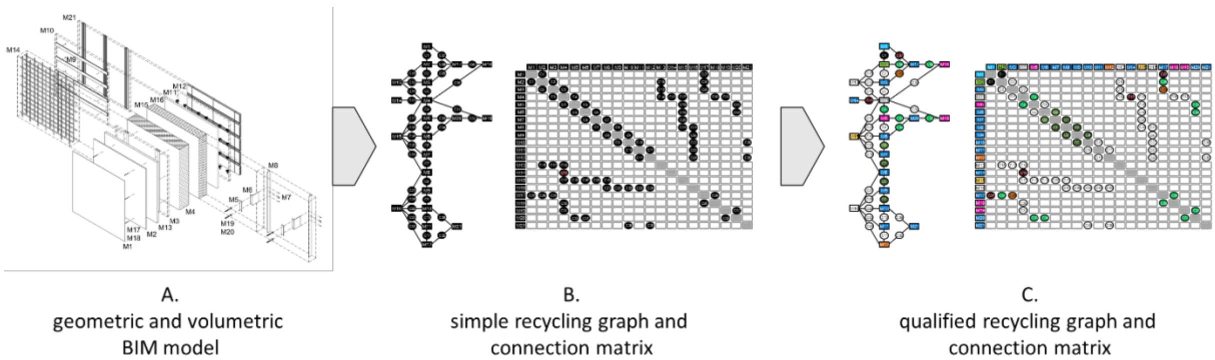

Figure 2. workflow from a BIM model into an analysis model for optimization for disassembly and recyclability. A. geometric and volumetric BIM model, B. simple recycling graph and connection matrix, C. qualified recycling graph and connection matrix.

In first applications of the method the resource demand (e.g. “mass”, “primary energy consumption”) and the environmental impact (e.g. “global warming potential”) were added to the material element data sets [11] as well as the general ability to be recycled [9]. The connection elements have been modelled with information on the “ability to be disassembled” and the “compatibility for processing” of the two connected material elements [9]. Further information can be added to both element categories for detailed assessment and planning as suggested below.

material elements parameters (examples)

- Mass of material
- Environmental impact for LCA
- Resource demand for LCA
- Durability of material
- Classification of hazards for health
- Classification of hazards for environment
- Economic value/burden after recycling
- Specification of applicable ways of processing

connection elements parameters (examples)

- Ability to be disassembled
- Compatibility of elements for processing
- Worktime for disassembly
- Required tools for disassembly

Qualities such as the “ability to be disassembled” can then be rated on a given scale. The rating in a connection element dataset can thereby also differ depending on the direction to indicate that one member will remain intact, while the other member is destroyed in the process of disassembly. Such information can be depicted in the RecyclingGraph and the ConnectionMatrix by numeric values and by colour codes. Related qualities of the design object can be assessed visually and through mathematical evaluation. Integrated evaluations can be produced by overlaying ratings of individual criteria. In [9] it has been demonstrated that the overlay of the rating of “ability to be disassembled” and the rating of “compatibility for processing” can be used to identify the best process for deconstruction to recover the resources in a given structure.

With the translation of a designed structure into a qualified graph and matrix representation its constructive characteristics become accessible for computational evaluation and based on that for processing for optimization. BIM models can be analysed, and related computer aided algorithms can be implemented in BIM design environments.

In a first step the optimization will be performed by the designer based on depicted analysis results as shown below. In future alternative selections of materials and connection types can be suggested by a computer aided system based on information from material and connection databases, as well as based on learning from the analysis of structures with a proven high degree of recyclability stored in element catalogues.

4. Results

The method has been applied to four different wall structures, which are modelled in detail with all required connection elements and fixtures as well as all functional layers to comply with the requirements of the current German energy code (EnEV 2016). The same wall structures have already been analysed regarding their ability to be recycled in [9] and regarding life-cycle impact and resource consumption including all constructive elements in [11].

In Figure 3 the four wall structures and their ConnectionMatrixes are depicted for the “ability to be recycled” (A), “compatibility for processing” (B) and the “integrated assessment of recyclability” (C = SQRT(A x B). For each material element in the four structures simple indicators are determined to analyse the bonding of material elements. The indicator “number of connections to other material elements” (#) indicates if the material element is connected to multiple neighbours. A value of 1 identifies a material element that is either a coating or embedded in another material. A value of 2 indicates a material element which is fitted in sequence with its neighbouring material elements. A further indicator is the “average rating” (∅) in the categories A, B or C. The rules for the analysis depicted in Figure 4 are given in Table 1.

As a result of modelling and optimization of individual design objects the demolition material flows can be predicted as required for management of removal logistics and recycling. In difference to the assessment based on the bill of quantity alone the quality of the material flow can be assessed from the BIM model already in the design. Not only the volume of a material fraction can be determined, but also which combinations of materials are to be expected and which technology would be necessary to process such material fractions into secondary resources.

Table 1. assessment rules for the assessment of disassembly and processing of material elements

number of connections # of a material element M		
1	M is only connected to one other material element. M is either a coating or M is embedded into another material (such as steel in concrete).	
2	M is fitted between two other material elements. M is either a connection or a separation element fitted in sequence with two neighbours. M might also be bridging between two neighbouring elements (coating spanning over different elements).	
>2	the material element is connected to several other material elements. It is possible that the element is locked-in and disassembly is restricted (might require a certain sequence of work steps)	
average rating ∅ of a material element M (A, B or C)		
1	A	material element M can be disassembled from all its direct neighbouring material elements
	B	material element M can be processed together with all its direct neighbouring material elements, the composition is a mono-material system or a material system that can be processed together without reduction of quality.
	C	material element M can either be disassembled from or processed together with all its neighbours

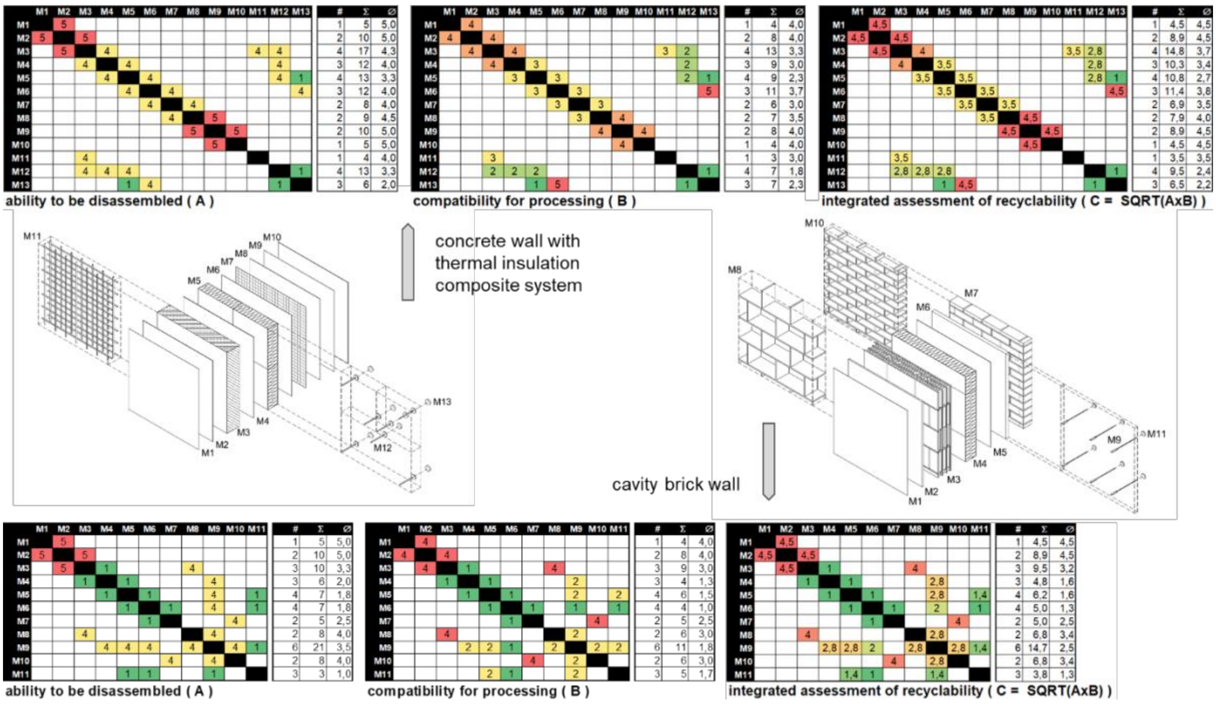

Figure 3. qualified connection matrixes with the properties "ability to be recycled" (A), "compatibility for processing" (B) and the "integrated assessment of recyclability" (C = SQRT(A x B)). (continued next page).

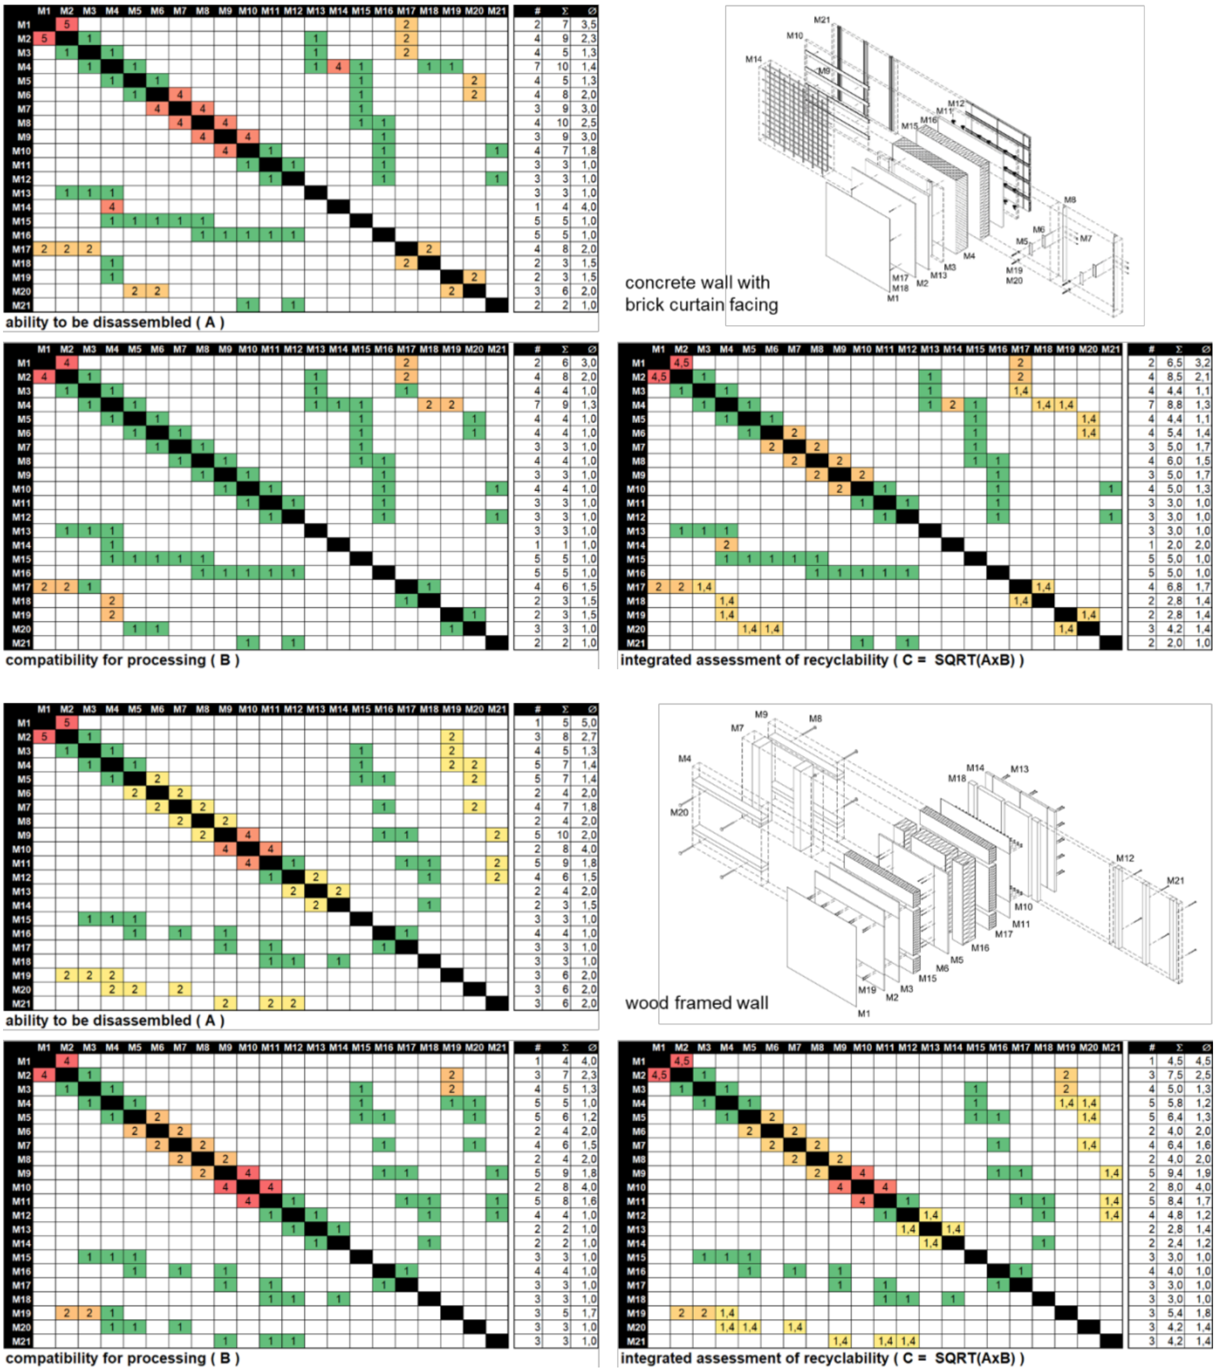

Figure 3 (continued). qualified connection matrixes with the properties "ability to be recycled" (A), "compatibility for processing" (B) and the "integrated assessment of recyclability" (C = SQRT(A x B)).

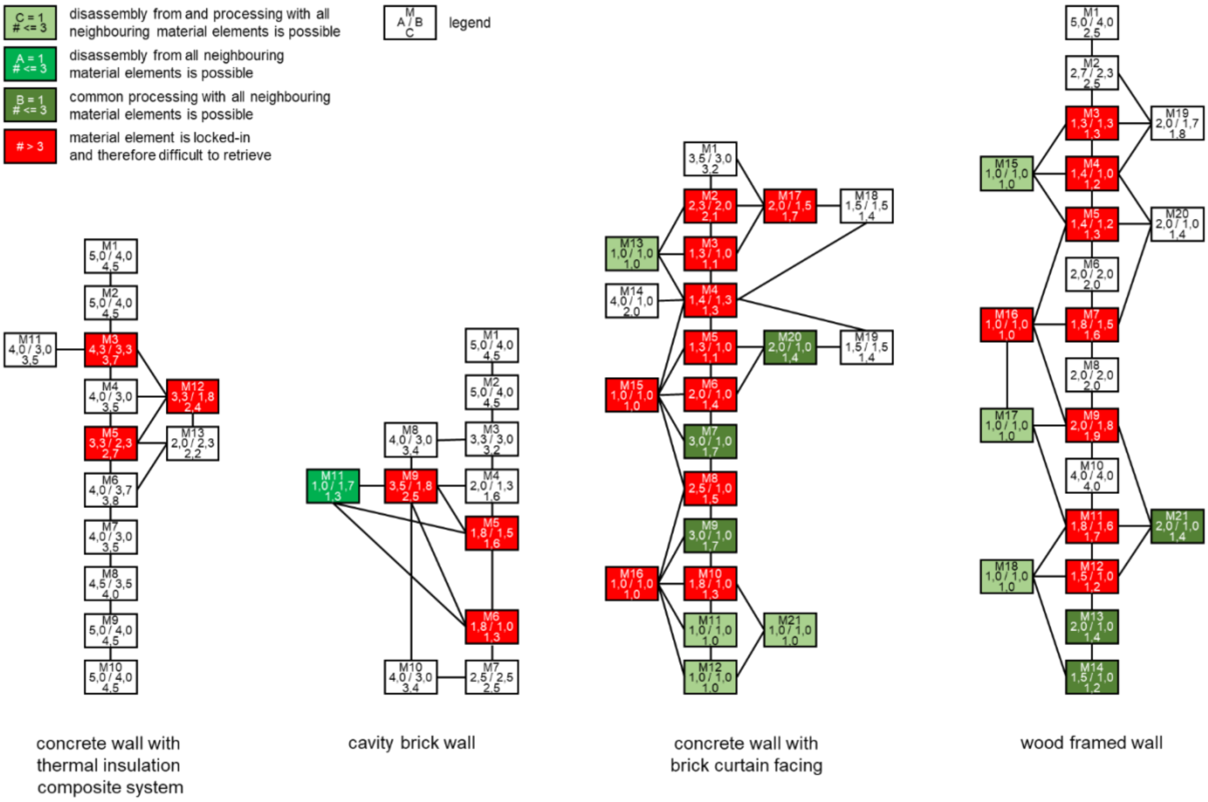

Figure 4. simple rule-based analysis of four wall structures. Colour codes indicate the recyclability of the material elements in the structure.

5. Conclusion

Resource-efficiency, recyclability and a low life-cycle impact are new criteria in building design and construction that require a detailed and data-rich evaluation [9,11]. A detailed analysis of the structural elements, not only of their individual materials but also of their connections and the compatibility of the fitted materials, is required to build truly sustainable structures. The RecyclingGraph approach presented in this paper can be used to translate detailed models of constructive designs into a numerical representation that can be processed by computational algorithms and design tools. This method can be utilized to evaluate designed and pre-designed structures and a catalogue of qualified design templates can be build up to support the BIM-based design development.

The presented RecyclingGraph approach must be developed further and an applicable design tool must be implemented. Research is also needed on the ability of disassembly for common connection principles and especially on the compatibility of material combinations.

Abstract. Planning quality is a key aspect for the development of sustainable buildings. This particularly applies to mechanical, electrical and plumbing (MEP) systems, which have a high impact on the building performance. The design of these systems considerably affects construction and operational costs. Moreover, it has a substantial impact on the consumption of resources such as energy or water and also on the building quality in terms of user satisfaction. Building information modeling (BIM) is a method capable of substantially improving the quality of MEP design. This requires adequate component models as well as processes describing the proper use of these models in a BIM project. This paper presents a Business Process Model and Notation (BPMN) model which describes the required interactions between project stakeholders during the design phase of a geothermal heat pump system. It describes the roles, tasks and responsibilities of the involved stakeholders and outlines which kind of information is required from whom at which point of time. The specific activities of the stakeholders are linked by information flows. In addition to the process model, a set of parameters describing a heat pump is presented. The parameters can be used as attributes in a BIM model. Each parameter is assigned to the design phase in which it is needed for the first time. This establishes a link between the attributes in the BIM model and the process model. Both, the process model and the parameter set were evaluated by MEP experts.

1. Introduction

The building sector has the highest final energy demand globally representing 31% of the total final energy consumption. Heating accounts for 75% of this energy consumption. The utilization of digital technologies has the potential to save up to 12% of energy for domestic hot water, heating and cooling until 2040 [1].

Building information modeling (BIM) is one of the most promising digital methods in the architecture, engineering and construction (AEC) industry [2]. Hartman et al. [3] pointed out that for a broad implementation of BIM two kinds of languages are required: one language to describe data models for BIM implementation and another one to describe the multidisciplinary BIM work processes [3]. Usually, many stakeholders are involved in the planning process of a construction project. Information management between these stakeholders across the various project phases is an important factor for successful BIM collaboration. A major challenge in project coordination is the question of responsibility for delivering data at the right time in the different project phases [4]. This is especially true for mechanical, electrical and plumbing (MEP) as this domain has many interfaces to other disciplines. One of the reasons why BIM has not yet fully been adopted is that there is a lack of well-defined process models for BIM collaboration. Moreover, there is a need for practicable descriptions of project requirements and BIM components [6].

The objective of this paper is to provide a process model for the BIM-based design of a geothermal heat pump with a vertical closed-loop borehole heat exchanger (BHE). Heat pumps have become an important heating system in Europe with steadily increasing annual sales [7]. BPMN (Business process model and notation) is used to represent the process model in this paper. To facilitate the practical applicability of the process model, a data set with design parameters of a geothermal heat pump is presented. The parameters can be used as attributes in a BIM model of a heat pump. Each parameter is rated according to its importance in the design process and assigned to a design phase. Parameters ranked with a high degree of importance are presented and discussed in detail. The results can be used for setting up and managing BIM projects where a geothermal heat pump system is used as heating system for the building.

2. Methodology

The use of process models is a common way to describe the tasks, responsibilities and workflows in a BIM project. Integrated Definition for Function Modeling (IDEF) [8] [9] as well as BPMN [4] have been used to represent process models for BIM projects. International standards such as EN ISO 29481-1 propose BPMN for generating process diagrams for the development of information delivery manuals (IDMs) [10]. For this reason, BPMN has been chosen to describe the design process of a heat pump system in this paper. The presented process model should support the creation of IDMs or relevant BIM documents in case the building is equipped with a geothermal heat pump system. It should also help to manage and monitor the digital information flow between the project participants in the course of the development of the BIM model. This includes the development of rulesets for automatic BIM model checking.

The IFC4 Add2 (Industry Foundation Classes) data model defines a heat pump as unitary equipment (IfcUnitaryEquipment), which means that the heat pump model consists of models of the individual subcomponents of the heat pump (e.g., evaporator, compressor, throttle or condenser etc.). In practical MEP planning however, it is unusual to consider individual components of a heat pump. It is a common practice to handle a heat pump as a whole device. For this reason, characteristic parameters of a heat pump were collected in order to create the basis for a heat pump data model on device level. The collected parameters were subsequently assigned to different design stages and evaluated by four MEP experts each on having more than 10 years of practical experience. The presented heat pump parameters can be used to set up custom heat pump models in BIM authoring software. It may also be used as a basis for an alternative heat pump model in IFC or to extend the current IFC4 Add2 model with parameters which are not yet implemented.

3. Results

The results are presented in two parts. First, the workflow and data exchange through three design stages of geothermal heat pump planning are illustrated by means of a BPMN process model. In the second part, collected heat pump parameters are presented and categorized, including a rating of their importance in different design stages.

3.1. BPMN model of the BIM-based design of geothermal heat pumps

Figure 1 shows the workflow and information flow during the design process of a geothermal heat pump with a vertical closed-loop BHE using BPMN (based on the ISO 22263 standard [11]). It shows the interactions of project participants from six disciplines: architecture, heating, ventilation and air-conditioning (HVAC), civil engineering, geotechnical engineering (GEO), electrical engineering and building automation (BA).

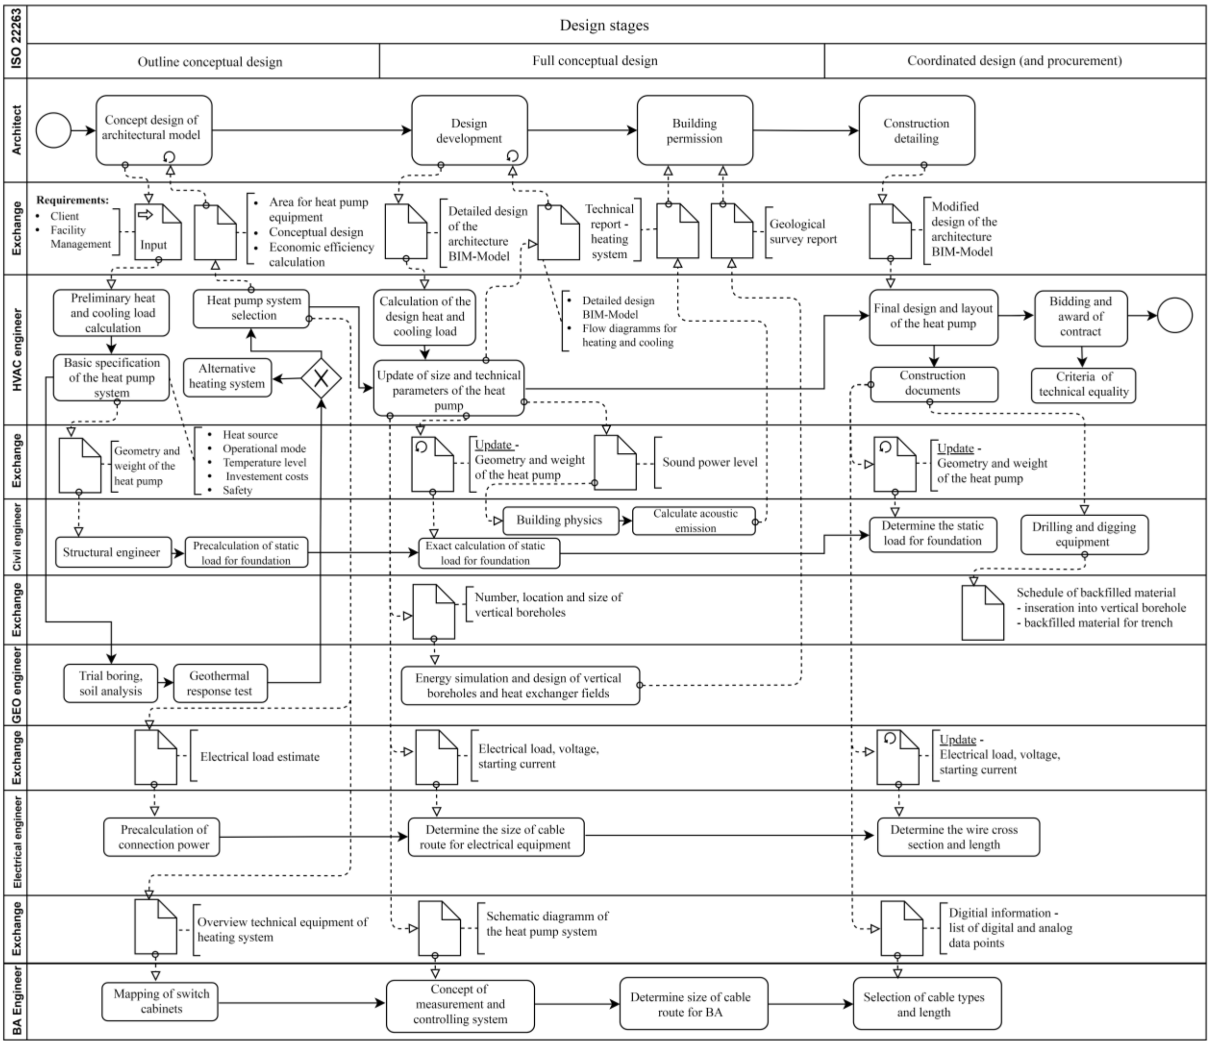

Figure 1. BPMN model of a heat pump for different design stages during the design phase.

At the beginning of the outline conceptual design phase, the architectural model and the requirements of the client and facility managers are analyzed by the HVAC engineer. Based on these requirements and a preliminary heat and cooling load calculation the basic operating conditions of the heating system are specified and main parameters of the heat pump system such as the required heat output, the electric load, dimensions, weight etc. are estimated. The refrigerant type and the basic system configuration are chosen. In large scale projects, the geotechnical engineer plays an important role in the course of system selection: The results of the thermal response test indicate whether the geothermal conductivity of the soil is sufficient or not to provide the required heat output. At the end of the outline conceptual design phase, the architect gets a technical concept of the heat pump system and requirements concerning the space needed for the technical equipment in the building and for the BHE in the surrounding area.

In the full conceptual design stage the parameters specified in the previous stage are extended and refined. The capacity of the heat pump is determined based on a detailed heating and cooling load calculation. This allows for a more precise specification of the dimensions and technical parameters of the heat pump. The results are required for the subsequent building permission process. In the coordinated design phase, the design and layout of the heat pump system is refined and completed and documents for the bidding and negotiation process are prepared. Engineers from all domains should be integrated into the design process as early as possible as shown in the process model.

3.2. Data set of design relevant parameters for geothermal heat pumps

Data was collected from different sources such as national and international standards (e.g., [12]), product data sheets and data schemes such as IFC4 Add 2 in order to compile the following parameter set for a geothermal (brine-to-water) heat pump as described in [13]. Overall, 76 parameters relevant to the design phase were identified. Figure 2 shows different categories to which the individual parameters were assigned.

Each parameter was subsequently assigned to the design phase, in which it is required for the first time. The initial assignment was done by four HVAC experts. In general, the assignments of the experts were in good agreement. In cases of differing opinions, parameters were assigned to the phase with the most entries. The parameters were finally assigned as follows: 30 to the outline conceptual design phase, 28 to the full conceptual design phase and 18 to the coordination design phase.

	Category	Number of parameters	Outline conceptual design	Full conceptual design	Coordinated design
Heat pump (IfcUnitaryEquipment)	Thermal and efficiency parameters	10	4	2	4
	Electrical parameters	9	5	3	1
	Geometry	6	6	0	0
	Refrigerant	6	6	0	0
	Operational parameters	8	3	5	0
	Fluid mechanics	14	0	14	0
	Cost	2	1	1	0
	Temperature range	4	4	0	0
	Machine specific parameters	12	1	3	8
	Building automation	5	0	0	5
Sum of attributes		**76**	**30**	**28**	**18**
Distribution		100%	39%	37%	24%

Figure 2. Categorized parameters of a geothermal pump and distribution among different design stages.

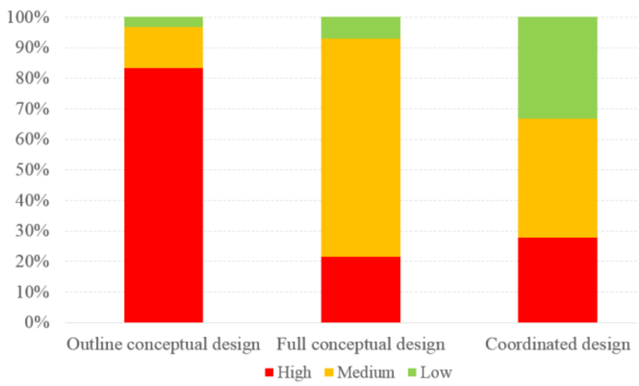

Figure 3. Distribution of the degree of importance of parameters in each design stage.

The four HVAC experts were also asked to rate the relative importance of each parameter. For this purpose, three importance categories ('high', 'medium' and 'low') were defined as outlined in table 1. The rating should help to establish a common sense between all project participants about the priority specific parameters should receive in the course of the development of the BIM model. Particularly for parameters rated with 'high' degree of importance, care must be taken to ensure that they are duly defined, fully incorporated in the digital building model and kept up to date throughout all project phases.

Figure 3 shows the distribution of the parameters according to their degree of importance in each design stage. It can be seen that the parameters with a 'high' degree of importance are predominant in the outline conceptual design phase. This result underlines the importance of early design stages in which requirements and the basic design-relevant parameters are specified. This is especially true for BIM projects as the establishment of BIM triggers a trend towards more detailed planning in early design stages.

Table 1. Categories for rating the degree of importance of the parameters.

Importance category	Criteria
High	• Parameters to be defined together with the client in order to determine the basic requirements for the planning task. • Parameters that are required to fulfil the planning task and which are essential for the work progress of several of the involved project participants. • Parameters needed for the building permit and parameters that represent criteria required to assess technical equality in the tendering and award process.
Medium	• Parameters that are required to fulfil the planning task and which are essential for the work progress of a specific project participant (e.g., parameters required by HVAC engineers to dimension a specific component).
Low	• Parameters which are not required for common planning tasks but which may be required for optional or special tasks (e.g., additional or more detailed simulations, additional documentation etc.).

Table 2 summarizes all parameters rated as 'high'. It also shows the design phases in which the parameters are relevant for the first time. The table reflects the opinion of the four HVAC experts consulted. The following examples illustrate the application of the criteria in table 1.

The heat output and electrical power at specified operating conditions for example are important for estimating the size and capacity of the heat pump. The two parameters are classified 'high' as other important parameters depend on them. The geometric dimensions and the weight of the heat pump depend on the heat pump capacity. This information is required by the architect and the structural engineer (e.g., to determine the location and size of technical rooms). The refrigerant charge is another important parameter derived from the heat pump capacity as pointed out below. Estimating the coefficient of performance (COP) and the energy efficiency ratio (EER) at specified operating conditions is also essential in the outline conceptual design as the granting of subsidies often relies on these parameters. This has a significant impact on cost calculations, which, in turn, are an important basis for decision-making by the client.

Refrigerant parameters (refrigerant type and charge, toxicity, flammability) are highly important because they determine the required extent of safety measures as specified in the EN 378 standard [14]. This concerns for instance the installation site (e.g., permissibility of an indoor installation) or requirements to equip the technical room with additional systems (e.g., additional ventilation, fire protection systems etc.). The parameters thus have an impact on the floor plan and on the scope and configuration of MEP systems. As the refrigerant choice and the refrigerant charge are safety-critical parameters, they also play an important role in the building permit.

Parameters required to assess technical equality of products in the tendering and award process include the nominal heat output, cooling output, COP and EER, the sound power level, the refrigerant type and the refrigerant charge. This justifies the rating 'high' of theses parameters.

Table 2. Geothermal heat pump parameters with a 'high' degree of importance.

Category	Parameter	Unit	Outline conceptual design	Full conceptual design	Coordinated design
Thermal and efficiency parameters	Required heat output at specified operating conditions	kW	•		
	Required Coefficient of Performance (COP) at specified operating conditions	(-)	•		
	Required Energy Efficiency Ratio (EER) at specified operating conditions	(-)	•		
	Nominal heat output	(kW)			•
	Nominal cooling output	(kW)			•
	Nominal Coefficient of Performance (COP)	(-)			•
	Nominal Energy Efficiency Ratio (EER)	(-)			•
Electrical parameters	Required power at specified operating conditions	(kW)	•		
	Starting current	(A)		•	
	Connection voltage	(V)		•	
	Nominal power	(kW)			•
Geometry	Length of unit	(m)	•		
	Width of unit	(m)	•		
	Height of unit	(m)	•		
	Length of required maintenance area	(m)	•		
	Width of required maintenance area	(m)	•		
	Space required for installation	(m^2)	•		
Refrigerant	Type of refrigerant	(-)	•		
	Refrigerant charge	(liter)	•		
	Toxicity	(-)	•		
	Flammability	(-)	•		
Operational parameters	Type of heat source	(-)	•		
	Range of functions (heating / domestic hot water / cooling)	(-)	•		
	Operation mode (monovalent / bivalent)	(-)	•		
	Temperature level of antifreeze	(°C)		•	
	Heat pump with integrated hot water tank	(-)		•	
	Volume of hot water tank	(m^3)		•	
Cost	Capital cost	(€)	•		
	Operational cost	(€)		•	
Temperature range	Maximum flow temperature heating	(°C)	•		
	Minimum flow temperature heating	(°C)	•		
	Maximum flow temperature cooling	(°C)	•		
	Minimum flow temperature cooling	(°C)	•		
Machine-specific parameters	Total weight	(kg)	•		
	Sound power level	(dB)		•	
Building automation	Interface type to automation and control system	(-)			•

4. Conclusion

In this paper, a process model and parameters for a data model for the design of geothermal heat pump systems were presented. BPMN was used to describe a standardized workflow and information flow for the design process. The process model shows that the interaction between different project participants is high. A data set with 76 geothermal heat pump parameters was compiled by analyzing different information sources. These parameters facilitate the design of the heat pump according to the requirements in different design stages. In BIM projects, these parameters can successively be adopted as attributes in the model. All parameters were thus assigned to design stages and rated according to their importance. The result shows that the degree of importance of the majority of parameters assigned to the first design stage (outline conceptual design) is classified as 'high'. This underlines the importance of early design stages in MEP and BIM planning.

The presented process model and parameter set should support the set-up and management of BIM projects in which a geothermal heat pump is used as heating system for the building. This includes the creation of relevant BIM documents (e.g., employer's information requirements, information delivery manuals etc.), the implementation and execution of rules for BIM model checking and the management of attributes in BIM models of geothermal heat pumps.

A next step would be to assign the identified parameters not only to design phases but also to specific use cases such as lifecycle analysis, building simulation, clash detection, BIM-based tenders etc. BuildingSMART Switzerland has recently introduced an online platform where such use cases are comprehensively described and documented. The methodology presented in this paper will subsequently be applied to other MEP components in order to build up a pool of MEP models which can be readily used in BIM projects.

Acknowledgements

The researchers would like to thank the four HVAC engineers for their contributed time to evaluate the process model and help to determine and rate the parameters of the geothermal heat pump. The work presented in this paper is part of the metaTGA project (FFG Grant No. 861729) funded in the framework of the program 'Stadt der Zukunft', which is a research and technology program of the Austrian Federal Ministry of Transport, Innovation and Technology. 'Stadt der Zukunft' is managed by the Austrian Research Promotion Agency (FFG) together with Austria Wirtschaftsservice Gesellschaft mbH and the Austrian Society for Environment and Technology (ÖGUT).

Criteria catalogue and analysis model to manage complexity in prefabricated timber construction

Geier S, Schwehr P

Lucerne University of Applied Sciences and Arts, Competence Center Typology & Planning in Architecture (CCTP), CH-6048 Horw

sonja.geier@hslu.ch

Abstract. Prefabricated timber construction often comes with demanding planning processes and uncertainties due to higher complexity. Hence, a great potential to optimize design, construction, and economic efficiency is not put to use. In the future, the challenge will be to have project management that is able to handle complexity. The criteria catalogue and the analysis model, developed in my doctoral thesis at TU Munich, are a first step towards the systematic and typological structuring of prefabricated timber construction in terms of complexity. The criteria catalogue makes it possible to describe and record functional and technical specifications as well as the aspects of the design and construction process and implementation, in terms of less or greater complexity. The project-specific system presentation in the analysis model is the basis for a common understanding and a transparent and target-oriented exchange of information among different disciplines, including the client. The application of the model in practice is described by means of a case study. The outlook of this paper describes how the developed analysis model provides a new approach in order to support planning security in Building Information Modeling (BIM).

1. Starting point

1.1 Complexity and planning security in prefabricated timber construction

«Timber Construction is complex», this statement stubbornly persists in practice without any plausible or profound hypothesis in literature. The «Manual for Multi-Storey Timber Construction» (*Atlas mehrgeschossiger Holzbau 2017*) describes timber construction as *«more multi-layered, thus more complex.»*

It says: «*The market offers an almost over-differentiated selection of different materials with many different construction possibilities»* [1]. Published in 2017, this comprehensive manual does not specify, why timber construction shall be «more complex». The question about complexity, however, is relevant, as in practice, it is this alleged complexity that is blamed for many difficulties and deficiencies that might arise in the planning process for prefabricated timber construction. For example:

- <u>Uncertainties</u> in the estimate of costs of alleged «complex» timber constructions in early planning phases. If a project team lacks the experience in early project phases of timber construction, the estimate of costs can be a major challenge: In Switzerland SIA 102:2014 Service Modell demands a cost accuracy of 15% in the Preliminary Project (SIA Phase 3.1) [2]. In Germany it is 10% in the Draft Planning Phase [3]. With the lack of experience and knowledge as to which constructions are simple and uncomplicated to realize and which situations require more effort and/or higher costs, safety margins are the rule. The worst case scenario is significant costs overruns. Both scenarios fail to rebut the widespread prejudice that timber construction is more costly [4] or correct the ratio.

- Concerning the interdisciplinary communication, those involved in the planning process complain about misunderstandings, double or bad planning, which effects the cost and schedule reliability as well as the process and the quality of design and execution [5].
- Concerning the expert-layman communication between the timber company and the developers, people report about the difficulties in transparent communication of context and impact of specific requirements or constructions in timber construction. Non-experts often do not have the understanding for cost-drivers, as these are not «visible» [6].

So although ecological arguments are in favour of wood, many actors raise arguments against it in the planning phase, summarized under the title «timber construction is complex», albeit without giving any reasonable explanation. The aim of my thesis at the Technical University in Munich was to close this gap and to contribute to the planning security in timber construction. The main focus was to determine the reasons for the complexity of timber construction and to derive solution approaches for handling complexity in planning and construction processes.

1.2 Definition complexity in the building construction and prefabricated timber construction

There are various definitions of the term complexity (in general). What is common to all of them is that complex systems are characterized by changing relations and they are unpredictable and cannot be planned ahead. They develop, they change and cannot be broken down into linear chains of cause and effect. If you follow these explanations, (planned) mechanisms and structures (including airplanes) per se are not complex at all, only complicated. Thus a timber construction is not complex but only complicated.

Literature (in general) provides various discussions and definitions of the complexity in building construction: Williams T mentions structural and organizational uncertainties [7], Bertelsen S refers to internal interdependencies, dynamic ambient conditions for the process, fragmented structures of building enterprises and the temporary system of social interactions [8]. That means the term complexity in building practice is used inaccurately. A challenge in construction, technology or design does not necessarily generate complexity (only in exceptional cases).

Within the framework of a situation analysis, my thesis identified and discussed further causes, specifically for timber construction with high levels of prefabrication:

- The lack of standardization of superstructures and over-differentiated variety of products cause uncertainties and the lack of overview within the planning team. [5]
- Functional requirements such as sound protection, fire protection, thermal insulation and moisture protection must be guaranteed in the interdisciplinary, cross-sectional analysis of primary, secondary and tertiary structures. Conflicts of interests and goals must be solved.
- Product specifications/capacities, supply chains, transport and logistics may already influence the design and should be considered early enough – albeit they cannot be controlled by the planning team only, and thus lead to uncertainties. [9]
- Pre-fabrication requires clear and complete execution planning for the production planning. Thus, decisions must be made earlier than with conventional construction methods. Interdisciplinary interaction in order to clarify all (relevant) planning details, takes place in a shorter period of time and with a higher network density. [10]
- The period between a decision (upon planning) and the visible assembly on-site is longer, thus increasing the risk that volatile influences or unforeseen events might thwart the plans. [10]

Thus, the complexity of prefabricated timber construction is not due to construction or architecture but to uncertainties, interdisciplinary interdependencies, conflicts of interests and goals and a higher density of social interaction. A web of manifold «complicated» challenges regarding how to manage interdisciplinary collaboration is thus the reason for any complexity in timber construction with a high level of pre-fabrication.

1.3. Managing complexity in the planning process
Building means deciding – despite all uncertainties, conflicts of interests and goals and the risk of the unforeseen. According to Schwehr P, a project team can only function with a solid base of knowledge and decisions [11]. In line with the interpretation of complexity discussed above, planning security means that it is impossible to foresee everything. Planning security means rather the security to deal with uncertainties, unforeseen events and to solve conflicts of interests and goals during the negotiation processes, through a high level of interdisciplinary interaction. So the management of complexity requires project-specific support through:

- establishment of a common understanding of the project, of terms and language and the priorities during project development (Big Picture).
- transparency and traceability of influential factors, dependencies and possible interactions (internal and external).
- knowledge and understanding of negotiable and not negotiable aspects.
- clarity in the exchange of information in inter-disciplinary communication (expert- and expert-layman-communication).

The conclusion in my thesis was to develop a typological structure of project characteristics and influencing factors in pre-fabricated timber constructions, demonstrating the project specific interaction of all complicated (und thus complexity generating) aspects and criteria in order to support interdisciplinary collaboration in the project team.

2. Criteria catalogue and analysis model

2.1 Methodical procurement and set-up of criteria catalogue
This typological structuring and the «complicated» i.e. complexity-generating criteria are derived from finished projects as part of the WoodWisdomNet research cooperation leanWOOD [12]. A total of 14 projects were investigated. In 45 narrative interviews and 9 interdisciplinary discussion groups criteria, qualified as «difficult» in planning and execution, were discussed from multiple perspectives.

These criteria were classified (less difficult to very difficult), supplemented with all normative and legal references and summarized in a criteria catalogue. Having finished the first version of the criteria catalogue, its validity was tested against the leanWOOD-case studies and other timber construction projects from previous research projects and double checked with practice partners for relevance and practical suitability.

2.2 Structuring of the Criteria Catalogue
Right now, the Criteria Catalogue comprises 35 criteria. The criteria were divided into three categories:

- Criteria that define the «Requirements» relating to task, functionality, surroundings, legal and normative framework conditions and the needs/wishes of the developers.
- Criteria that define the technical and design-related system approaches and details that are developed and/or decided by the project team in «Design + Construction».
- Criteria that influence the «Implementation» in production, logistics and assembly.

Each criteria category is documented in the Criteria Catalogue in a separate chapter. Figure 1 shows screenshots of individual pages of the criteria catalogue.

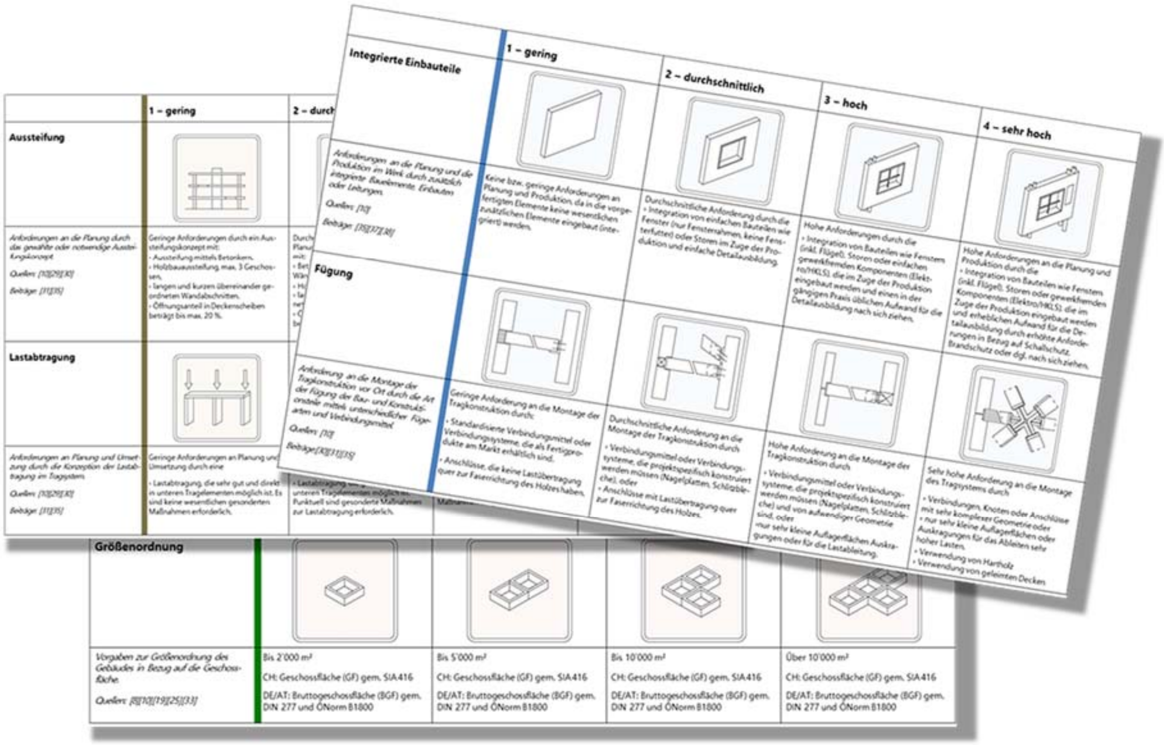

Figure 1: Screenshots of individual pages of the criteria catalogue [13].

As an example for one of these criteria the «Height Limitation» in the chapter «Requirements» shall be explained (see Figure 2):

Buildings in urban areas may be limited in height, because it might have to correspond with the roof line of the neighboring buildings. In order to achieve acceptable room heights, thin ceiling constructions must be applied, which exclude certain ceiling systems a priori, and also have an impact on horizontal cable and pipe ducts in suspended ceilings. This could possibly be compensated with horizontal space resources, where groups of ventilation lines could supply a smaller area and thus have smaller dimensions. If neither applies (level 3 or 4) the choice of ceiling systems is even more limited and/or inevitable crossings of lines and tubes require partial lowering.

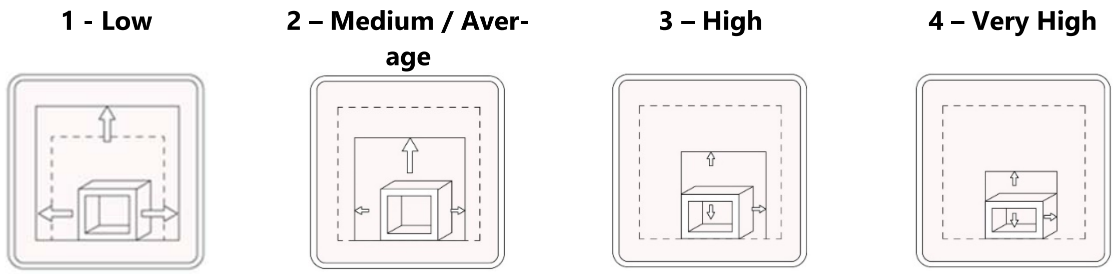

Figure 2. Criteria «Height Limitation» shows four levels of difficulties from level 1, (Low) to 4 (Very High) [14]. Level 1 (Low) shows no limitations in heights and horizontal expansion. Level 4 (Very High) shows a massive limitation in horizontal and vertical expansion.

The criteria «Height Limitation» describes the example as to how architects, timber structural engineers, building technicians and experts in fire and sound protection and structural physics have to tackle the challenges of room and ceiling height as well as cable and pipe ducts. In the case of different interpretations of priorities in the project, such as the priority of system separation, the condition that ducts may only be placed in suspended ceilings, or the question as to whether open ducts are possible, the key players may try to develop solutions on different assumptions.

2.3 Visualisation in the analysis model
The criteria catalogue systematically combines experience and know-how derived from individual, isolated experiences, summarized in a checklist. In order to visualize the assessment of a project and in order to support interdisciplinary communication through Visual Management, a visualization system was developed that generates a project-specific overall profile. In my thesis the Sunburst-Diagram was further developed (see Figure 4). The set-up of an analysis model and the derivable parameters for the planning team are explained below on the basis of real specific case studies.

3. Case study «Top Floor Addition Saumackerstrasse»

3.1 Project description [15]
The case study «Top Floor Addition Saumackerstrasse» describes the refurbishment of a multi-family house (year of construction 1948) in an urban area (Zurich). The total set of 21 apartments on three floors was to be left untouched as far as possible. The facade was insulated, new balconies were added to the facade and a controlled domestic ventilation was installed. The top floor addition replaced the uninsulated roof construction and made room for six new apartments. The element construction method was applied using box beam elements. The developer's goal was to create low-cost housing, thus the project had to be carried out in a tight financial framework.

Number of apartments:	21 + 6	Total construction time:	7 Months
Main usable area	1.970 m^2	Timber elements assembly:	3 Months
Completion	October 2015	Construction costs:	1.227 CHF / m^2 HNF
Architekt	*kämpfen für architektur ag*	Total costs:	1.580 CHF / m^2 HNF

Table 1. *Overview of the basis parameters of the project «Saumackerstrasse» (source see above)*

Figure 3. Installation of the pre-fabriacated roof elements. Photo: *kämpfen für architektur ag*

Figure 4. Interior view loft. Photo: *kämpfen für architektur ag*, Photographer: R. Rötheli

3.2 Assessment by means of the analysis model
Figure 5 shows the case study «Top Floor Addition Saumackerstrasse» in an analysis model. The three categories, Requirements, Design + Construction and Implementation are highlighted in different colors (green/brown/blue) and the difficulty levels (1-4) are graphically displayed with bars of different lengths.

The grey bar in the background shows the so-called «Reference Profile». The Reference Profile makes it possible to display experiences from previous projects and to constantly specify them in the course of future projects.

Figure 5 clearly shows that the «Requirements» in «Saumackerstrasse» were low to average, compared with the Reference Profile. For example fire protection was no big challenge. The required standards for sound protection, energy efficiency and earthquake protection were not unusual. However, Figure 4 shows one challenge. The «Existing Structures» were assessed as level 4. The reason was that the existing apartments had to remain untouched, thus offering little space for ducts in the staircase. The ducts to the new apartments had to be split without any system separation. As a result, the installation along the basement ceilings to the building services had to be solved on-site. In an interview the construction manager admitted that there were no additional costs, but that deadlines has been exceeded. The advantage of a rapid construction progress could not be transferred to the entire construction period. This might have been avoided through better planning during the early planning phase.

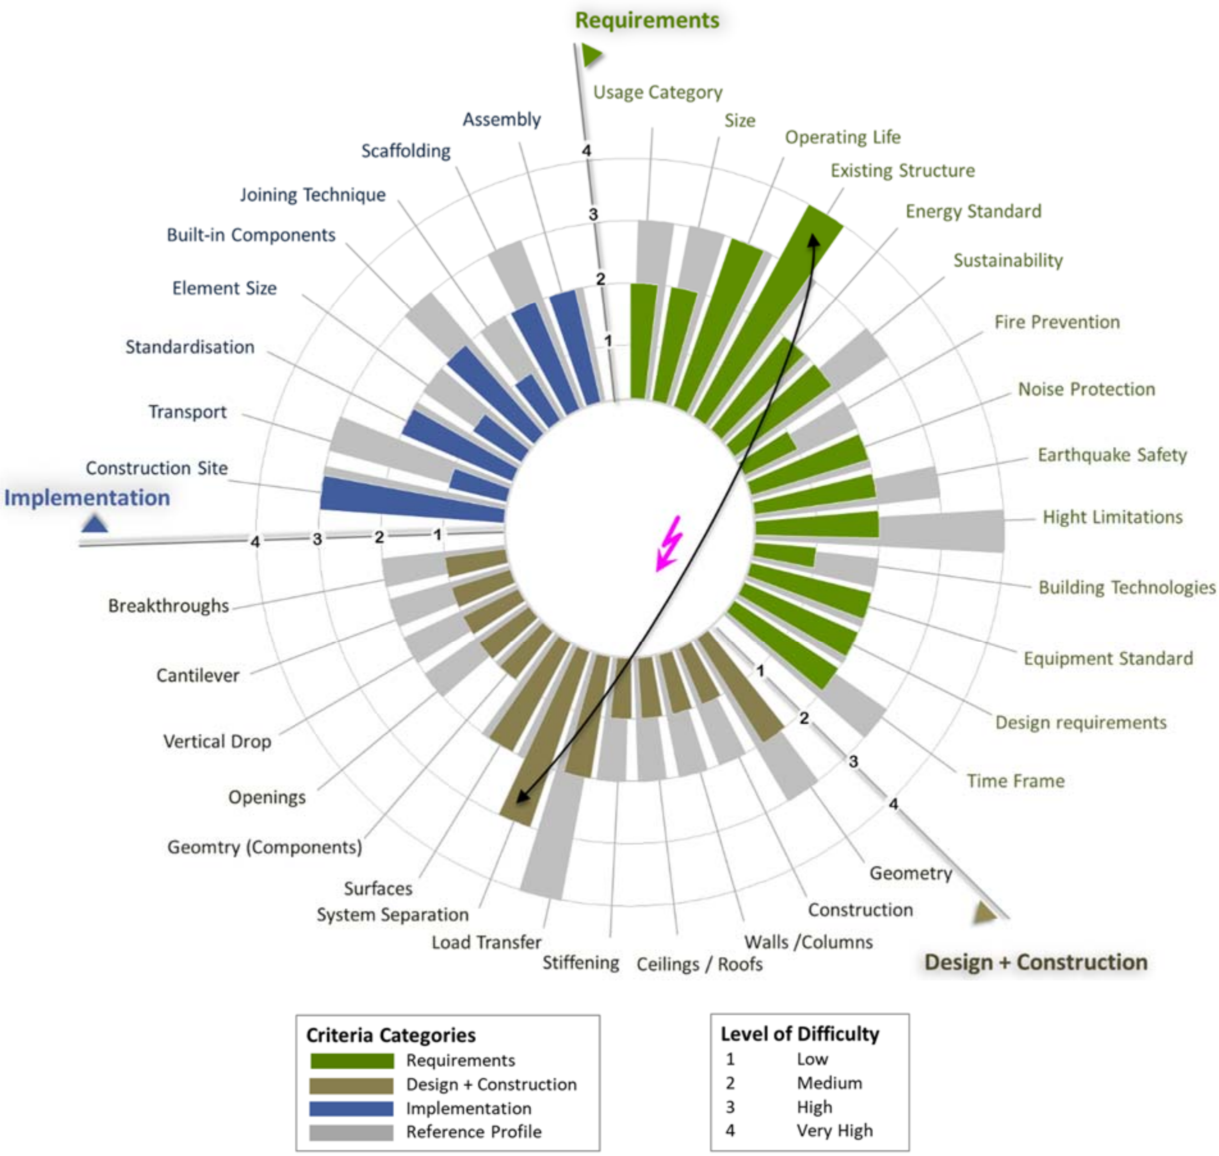

Figure 5. Diagram of the results of the project «Saumackerstrasse» in an analysis model

4. Application and limits

4.1 Use as strategic project support

The main application field of the criteria catalogue and the analysis model is in strategic project support. Complexity-relevant information concerning the project can be scaled gradually and specified in the course of the project. The assessment of the criteria referring to «Requirements» can indicate potential challenges, also in comparison with the Reference Profile. These can be communicated to the developers in a transparent way. Subsequently, a comparison of different designs based on the criteria (mainly concerning the cost estimate) can also be supported.

As an instrument of visual communication the analysis model enhances the exchange of information and knowledge management within the interdisciplinary team and the communication with the developers in the course of the entire planning phase. Dependencies, interactions and the necessary settings of priorities become transparent, thus comprehensible. The clarity of the information transfer and a consistent meaning are supported, so misunderstandings in interdisciplinary collaboration and in expert-layman-communication are avoided. Also, it becomes easier for new team members to get acquainted with the project. Furthermore, the visualized project profile can support the transparency of project descriptions or requirement specifications.

The communication of superior and essential aspects in a project facilitates the handling of uncertainties in the decision-making process. The project leaders have a solid basis for targeted quality, deadline and cost oriented project management. The comprehension of the overriding assumptions enables appropriate project-specific action on the part of everybody involved («Empowerment»).

The assessment of the complexity to be expected and an overview of the project specifications also support the procurement and cooperation model. The relevant disciplines are already being applied in early and subsequent phases. The selection of the contract awarding procedure can take into account specific complexities.

4.2 Conclusion

The assessment by means of a criteria catalogue and the visualization of the analysis model contribute to the typologically structured understanding and communication of causal networks in prefabricated timber construction. The added value is the assessment of possible challenges and the creation of a common understanding for the project within the interdisciplinary team. It is no dogmatic classification.

Flexible criteria can also be supplemented or deleted, depending on the application, without limiting the functionality or significance. The recording of experiences from previous projects in a reference profile supports the people involved and provides a checklist for the project management. However, it does not provide a generally applicable algorithm that can replace expert conclusions.

5. Outlook

The digitalization of the building industry and the successive implementation of the Building Information Modeling BIM initiates a new methodical culture. Model-based automated interdisciplinary collaboration will characterize future planning processes. The understanding of the terms, the interpretation of the meaning, the orientation and the comprehension of the priorities are essential for information management and communication for interdisciplinary collaboration. In this context the analysis model offers a typological approach that has the potential to support the structural transformation into new management and collaboration models in general. In addition a further operationalization of the analysis model may contribute to the following areas:

- The development of a BIM-cost model is challenged by the transfer of parameter-based cost estimates to component-based cost calculations. Today parameter-based models (in early phases) for the assessment of different execution options in timber construction can hardly be verified with cost factors. If reference profiles of previous projects could be set up in an internal data bank, it could provide increased accuracy. Subsequently, the data banks or catalogues could be pooled (e.g. BKI data bank for construction costs [16] or EAK catalogues of elements [17]) making a major contribution to cost security in timber construction.

- In in Switzerland the calculation of fees are on SIA 102:2014 [18], in Austria on LV.VM 2014 [19] and in Germany on HOAI 2013 [20]. What is common to all of them is that the basic services of the architects can be adapted to the increased expenses by means of adjustment factors or categories. However, these factors are rather vague in connection with prefabricated timber construction. The analysis model could enable an adequate assessment and, where appropriate, provide a billing system for architectural and engineer services in timber construction.

Thus, the criteria catalogue and the analysis model are the first important steps towards a typological structuring of prefabricated timber construction. The involvement of the digital planning environment could prove that timber construction is in fact attractive both ecologically and economically.

Chair of Technical Information Systems, Technische Universität Dresden, 01062 Dresden, Germany

{bastian.wollschlaeger, elke.eichenberg, klaus.kabitzsch}@tu-dresden.de

Abstract. Building automation systems are vital for reducing both energy consumption and carbon footprint of modern buildings. However, the engineering of such building systems is becoming increasingly complex, such that automating the engineering tasks is inevitable. Therefore, semantic component models of high quality and high expressiveness are required. But, as of today, existing models suffer from focusing on isolated aspects, high effort for component model specification, and low expressiveness in terms of the provided model structures. To close this gap, this paper proposes to adapt a holistic approach for modeling components. Firstly, we investigate different dimensions of component aspects and their interrelations and secondly, we develop BA-GSem, a graph-based semantic component model for building automation. Using a case study of a multi-variant room control unit, we illustrate that the correctness of system design results can be determined more precisely when using the detailed semantic model BA-GSem. The results offer a suitable foundation for improving the quality of automated design approaches for building automation, thus facilitating the creation of modern and sustainable buildings.

1. Introduction

Building automation systems (BAS) facilitate demand-based building operation and are therefore a key concept for reducing both energy consumption and carbon footprint of modern buildings [1–3]. The application areas of smart building technologies are not limited to building automation itself, but they are also important drivers for shaping the digitalization of home health care and customized precision health care by means of smart home and assistance technologies [4]. However, the engineering of smart building systems is highly complex due to a large number of components and component variants to choose from, highly interconnected information flows and interoperability issues among components of the building system [5]. Human engineers are unable to keep up with the pace of component development in the smart building and smart home sectors: they are only familiar with a small number of the available components, which leads to sub-optimal solutions and wasted potential of energy savings [6].

Consequently, automating the engineering tasks is inevitable to cope with the growing complexity of BAS. The major engineering task is the design of the BAS, which, besides for the system development, can also be used in redesign or self-adaption [7] use cases. This component-based design process requires formal component models of high quality and expressiveness, fulfilling the following requirements: They need to offer structures with a high level of detail (*Precise Modeling*) and in order to be usable by engineering algorithms, the effort for creating and using the component models needs to be in an acceptable magnitude (*Ease of Specification and Use*). Furthermore, design algorithms will need to cope with heterogeneous levels of detail in the component database (*Robustness of Use*).

However, state-of-the-art component models suffer from low model expressiveness, focus on isolated aspects or high effort for specification and therefore fail to provide a foundation for successful automated design. This paper addresses these gaps with the following contributions:

1. **Precise Modeling:** Proposal of the *graph-based semantic model BA-GSem* for detailed modeling of component semantics in context of a holistic perspective.
2. **Ease of Specification and Use:** Identification of *important component aspects and their interrelations* as a basic prerequisite towards adopting modularization approaches.
3. **Robustness of Use:** Discussion of *the impact of different levels of detail on specific system design tasks* as foundation to assess feasibility and quality of system design.

The remainder of the paper is structured as follows: Section 2 discusses related work on formal component models for automated engineering approaches. Afterwards, the holistic perspective on component models for building automation (BA) is discussed in Section 3. Subsequently, a case study of a multi-variant generic room control unit is used in Section 4 to validate the applicability and benefits of the holistic perspective and the semantic model *BA-GSem*. Section 5 concludes the paper with a summary and an outlook towards further research.

2. Related Work

The overall task of automated design consists of fulfilling the user requirements by selecting and combining available components. Semantic specification approaches for functionality allow transforming user requirements into an intermediate, neutral and machine-understandable formal representation of required system functionality. Sub-tasks for the design of BAS are [8]: Selection of *suitable components* for system functions ("T1-ComponentSelect"), identification of required *data flow* between components ("T2-DataFlowIdent"), *interoperability*-check of all interconnected components ("T3-CheckInterop"), and ensuring that all components are capable of *providing their functionality* ("T4-CheckOperational"). Following this concept, a multi-stage *automated design approach* for room automation (RA) systems has been proposed [8, 9]. This approach is based on the common functional vocabulary of RA systems standardized by the VDI 3813-2 [10]: The first design step maps the user requirements to a formal semantic model for system functionality. In the second step, this neutral requirement model is transformed into several design suggestions using a component repository that contains formal models of the available RA components.

Existing approaches for formal device modeling include classification approaches [11–13]. These focus on isolated aspects, e. g. eProcurement or eCatalogs. Functional semantics are only annotated on a very coarse level. Several communication technologies for BA provide electronic self-description documents [14, 15]. Such documents contain models of software interfaces as well as basic functional aspects, but are technology-specific and lack detailed semantic information. Finally, Dibowski and colleagues proposed a technology-neutral semantic component model [16], specifying the device interface coarsely on both software and semantic level. Yet, the link between both levels is missing and device models are specified in a non-modularized fashion, creating a high modeling effort for different variants of a product family.

With regard to automated design, especially step *T4* is currently not sufficiently supported by any of the existing component model approaches. A holistic approach for modeling devices is required, taking into account aspects such as hardware, software, functionality, and their interrelations. We will extend the approach of Dibowski [16] to meet the practical needs of automated design approaches.

3. A Holistic Perspective on Component Models for Building Automation

3.1. Important model aspects and their relations

A general model of an automation device is shown in Figure 1. It is focused on the *Device* as the central entity and describes its inner structure as well as its interfaces. Depending on the role of the device, its

Hardware-interfaces may include connections to the process (i. e. the physics of rooms in a building), human-machine-interface elements (operating elements and display functionality), or the communication medium (automation network). The network interface is displayed on the lower right by a connection to a field bus and the appropriate *Network Stack*, which handles wrapping and un-wrapping payload with the bus' telegram structure. On the other hand, *Periphery Drivers* handle the pre-processing and integration of electrical signals received from or sent to the electric terminals (pins) of the device.

The second area of a Device's inner structure is its *Software*, which is modeled in terms of a whole *Device Application*. To allow for better modularization, the general device model allows the Device Application to be composed of individual *Software Modules* that can be managed and used independently of each other. The Device Application may restrict the number of available instances of each Software Module to account for a limited computational or storage capacity. Software Modules can also be modeled according to their interfaces and inner structure. The Software may receive and send information as payload of the communication platform (i. e. field bus). This data is shown as data points of the *Network Interface* (`nwIn` and `nwOut`). In addition, a Software Module may exchange data with the physical process by means of electrical signals, constituting the *Peripheral Interface* with the data points `pIn` and `pOut`. Lastly, a formal *Semantic Model* of a Software Module's functionality processes and generates this information on an abstract level.

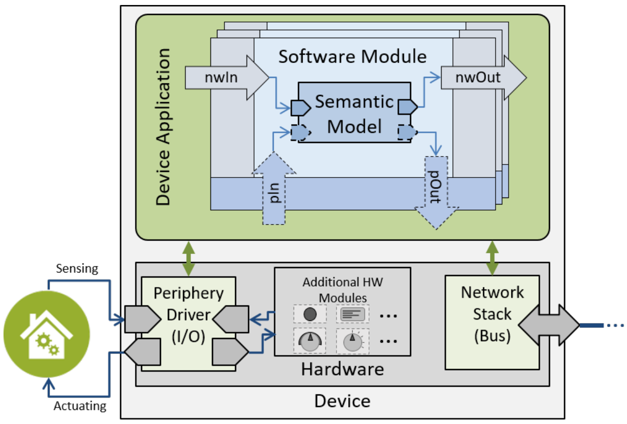

Figure 1. General Device Model of an automation device

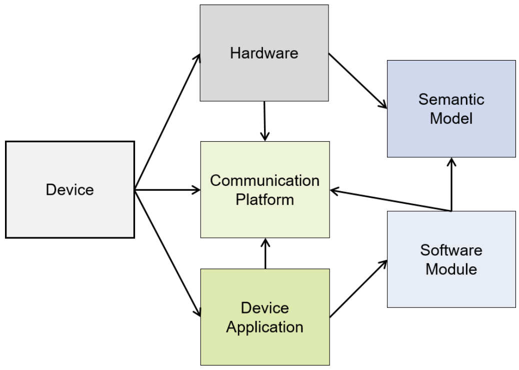

Figure 2. Model aspects and interdependencies

As can be seen from the general device model, there are several key aspects that need to be modeled for an automation device. Decomposing a device model into different aspects proves valuable if product families and therefore a great degree of similarity are involved. Instead of having a monolithic device model, each device aspect can be defined in a modular and reusable way, which makes the specification and use of device models more efficient. As part of our investigation, we examined which model parts would prove suitable for modularization. The identified aspects and their dependencies are depicted in Figure 2. A directed edge in this graph means that model artifacts of the aspect at the origin make use of model artifacts of the aspect at the target end of this edge. Starting from the *Device* as the main entity, several other model aspects are linked: Firstly, a device consists of a specific *Hardware* and a software *Device Application*. Secondly, individual variants of a product may target different communication technologies; thus, another important aspect of a device is its *Communication Platform* (which only needs to be modeled once). The communication platform is again referenced by both hardware and device application, since the first needs to contain a compatible transceiver required for communicating with this particular network and the latter makes use of the communication platform's application layer data types.

Further references can be identified from the general device model: the device application can be

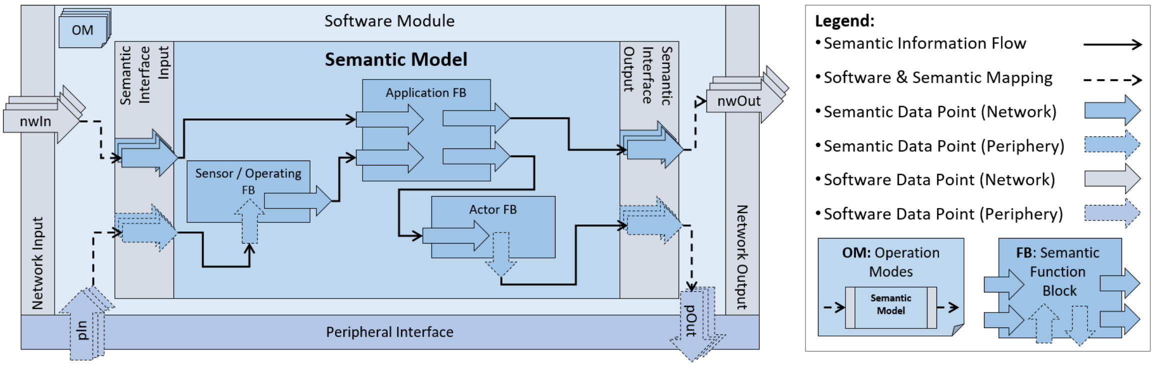

Figure 3. *BA-GSem*: Graph-based semantic model of a software module

made up out of *Software Modules*, which each contain *Semantic Models* and reference types from the communication platform. Finally, the hardware aspect referencing the semantic models is less obvious: It can be inferred from the general device model that a semantic model may only receive information from the network interface (i. e. software aspect) or from the peripheral interface (i. e. hardware aspect). Thus, a specific hardware equipment may determine, which parts of the semantic model can be chosen.

3.2. Conceptualization of BA-GSem – a Graph-based Semantic Model for Building Automation

The related literature analysis in Section 2 shows that the available structures for specifying component functionality are limited to a plain list of functions without taking into account the inner flow of semantic information as well as neglecting the distribution of data from the semantic interface to the semantic functions and vice versa. In order to provide a more fine-grained structure to model device semantics, we developed a *graph-based semantic model* for software modules of BA devices (cf. Figure 3). This model uses the function block (FB) structure proposed by the VDI 3813-2 [10]: a semantic function is represented by a specific block that defines its information flow interface. More specifically, semantic information of a certain type may be provided to the function block by directing the information flow to connectors, so-called data points, on the input side of the block. Information flows generated by the function block originate at data points on the output side of the block and can be directed to other data points. These connectors also have a specific type and the semantic linking is only valid, if the types of data points and information flow match. In case of function blocks connected to the periphery (i. e. sensor, operating, actuator, and display blocks), data points handling information flows from the peripheral interface will be drawn vertically with a dotted outline, whereas all other data points are visualized in a horizontal style with a continuous outline. This distinction is motivated by the physical connectors in [10].

With information flows connecting function blocks, a function block network as a directed graph is created. In order to be able to interact with further semantic models (contained in other devices or software modules), a semantic model also needs an interface. This semantic interface is depicted on the left (semantic input) and right (semantic output) side of the function block network. If a semantic information is created inside the function block network, this information can only be used outside the semantic model if it is represented in the semantic output interface. The semantic model is used as an abstract and formal description of how the software code of a software module processes data. Therefore, data available at the interfaces of software modules need to be mapped to the semantic interface of the semantic model, distinguishing between periphery and network. Since semantic models are more abstract than software modules, this mapping will be an abstraction (software types to abstract semantic types) or a specialization (abstract semantic types to specific software types).

Even after production and programming, automation devices can be adapted to a specific use case by configuring a set of parameters. Usually, data types can be changed and even some functionality

Table 1. Levels of detail (LoD) for model aspects

Aspect	Level	Label	Description	Example
Semantic	0	Sem0	no semantic model	-
	1	Sem1	functions annotated as *plain list*	[13], [11], [12]
	2	Sem2	additional model of *semantic interface*	[16]
	3	Sem3	detailed *graph-based semantic model*	*BA-GSem*
Software	0	SW0	no software model	-
	1	SW1	*software interface* of device application	[15]
	2	SW2	software divided into *individual SW modules*	[14]
	3	SW3	*operation modes* of software modules	*BA-GSem*
Hardware	0	HW0	no model of hardware features	-
	1	HW1	*communication technology* and transceiver	[14], [16]
	2	HW2	*number and type of peripheral connectors*	[13], [11], [12]
	3	HW3	*semantic of peripheral connectors*	*BA-GSem*

can be (de-)activated. The graph-based semantic model accounts for such post-production flexibility by the concept of *Operation Modes* (OM), which possibly alter the semantic graph, the mapping between semantic and software data points as well as their respective types in a pre-defined way. By doing so, an operation mode acts as a wrapper for the semantic model of a software module.

3.3. The impact of the level of expressiveness on the feasibility of automated design

With the proposed graph-based semantic model offering more detailed structures to model components' functional semantics, more fine-grained analyses and consistency checks become available at the level of automated design. However, it has to be expected that the semantic models in a component repository will not always be homogeneously described. The available level of detail (LoD) of semantic component descriptions in a component repository restricts, which analyses and consistency checks can be performed by the automated design algorithms.

We will now define different levels of detail for key aspects of component models (i. e. Semantics, Software, Hardware) and subsequently discuss their impact on typical automated engineering sub-tasks from Section 2. Table 1 defines the different levels of detail for the three main aspects of device models, including a short description and examples.

The first sub-task of automated design – "T1 Component Selection" – benefits from detailed semantic models since components are selected based on neutral functional requirements using the same functional vocabulary as the semantic model. Levels *Sem1* and *Sem2* already allow a proper querying of devices based on functions. *Sem3* adds the ability to query sub-graph-structures, which can be used by sophisticated device selection algorithms to solve the cover problem. The next step, "T2 Data Flow Identification" benefits from detailed models of the software and semantic aspects. The levels *SW1* and *SW2* offer a basic understanding of the software's interface; however, since they – unlike *SW3* – do not include operation modes, they incur a model error when describing the device's flexibility. On the semantic dimension, *Sem2* enables an identification, which semantic data might be communicated on a possible software connection. However, if *Sem3* is not available, there is no way of exactly assessing, what the purpose of the semantic data is and whether it is used at all.

The step that benefits the most from detailed models is step "T3 Check Interoperability". Each data flow connection needs to be investigated for validity on different levels: semantically using information starting from level *Sem2* (*Sem3* allowing more detailed checks), syntactically on software level (feasible

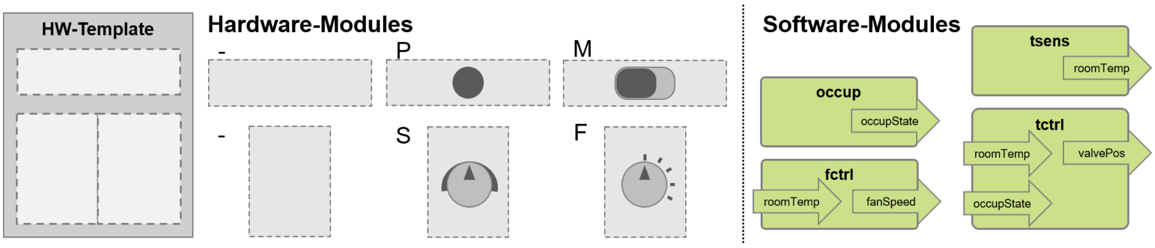

Figure 4. Building blocks of RCU Product Family – Hardware (grey) and Software (green)

at *SW1* and above with *SW3* removing uncertainty even further) and on hardware level (*HW2* and above). Finally, step "T4 Check if Operational" needs to make sure that all devices are delivered the information they require for proper functioning. This can only be assessed, if the interfaces are modeled (*Sem2* and above, *SW1* and above, *HW2* and above). The more information is available, the more accurate the operational state of components can be evaluated. For a device to be operational, it has to be ensured that all information required by semantic models is provided by either the software interface or appropriate hardware modules.

4. Case Study: Product Family "Generic Room Control Unit"

In order to provide a validation for the proposed semantic model *BA-GSem* and to show its applicability for product families in BA, we apply the method of a case study. The core element of the case study is a generic room control unit (RCU) product family, which is inspired by actual products to depict the real complexity of component models in the context of automated design approaches. The RCU product family is made up of eight similar variants that differ in their hardware configuration, which introduces subtle constraints and dependencies with respect to the functionality an RCU variant is able to fulfill.

4.1. Set-up of the Case Study

Figure 4 depicts the building blocks of the case study. All RCU variants are based on a common hardware template, which includes a temperature sensor and a small as well as a large panel for optional extension with hardware modules. There are two small and two large hardware modules: The small modules (P: *Presence button* and M: *Manual presence slider*) offer different interaction mechanisms for manually indicating the presence of persons in the room. Module P contains a button that is pressed when entering the room, while module M contains a slidable presence switch that is usually used for a distinction between day and night mode. Each large module (S: *Set point temperature* and F: *Fan speed*) features a rotary switch. Module S allows a continuous adjustment of the temperature set point (usually with an offset of ±5K), while module F has five distinct levels for the fan speed.

Restrictions regarding the large panel are: Each module can only be used once and if the large panel is equipped, module S must be present. Furthermore, if module F is chosen, the small panel must not be empty. As can be seen, the panels cannot be considered independently from each other. In total, the RCU product family consists of eight product variants.

As can be seen from the green function blocks in Figure 4, the software for the product family has been modularized into four independent software modules: *tsens* (Temperature Sensor), *tctrl* (Temperature Control), *occup* (Occupancy), and *fctrl* (Fan Control). For simplification, the imaginary manufacturer of the RCU product family supplies each product variant with a uniform device application consisting of those four modules.

4.2. Comparison of semantic models

The comparison of different semantic modeling approaches will be presented using the example of the *tctrl* software module, since it offers a degree of complexity to illustrate issues when dealing

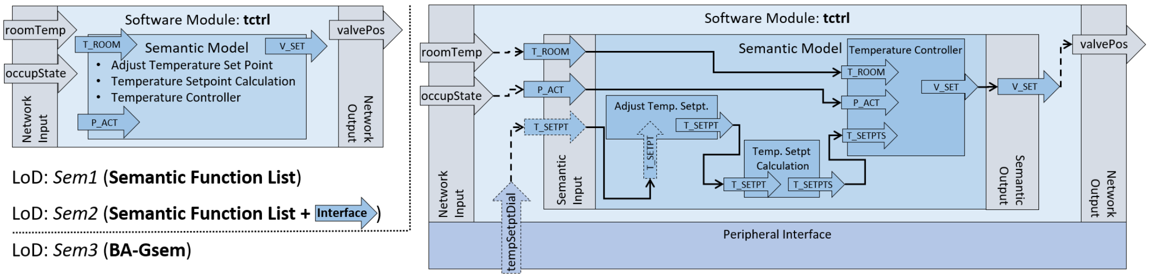

Figure 5. Comparison of Semantic Models with different level of detail (LoD)

with semantic component models. The *tctrl* software module implements a demand-based closed-loop temperature control for room temperature. The temperature controller computes a valve set point, which is transmitted from the software data point "valvePos" to a remote valve actuator using the communication network. The controller requires information about the current room temperature, the chosen temperature set point, and the current occupancy information, which is taken from both the network and the periphery: Network-wise, the room temperature and occupancy information are received by the software data points "roomTemp" and "occupState", respectively. Finally, the temperature set point is calculated from a base set point and a set point offset that can be adjusted using the temperature set point dial of hardware module S. To convert the electrical signal from the peripheral interface, a driver block "Adjust Temperature Set Point" is required. In order to keep the example concise, a simplified notion based on VDI 3813-2 [10] is used for specifying semantics. Usually, temperature control would also involve functionality like *energy mode selection* or *function selection*, which however do not add any relevant information for this case study.

For a validation of the capabilities of *BA-GSem*, different semantic models of the RCU software module *tctrl* have been created as a manual enrichment of the existing ontology component models [16] using the OWL ontology language [17]. They are presented for each LoD from *Sem1* to *Sem3*. Figure 5 depicts these three models: As a base line, model 1 depicted on the left (without the semantic data points in blue) is a semantic model consisting of a list of semantic functions. For semantic aspects, it achieves LoD *Sem1*. The second model is an extension by adding semantic interface information (i. e. data points of semantic model). Model 2 achieves LoD *Sem2*. On the right, the third model following the *BA-GSem* approach is depicted. It consists of a graph of semantic functions and thus achieves the highest ranking *Sem3* in terms of semantic LoD. Since all variants of the RCU product family are supplied with the same device application, implicit constraints on which software modules are usable for a specific variant arise. Variants that do not have the hardware module S cannot use software module *tctrl*, since the set point offset dial is required for a proper functioning of *tctrl*. This static constraint can be evaluated at time of device modeling without need for any context information.

Furthermore, *tctrl* is dependent on a presence information being available. Thus, variants without the P or M hardware modules need to be provided with a presence information from the network. This is a dynamic constraint that needs to be taken into account during step *T4* of the automated design process – it cannot be sufficiently evaluated during device modeling.

As can be seen from Figure 5, the function-list-based semantic models on the left are not sufficient to evaluate both static and dynamic constraints. The static constraint regarding hardware module S cannot be specified at all for both LoDs *Sem1* and *Sem2*. The dynamic constraint requiring an occupancy value is also not modeled appropriately. While the software interface features a data point for an occupancy state, it is not clear for *Sem1* if this information is evaluated by the semantic model and if *tctrl* is operational without a presence information. LoD *Sem2* specifies semantic interfaces, so it is sufficient to assess that presence information "P_ACT" is required, but not if *tctrl* is operational without "P_ACT".

In contrast, the semantic model of *BA-GSem* contains a sufficient level of detail for both constraints to be checked. In the static case, explicit modeling the peripheral interface reveals that the operational state of the semantic model depends on the availability of signals from the set point dial. For a dynamic evaluation of the occupancy constraint, it is explicitly modeled that the temperature controller is not operational without occupancy information.

In general, implicit constraints on provided functionality need to be detected and taken into account when modeling components. However, until now, functionality could not sufficiently be determined by analyzing the device software only, especially not in case of re-used uniform device applications. Using the detailed *BA-GSem* model, relevant constraints can be inferred, which allows to model modularized software components only once and without using error-prone copy-and-paste techniques. As a summary, providing additional levels of detail increases model quality and fosters the reduction of modeling errors induced by implicit constraints and inconsistencies amongst variants of product families.

5. Conclusion and Outlook

Smart building systems play a vital role for sustainable and smart cities in the future. However, the engineering of these building systems is a complex process, which still suffers from available products not being semantically modeled in sufficient detail. In this paper, we proposed *BA-GSem*, an enhanced graph-based semantic model for BA components. This model is part of a holistic perspective on component models, which also takes into account dependencies to hardware and software aspects. Thus, it is a foundation for capturing the real-world complexity of building automation product families, providing input for automated engineering algorithms. To this end, we used a realistic case study to discuss the influence of different model granularity on the steps of the typical engineering process.

Component manufacturers' expertise on product functionality and inner working mechanisms is a most valuable asset and allows for a high component model quality. The level of detail offered by *BA-GSem* implies that manufacturers need to invest more time and effort in modeling their products. While *BA-GSem* provides appropriate structures to capture this knowledge, further research should investigate, how the effort of model specification can be reduced and which quality assurance mechanisms can be put in place. To this end, we intend to provide tooling support for model specification. It is also conceivable to investigate an integration of this component model with already applied solutions for product information modeling as well as using the detailed information from the different model aspects for consistency checking. Finally, further research on how the levels of detail affect further engineering tasks is required to tap the full potential of automated engineering.

The practical use of module D in a building case study: assumptions, limitations and methodological issues

Laetitia Delem & Lisa Wastiels

Belgian Building Research Institute (BBRI-CSTC-WTCB), Brussels

laetitia.delem@bbri.be

Abstract. According to the EN 15804 and EN 15978, a material or building life cycle consists of three major life cycle stages or so-called modules: Production and Construction (module A), Use (module B) and End-of-life (module C). Potential benefits and loads occurring beyond the building's life cycle as a result of recycling, reuse or energy recovery can be declared in an additional module D. As part of the upcoming amendment of the EN 15804 a formula was developed to facilitate the calculation of module D. This paper provides a critical discussion on the practical use of module D. First of all, the development of the formula revealed specific methodological issues, such as the unequal approach to closed and open loop recycling. Secondly, the consideration of module D in a Belgian building LCA case study provided insights in the different methodological choices, interpretations, and assumptions related to the calculation of module D. This concerns for example the calculation of net output flows of secondary materials, modelling of avoided primary production, definition of the point of functional equivalence, efficiency of incineration, etc. Aspects that are not clearly specified in the standard and therefore can be open to interpretation are illustrated with concrete examples from the building case study. Where possible, recommendations for a harmonized approach are made. In any way, the results from the case study analysis reveal that the methodological choices can have a significant effect on the results and that module D results should therefore be considered with care.

1. Introduction

Probably one of the most controversial issues in building Life Cycle Analysis (LCA) is how to allocate impacts and benefits from recycling and energy recovery of materials at end-of life between the system (building (material) life cycle) that generates the secondary resources (output) and the one that uses them as input. According to the European standards for the environmental evaluation of buildings (EN 15978 [1]) and the environmental product declaration of building products (EN 15804 [2]), the system boundary between both systems shall be set where materials/fuels have reached their end-of-waste (EOW) state. This state is reached when the criteria derived from the European Waste Framework Directive are met (e.g. the recovered material is commonly used for specific purposes and fulfils the technical requirements for that purpose, a market demand exists, and its use will not lead to overall adverse environmental or human health impacts) [3]. All impacts occurring prior to EOW are attributed to the first product system and all impacts occurring after EOW are attributed to the next product system.

Consequently, the first life cycle benefits from the fact that the (demolition) waste is valorized as it does not have to carry the impact of waste disposal (landfill, incineration). The subsequent life cycle benefits from using secondary materials/fuels as it does not have to carry the impact from primary material extraction/production (which is fully attributed to the first life cycle), but only the impact from transport and further processing of the secondary materials after EOW.

Often the highest benefit from secondary material valorization is the avoided impact from substituted primary production. The reason why the European standards keep these avoided impacts outside the system boundaries of the system that generates the secondary output flow is that the uncertainty concerning the potentially avoided impact is very high, given the long life span of a building (e.g. energy mixes and production processes are very likely to evolve, and the demand for recycled products at the time of demolition is uncertain). Moreover, it would be unfair to credit "highly uncertain potential" benefits that will occur in a distant future against consumption today [4].

Nevertheless, information on the potential benefits from recycling, reuse and/or energy recovery of materials after the building life cycle could stimulate planning and design choices that facilitate greater valorization potential at the end of the use period. Therefore, the European standards provide rules to calculate this information and declare it as supplementary information "beyond" the building life cycle, in the so-called module D (modules A, B, and C represent the production stage, the use stage, and the end-of life stages of a building, respectively). Until now, this module was optional and therefore often not included in building (material) LCA. However, with the proposed amendment of the EN 15804+A1+prA2 [5] module D will very likely become mandatory.

2. Module D: the theory

Module D represents the potential benefits and loads from "net" output flows of materials for recycling (e.g. secondary materials), reuse or energy recovery (e.g. secondary fuels), but also from energy exported to the outside of the building system boundaries. The latter can be energy produced during waste disposal (incineration or landfill) of construction materials or energy generated on the building site (during the use-stage) that is exported for other uses (e.g. electricity produced by photovoltaic panels on the roof that is exported to the grid).

The potential benefits reported in module D represent the avoided impact from primary material production/extraction (which is substituted by the secondary materials) and avoided generation of primary energy (heat and/or electricity production substituted by the use of secondary fuels or energy exported from waste disposal and on-site energy production). The potential loads relate to the recycling and recovery processes occurring from beyond the system boundary (point of EOW) up to the point of functional equivalence, where the secondary material, fuel or exported energy substitutes primary production. If the output flow does not reach the functional equivalence of the substituted process a justified value-correction factor has to be applied. Both benefits and loads shall be calculated based on current average technology and practice. If information on current practice is lacking, a conservative approach shall be used [2].

The "net" output flow of materials for recycling or energy recovery represents the difference between the output flows of a specific secondary material or fuel leaving the system at EOW and the amount of this secondary material or fuel initially used as input during the production stage.

3. Objectives and methodology

The objective of the present paper is to provide a critical discussion on the practical implementation of module D based on the insights gained from (1) a Belgian building LCA case study including module D, (2) discussions with LCA experts, and (3) the translation of module D into a formulae as part of the latest amendment proposal of EN 15804+A1+prA2 [5]. The main issues handled in this paper relate to the identification of the point of functional equivalency, the calculation of net output flows and the potential benefits from avoided (primary) production.

3.1. Case study

The environmental performance of a 4-level multi-residential building, with 25 living units and a total net floor area of about 2000 m², was calculated using LCA. Different load bearing structures and material combinations were tested (e.g. wood-skeleton, concrete, cross-laminated timber, and sand-lime bricks) in order to evaluate how and whether results would be influenced by the construction mode. The LCA was performed with SimaPro, using generic data (ecoinvent v3.4, cut-off by classification), and end-of-life scenario's representative for Belgium [6]. More information on the case study, the results on the relative importance of module D on building level (compared to other life cycle modules) and the main materials contributing to module D are presented in a separate publication [7].

An additional goal of the case study was to get a better insight into the practical implementation of module D. For example, can the standard be applied univocally or is it open for interpretation? Is all necessary data readily available to perform the calculations? What kind of hypotheses need to be made? The main methodological issues that were identified through this practical implementation are discussed in the next sections.

4. Results: issues related to the calculation of module D

4.1. Net output flows

In module D, benefits and loads are calculated only for the resulting net output flows (= output minus input) of secondary materials or fuels. The reasoning behind this approach is that secondary materials used as input to the production stage (module A) do not have to carry the impact from primary material extraction/production (which is attributed to the previous life cycle). Consequently, as benefits are already taken into account in the production stage, they cannot be considered again in module D. Moreover, this approach intends to prevent that output flows of secondary materials would be considered to substitute primary materials in a next product system, when the next product system (which is supposed to be identical to the one that generated the waste) is already (partly) using secondary materials in reality. The principle of calculating net output flows is illustrated in **Figure 1**. Case 1 represents the "basic" situation where the secondary material on the input side and the output side are the same (e.g. steel scrap), and the quantity of secondary material at the output side is larger than at the input side.

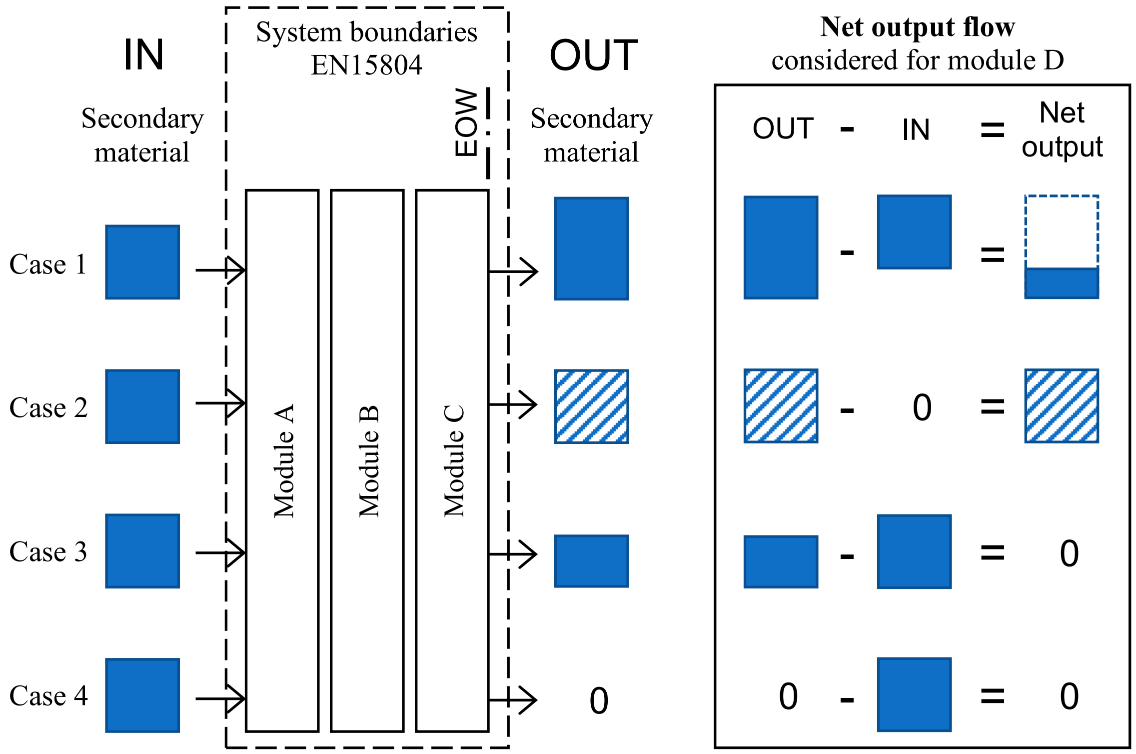

Figure 1. Conceptual representation for the determination of the net output flows depending on the type and quantity of secondary material at input and output side.

This approach for calculating net output flows can however only be applied in closed loop systems. Therefore it leads to an unequal treatment between open and closed loop recycling. Indeed, in open loop systems the secondary materials used as input (e.g. glass cullets for the production of glass wool insulation) are different from the secondary materials exiting the system (e.g. glass wool fibers that can be used as reinforcement for the production of composite materials). Therefore, the amount of secondary materials used as input cannot be subtracted from the output for the calculation of the net output flow (see **Figure 1**, case 2). Consequently, if the impact of the substituted primary material is of the same order of magnitude in open and closed loop recycling, this approach will tend to favor open loop recycling. Indeed, in open loop recycling the amount of net output flow considered for the calculation of module D will be higher since it is not reduced by the input flow of secondary materials.

Apart from clear open and closed loop recycling, there are also many cases where the calculation is open for interpretation. For example, crushed bricks are used as input for the production of a specific type of hollow bricks sold on the Belgian market. At end-of-life those bricks will probably follow the Belgian default scenario for inert waste, namely 95% of recycling into secondary granulates (e.g. for road construction). The nature of the input and output flows are essentially the same (crushed bricks). So in practice a net output flow could be calculated. Nevertheless, the substituted materials (clay in the first system and aggregates in the second system) are different. To our interpretation this should be treated as an open loop (as for case 2).

Another question that can be asked concerning the calculation of the net output flow is what to do in cases where the input of secondary materials is higher than the output (see **Figure 1**, case 3) and therefore the net output flow is negative? One approach would be to multiply the negative flow with the substituted impact from primary production, and therefore report net impacts rather than benefits in module D. However, materials with a recycled content that are disposed of at the end-of-life (e.g. landfill or incineration) could also be considered to have a negative output flow (output = 0, input > 0), but they do not have to report potential impacts from "not" recycling in module D (**Figure 1**, case 4). Moreover, negative output flows are in fact net input flows, while module D is intended to report net output flows of secondary materials (not net input). Therefore, the authors suggest that only positive output flows should be reported in module D.

Table 1. Loads and benefits reported in module D for 1 kg of concrete depending on the point of functional equivalence

Point of functional equivalence	Impacts reported in module D	Benefits reported in module D
OPTION 1 After crushing (recycling plant)	▪ None	▪ 1 kg limestone, crushed
OPTION 2 At (road) construction site	▪ No primary resource ▪ Transport of secondary aggregates to construction site *(30 kgkm by 16ton lorry, EURO5)*	▪ 1 kg Limestone, crushed ▪ Transport of primary aggregates to construction site *(100 kgkm by 16ton lorry, EURO 5)*
OPTION 3 At end-product level (gate of concrete plant)	▪ 1/X[a] m^3 of concrete made with . recycled aggregates (impact of the aggregates = 0 unless some additional crushing is needed) . 385 kg cement /m^3 concrete . 2.11 kg plasticizer /m^3 concrete ▪ Transport of secondary aggregates to concrete plant *(0 kgkm as recycling plant = concrete plant)*	▪ 1/X[a] m^3 of concrete made with . limestone crushed . 380 kg cement /m^3 concrete . 2.08 kg plasticizer /m^3 concrete ▪ Transport of crushed limestone to concrete plant *(100 kgkm by 16 ton lorry, EURO5)*

[a] With X = mass of secondary aggregates /m^3 of concrete

4.2. Point of functional equivalence

Potential loads and benefits reported in module D are calculated from EOW up to the point of functional equivalence where the secondary material/fuel/energy substitutes primary production [2]. Therefore, the determination of the point of the functional equivalence can have a major impact on the loads and benefits reported in module D. A first example is the case of inert materials (e.g. concrete). In Belgium, about 95% of concrete from demolition waste is recycled as aggregates, mainly for use in road construction. EOW is reached after crushing of the demolition waste (at the recycling plant). Once the concrete is crushed it can be used as infill for road construction instead of primary aggregates. For module D, the primary aggregates will thus represent the substituted primary production. However, the determination of the point of functional equivalence is open for discussion. A first option is to set it at the gate of the recycling plant. A second option is to set it at the construction site in order to account for the difference in transport between primary and recycled aggregates (**Table 1**). Indeed, there are many recycling plants in Belgium but only very few quarries. Therefore, primary aggregates are typically transported over larger distances than secondary aggregates. Consequently, although recycled and primary aggregates are technically "equivalent" for use in road construction, one could assume that they are only functionally equivalent once they have reached the new (road) construction site (see option2).

On the other hand, a third option is that the secondary aggregates are to be used as aggregates in concrete (instead of infill in roadbed construction). In this case the point of functional equivalence should be set at end-product level in order to account for variations in concrete mix (e.g. extra cement and superplasticizer) due to the (partial) replacement of primary aggregates by secondary aggregates (see Option 3 in **Table 1**). As can be seen from **Figure 2** the impact from the assumed additional use

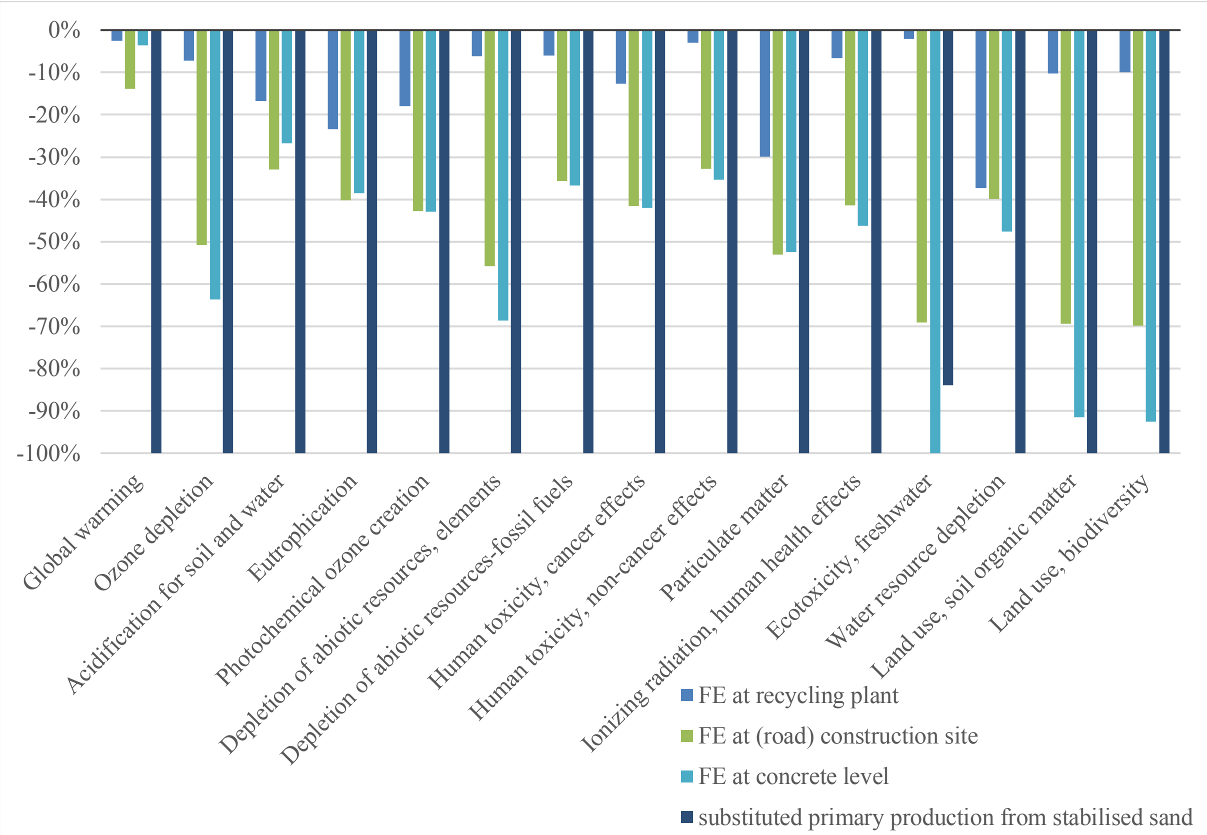

Figure 2. Impacts (net benefits) reported in Module D of concrete when recycled aggregates substitute crushed limestone and the point of functional equivalence (FE) is set at different levels, or when recycled aggregates substitute stabilised sand (MMG v1.05 LCIA model). [8]

of cement leads to a significantly lower net benefit for the impact category Global Warming Potential. Moreover, if the transport of secondary and primary aggregates were equally important, this option could even lead to a net impact instead of a benefit in module D.

Similarly, the case study showed that the outcome of module D of steel products varies significantly depending on whether the point of functional equivalence is set at intermediate product level (sorted steel scrap substitutes pig iron) or at product level (secondary steel substitutes primary steel) in order to account for the lower energy needed to produce steel from steel scrap (with an Electric Arc Furnace (EAF)) than from pig iron (with a Blast Oxygen Furnace (BOF)). Indeed, for most impact categories considered (**Figure 3**) the net benefits reported in module D are higher when the point of functional equivalence is set at the gate of the steel making process. These results are related to the lower energy demand from secondary steel production and in the case of Abiotic Depletion Potential - Elements the possibility to take into account not only the avoided impact from pig iron, but also from alloying elements contained in the steel. However, as the EAF and BOF use different energy mixes (EAF uses mainly electricity, BOF mainly fossil fuels) and produce different types of residues, substituting BOF production by EAF also leads to net impacts for some of the impact categories considered (Ionising Radiation, Ecotoxicity, Human Toxicity, Water Resource Depletion). The small net impacts observed for Abiotic Depletion Potential - Elements for the case where the functional equivalent is set at pig iron level can be explained by the fact that the impact from copper used for the sorting plant is higher than the reported benefit from the substituted pig iron. When the functional equivalent is set at steel level this impact is overruled by the additional benefit from the avoided production of alloying elements (e.g. molybdenite and ferrochromium).

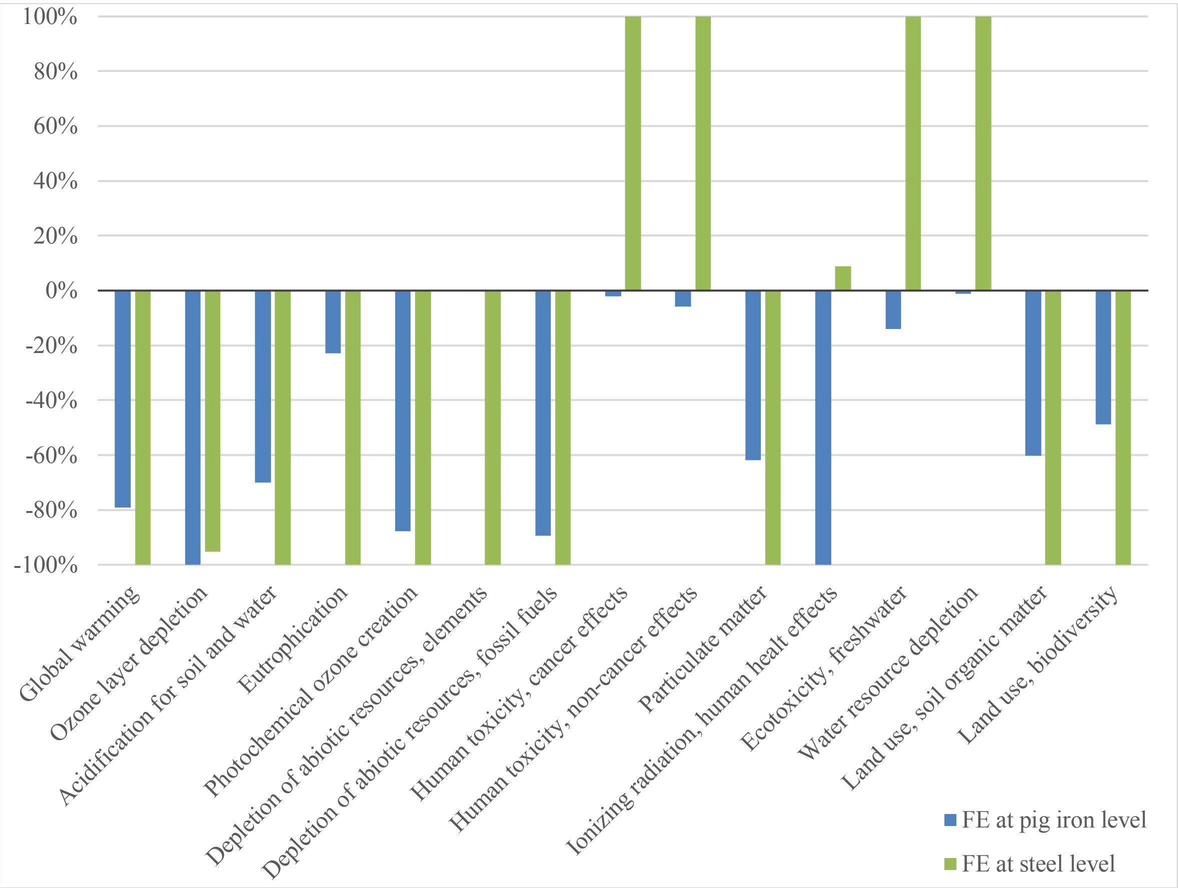

Figure 3. Comparison of module D for 1 kg low alloyed steel with functional equivalency (FE) set before (pig iron level) or after the steel making process (MMG v1.05 LCIA model). [8]

4.3. Avoided "primary" production

The primary production substituted by the use of secondary materials, fuels or exported energy determines which benefits are reported in module D. However, this primary production cannot always be determined univocally: it can be unclear what is actually substituted when the secondary material becomes part of common (usual) practice, the production process based on solely primary resources can be inexistent or the material might be recycled or reused unintentionally as an impurity.

A first example concerns secondary concrete aggregates. The net benefits calculated for module D of concrete in the previous section assumed that the secondary aggregates would substitute primary aggregates. However, in Belgian practice secondary aggregates are always used as infill for road constructions. So, there is some uncertainty related to what they really substitute. Some study suggests that secondary aggregates do not substitute primary aggregates in road construction but stabilized sand [9]. In that case the avoided impact (benefit) reported in module D would no longer be crushed limestone, but a mix of 90% sand and 10% cement. Seen the high impact of cement compared to aggregates, this hypothesis would result in significantly higher net benefits in module D (**Figure 2**).

In some cases, the use of secondary materials affects the production process, or 100% primary production does not exist and therefore needs to be determined artificially. This second example is related to "primary" steel production, where some steel scrap is still used in the BOF. Consequently, the life cycle inventory data of the BOF process have to be manipulated to obtain the (theoretical) impact from a 100% primary production [10]. This could be overcome by allowing the calculation of module D for closed loop systems to be based on the total output flow of secondary materials, provided that the assumed substituted production represents the current average production (with input of secondary materials). Loads reported in module D would in that case also be calculated for the full output flow and in practice this would lead to equivalent results as the net output flow approach with substituted primary production.

A third example concerns the material gypsum installed on inert material (e.g. bricks or concrete). According to the default Belgian scenarios [6], at EOL the gypsum will be crushed together with the inert materials to produce recycled aggregates. Therefore, one could argue that the gypsum (on inert material) substitutes primary aggregates. However, in reality the gypsum reduces the quality of the recycled aggregates and is only tolerated to a certain extent. Consequently, gypsum cannot be considered to be functionally equivalent to primary aggregates and to the author's opinion no benefit from substituted production should be reported in module D.

Finally, the calculation of module D becomes more complex when a waste fraction knows multiple applications (e.g. glass can be recycled as beads for sand-blasting, as secondary aggregates for roadworks, or used as input for glass wool production) and therefore multiple recycling routes have to be modelled and assumptions have to be made concerning the weight for each route. Moreover, although the standard only mentions the benefits from substituted "primary' production, the secondary materials can also substitute other secondary materials in an open loop system (e.g. recycled flat glass cannot only replace sand but also recycled consumption glass in the production of new glass products). Therefore, the benefits reported in module D can also represent the avoided impact from secondary production. This approach is reflected in the formula for module D included in the proposed amendment of the standard [5], which mentions the substituted primary material "or substituted average input material if primary material is not used".

5. Conclusions

"Module D recognises the "design for reuse, recycling and recovery" concept for buildings by indicating the potential benefits of avoided future use of primary materials and fuels while taking into account the loads associated with the recycling and recovery processes beyond the buildings life cycle" [2]. Until now the declaration of module D is optional so there is little experience with the calculation of module D at product or building level. Based on experiences gained from a Belgian building case study including module D as well as from the translation of module D into a formula as part of the EN 15804 amendment, several methodological issues were identified related to the practical implementation and significance of module D. In order to avoid double counting, the potential loads and benefits from secondary materials and fuels are only reported for the net output flows. However, as net output flows can only be calculated for closed loop recycling this leads to an unequal treatment between open and closed loop systems. Results from the study also indicate that assumptions regarding the point of functional equivalence and substituted (primary) production can have a significant impact on the results reported in module D. In addition, the substituted primary production may be difficult to assess when the use of secondary materials is part of the common practice and their use influences the production process. Moreover, in an open loop system, secondary materials/fuels can not only substitute primary materials/fuels but also other secondary materials/fuels.

Uncertainty concerning the potentially avoided impact is not only high because of all underlying assumptions, but also because energy mixes, production processes and demand for secondary materials/fuels are very likely to evolve over the long life span of the building. Consequently, results from module D should always (and especially in comparative LCA) be used with care and interpreted together with the underlying scenarios. Also, in order to avoid unequal treatment within product groups, product technical committees should be encouraged to provide, whenever possible, default scenarios for module D or at least guidance for the identification of the point of end-of-waste, the functional equivalence, and the substituted production.

6. Acknowledgements

This research has been made possible thanks to the Belgian federal agency (FOD economie) and the Belgian national standardization body (NBN) by funding the pre-normative research project "Methodological framework for LCA in the construction sector".

Abstract. With the current political focus on resource efficiency and circular economy, the consideration of all recycling aspects in LCA is becoming increasingly important, especially for metal products which are already recycled for many decades. For such purpose, a complementary module, the so-called Module D, was developed in EN15804 to report the additional environmental aspects resulting from the end of life stage. The metal industry and many LCA practitioners have already used this module for many years. This module D as well as module C (end of life stage) are now mandatory in the agreed amendments to EN15804 that will be published in 2019. This paper explains the methodology used by the metal industry to calculate modules A, C & D for a metal sheet in the light of the equation to be included in the amended EN15804. The calculation is then applied to 3 theoretical examples. Finally, the paper provides guidance on using LCI datasets developed by the steel and aluminium sectors. The collaborating authors have prepared this paper under the auspices of the METALS FOR BUILDINGS alliance that has been established to ensure reliable information on the sustainability of metal building products is available to policy makers and practitioners in sustainability appraisal policies and systems.

1. Introduction

Considering the growing concern regarding resource efficiency and the circular economy, recycling is seen as key enabler to move to a more sustainable European Union. In 2015, the European Commission adopted an ambitious Circular Economy Action Plan [1], which includes measures that will help stimulate Europe's transition towards a circular economy, boost global competitiveness, foster sustainable economic growth and generate new jobs. This action plan has been completed in 2018 by the publication of a circular economy package which includes a Monitoring Framework on progress towards a circular economy at EU and national level.

The waste framework directive [2] [3] is also targeting the building sector in a significant way, since article 11 requires that 70% of EU demolition waste shall be treated beyond 2020. Construction and Demolition Waste (CDW) represents about 30% of the waste flow produced in Europe. Hence, developing a legislation promoting good practices for construction and demolition waste is essential.

As part of its initiative of the single market for green products, the European Commission launched in 2013, the Product Environmental Footprint initiative which aims to harmonise the methodology of assessing environmental performances of products. This PEF methodology was tested during the pilot phase 2013-2018 and it enters now the transition phase where its potential transfer to product policies will be assessed. In particular for the building sector, the European Commission identified the need for closer alignment of CENTC350 standards to the PEF approach before they could be referred to in product policy. The amendment of EN15804, which defines the core rules for environmental product declarations, was a key milestone in this alignment process. The future amended EN 15804 will require calculation of end of life stage and environmental aspects of reuse, recycling and recovery in the context of the circular economy.

In the coming years, the Construction Product Regulation [4] will require in addition to technical information also environmental information related to building products when Basic Work Requirement 7 addressing the “sustainable use of natural resources” will be implemented in harmonised European standards.

All these legal and market developments show that it is of prime importance to properly consider the recycling aspects of building products when assessing life cycle environmental impacts.

2. Metals in buildings: key enabler to circularity

Metals are used in the building and construction sector for structures, reinforcements, cladding, roofing, window frames, plumbing, heating equipment and many other applications. Due to their high strength and high stiffness, metals can bear high loads, be used to reinforce other materials or can span great distances, allowing design freedom. Metal building products are weatherproof, seismic proof, corrosion resistant and immune to UV rays, ensuring a long service life. Most often, metal building products will satisfy the service life of the building itself.

In addition to their technical properties, metal products have also a unique characteristic which is their ability to be efficiently and economically reused or recycled without altering their properties. Already, today, more than 95% of the metal products used in buildings are collected at end-of-life. As an example, a study [5] performed on several demolition sites in Europe has demonstrated that more than 96% of the aluminium-content of these buildings was selectively collected and sent to recycling facilities. A survey carried out among UK demolition contractors [6] has shown that 99% of steel sections are recycled or reused.

High economic value is the main driver for the systematic dismantling, collection and recycling of metal products. As metal recycling provides energy savings of between 60% and 95% compared to primary production [7][8][16], depending on the metal and the metal-bearing product, metal recycling creates a win-win situation for both the environment and the economy.

3. Recycling in LCA and metals products

Today, two contrasting approaches are generally used to tackle recycling aspects: the recycled content approach [100:0] and the end of life recycling approach [0:100].

On one hand, the recycled content approach [100:0] uses a cut-off approach, which only considers the recycled material in the mass fraction of the product issued from recycling. This approach neglects the recycling performances of the product at the end of its life stage. Even though the end of life recycling rate of metal building products is usually high, e.g. around 90%-95%, the average recycled content in metal products does not reach such a level on a global scale. In reality, the recycled content is currently limited by the scrap availability which is the bottle neck of the metal supply from recycled sources. The growth in the use of metals over many years, and the fact that metal building products have a service life of decades, creates a shortage of available metal scrap that has to be supplemented using primary metals to satisfy demand. As an example, the crude steel production in Europe for the year 2017 [9], excluding imports, was 168,1 million tonnes, from which about 93,35 million tonnes were coming from scrap, i.e. from recycling. This shows that on average about 55% of the steel supply comes from recycled steel scrap. Thus, the recycled content metric alone is not adequate to reflect and integrate the recycling performances of metal products in an EPD.

On the other hand, the End-of-Life (EoL) recycling approach [0:100] considers the recycling rate of the studied product as the relevant parameter for tackling the environmental aspects of recycling. For metal products, the recycling rate corresponds to the actual amount of metals obtained from recycling with the amount of metal initially available within the product. The metal industry considers that this end of life recycling approach is the most relevant for metal products in order to maximise and preserve metal availability for future generations as explained in the common Metals Declaration on Recycling [10], published in 2006. This end of life recycling approach is also accepted in the scientific community as UNEP [11] and ILCD [12]. Under PEF, the circular footprint formula considers a contribution of the end of life recycling parameter for metals which is four times more relevant than the recycled content. This ratio demonstrates the higher relevance of the recycling rate metric for metals.

4. Recycling in EN15804: the hybrid approach

The cut-off approach was chosen for the Module A (production), Module B (use) and Module C (End of life stage) of EN15804 [13] meaning that the recycling benefits of building products at end of life cannot be reported in those modules. An additional module, the so-called 'module D', was therefore needed for transparently reporting the additional benefits which result from the recycling or energy recovery at the end of life of the building product. For closed material loop recycling, as in the case of metals, Module D avoids any double crediting or counting since only the net benefits of recycling are reported based on the net flow, i.e. the secondary material exiting the system boundary at the end of life minus the secondary material already considered at the production stage. Module D is not restricted to metal scrap, as it allows reporting the environmental aspects from the net flow resulting from any secondary material or secondary fuel entering and exiting the product system boundary. Description of an exemplative metal sheet case

Fig.1 gives an example of one possible scenario for a metal sheet. It provides the various flows of scrap, metal semi-finished product and product as well as the main processes included in the system boundaries of the various modules. In this example, it is assumed that the unit of analysis is 1 kg of metal sheet with a recycled content of 40%, i.e. 0,4 kg of metal sheet came from recycling, while the recycling rate at end of life corresponds to 90%, i.e. 0,9 kg of recycled metal is produced at end of life. In such a case, Module D shall calculate the environmental benefits resulting from the production of 0,5 kg of recycled metal, i.e. the net difference between both recycled quantities. The next sections explain how the equation reported in Annex D of the new EN15804 shall be interpreted and used to reflect this example and the associated flow sheet.

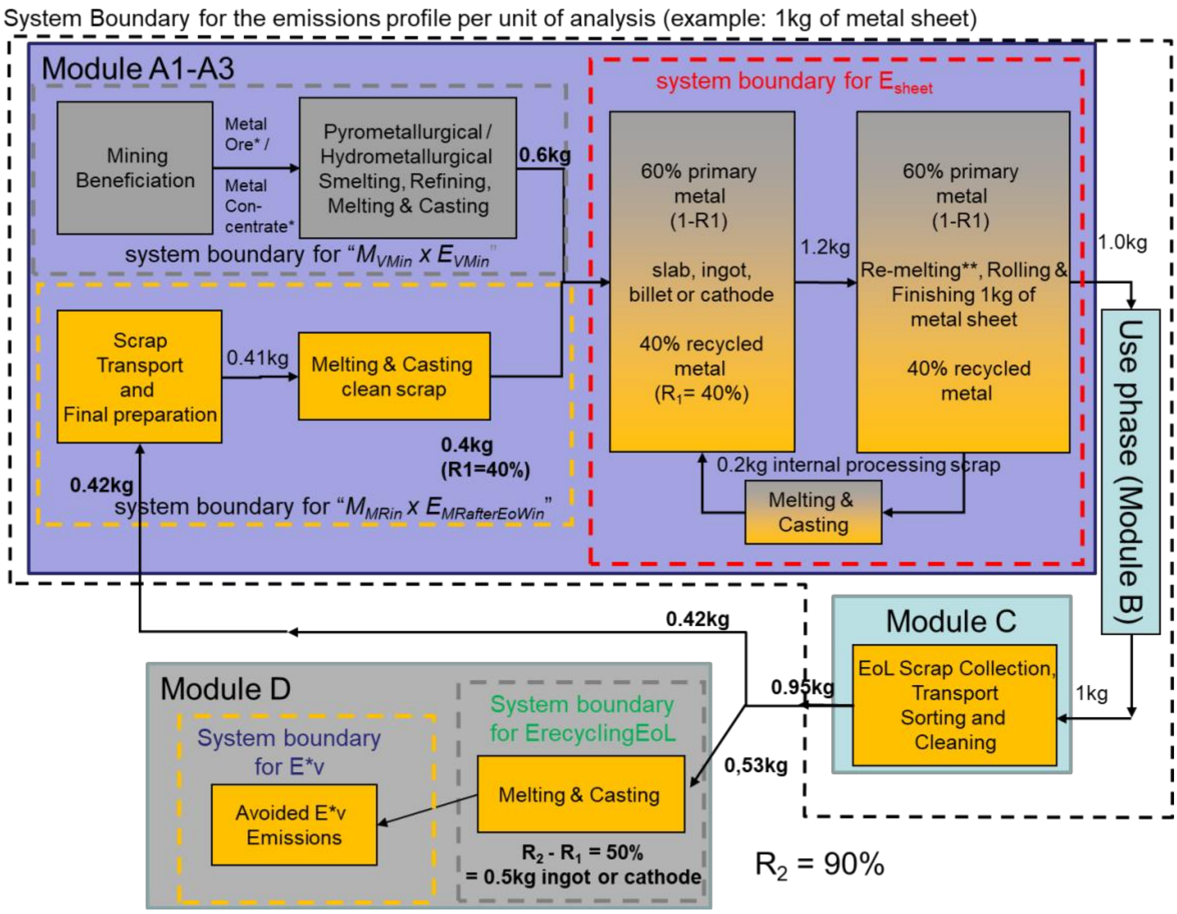

Fig. 1: Illustrative example of a flow diagram for a metal sheet

4.1. Module A1-A3

The applicable formula for the calculation of the emissions and resources consumed related to material resources and energy per unit of analysis for module A is the following:

$$e_{module\ A} = e_{PE} + M_{VM\ in} \cdot E_{VM\ in} + M_{MR\ in} \cdot E_{MR\ after\ EoW\ in} + M_{ER\ in} \cdot E_{ER\ after\ EoW\ in}$$

Where the first term covers the impacts related to primary energy inputs, the second term covers the impacts related to material primary inputs; the third term covers the impacts related to recovered material (recycled and reused) inputs from previous products and the last term covers the impacts related to use of secondary fuels. All terms are calculated per unit of analysis. For metal products, the second and third terms are the 2 most relevant ones.

$M_{MR\ in}$ represents the metal scrap input to the product system at the production stage. In our example, it corresponds to 0,42 kg of metal scrap entering the production stage. After a possible final cleaning and treatment operation, this scrap flow is melted, purified and casted in order to produce a metal ingot. These operations generate small metal losses so that the mass of the recycled ingot is slightly lower than the mass of metal scrap entering the system, i.e. 0,4 kg of recycled ingot in the example. This recycled ingot then needs to be converted into a metal sheet. Hence, "$M_{MR\ in} \cdot E_{MR\ after\ EoW\ in}$" shall cover the specific emissions and resources for producing 0,4 kg of metal sheet issued from recycling. Similarly, "$M_{VM\ in} \cdot E_{VM\ in}$" represents the specific emissions and resources for producing 0,6 kg of metal sheet issued from primary resources.

In practice, the point of substitution, i.e. the location in the production chain where recycled metal substitutes primary metal, is usually at the ingot level or cathode level for the specific case of copper [16]. Hence, often, the LCI datasets developed by the metal industry cover the primary processes or recycling processes up to the ingot level. The manufacturing of the metal sheet from the ingot can then be covered either by a separate LCI dataset (i.e. see aluminium LCI datasets) or aggregated with the ingot production (see steel LCI datasets). In the case of separate LCI datasets, the equation for "Module A1-A3" can be adapted for metal sheet as follows:

$$e_{module\ A} = (1 - R_1) \cdot E_v + R_1 \cdot E_{recycled} + E_{sheet} \text{ where:}$$

- R_1 percentage of recycled content of the metal sheet, i.e. fraction of metal issued from recycling
- E_v specific emissions and resources consumed per unit of analysis arising from acquisition and pre-processing of primary metal in the production of the metal ingot or cathode.
- $E_{recycled}$ specific emissions and resources consumed per unit of analysis arising from sorted metal scrap recycling of the previous system into metal ingot or cathode.
- E_{sheet} specific emissions and resources consumed per unit of analysis arising from the transformation of the metal ingot/cathode into the metal sheet.

For the module A1-A3 calculation, 60% of the metal supply is issued from primary metal and 40% from recycling. Hence, the equation can be simplified as follows for the exemplative case.

$$e_{module\ A} = 0{,}6 \cdot E_v + 0{,}4 \cdot E_{recycled} + E_{sheet}$$

The sheet manufacturing from the metal ingot generates some internal scrap which is re-melted but does not increase the recycled content in the LCA model of the overall product, since the recycled content has already been 'fixed' in the slab production process, and the subsequent scrap generated is an internal flow in the overall product system model.

4.2. Module C

The applicable formula for the calculation of the emissions and resources consumed per unit of analysis for module C is the following:

$$e_{module\ C} = M_{MR\ out} \cdot E_{MR\ before\ EoW\ out} + M_{ER\ out} \cdot E_{ER\ before\ EoW\ out} + M_{INC\ out} \cdot E_{INC} + M_{LF} \cdot E_{LF}$$

For metal sheets, the first term is the most significant since it is almost entirely collected and directed to recycling. At end of life, metal sheets are dismantled and specifically collected for recycling. These operations take place under module C1. The collected metal sheet is directed to specialised companies for shredding and sorting (module C3). In the context of EN15804, it can be considered as most appropriate that sorted metal scrap leave the system boundary and are addressed in Module D. It should be noted that there is no full harmonisation among the European countries regarding the application of the "End of Waste" status to metal scrap. Hence, from a legal perspective, the official "end of waste" status may be located at a different point in the recycling value chain.

In our exemplative case, it will be assumed that 99% of the metal sheet is collected and directed to the scrap preparation treatment from which 0,95 kg of sorted scrap is generated and directed for recycling. Hence, 0,95 kg of sorted scrap exits the product system from module C3. Only a tiny fraction can end up in landfilling from the scrap preparation operations.

4.3. Module D

As described in section 6.4.3.3 of EN15804, Module D aims at assessing the benefits and loads resulting from the net flow of secondary fuels or materials exiting the product system. The environmental aspects of these flows are assessed through system expansion using the so-called "substitution methodology" or "avoided impact" methodology. In such methodology, the secondary material needs to be processed up to the point of functional equivalence where substitution of primary material takes place. In the case of metal sheet, the point of equivalence is the ingot or the cathode for copper. Hence, module D calculation needs to consider on one side the burdens of the recycling processes up to the ingot or cathode level while the benefits are calculated by the burdens of primary metal which is effectively saved. If needed, a correction factor may be applied when full substitution cannot take place, i.e. when properties are not maintained through recycling.

For metal sheet, the applicable formula for the calculation of the loads and benefits beyond the system boundary per unit of output calculated for each output flow leaving the system boundary can be restricted to Module D1 related to secondary materials for recycling: For the metal sheet case, only one metal is considered. Hence the indice "i" is not necessary. A as result, the equation can be simplified as follows:

$$e_{module\ D1} = (M_{MR\ out} - M_{MR\ in})\left(E_{MR\ after\ EoW\ out} - E_{VMSub\ out.} \cdot \frac{Q_{R\ out}}{Q_{Sub}}\right)$$

- "$M_{MR\ out}$" is the quantity of sorted scrap exiting the product system, i.e. 0,95 kg in the example.
- "$M_{MR\ in}$" is the quantity of sorted scrap entering product system, i.e. 0,42 kg in the example.
- "$M_{MR\ out} - M_{MR\ in}$" represents the net quantity of sorted scrap generated by the product system, i.e. 0,53 kg of scrap.
- $E_{MR\ after\ EoW\ out}$ corresponds to the specific emissions and resources arising from the recycling at end of life of the sorted scrap up to the ingot. For the metal sheet case, it will be called $E_{RecyclingEoL}$.
- $E_{VMSub\ out}$ is specific emissions and resources consumed per unit of analysis arising from acquisition and pre-processing of the primary material from cradle to the ingot. For the metal sheet case, it will be called E_v^*.
- $\frac{Q_{R\ out}}{Q_{Sub}}$ is the quality factor between recycled ingot and primary ingot. For metals, the properties are restored through re-melting.. In the building market, only a limited number of metal alloys or grades are used. In addition, collection and scrap preparation routes from end of life metal building products are well developed. These routes generate high quality scrap with low level of contamination. Hence, it can be assumed that recycled metal is of equivalent quality as the primary metal, i.e. that the quality factor is equal to one.

For the metal sheet case, the net quantity of scrap can be substituted by the difference between the recycled metal at end of life and the recycled metal content at production, i.e. (R2 - R1) *1kg = (0,9 – 0,4)*1kg =0,5 kg under the condition that $E_{RecyclingEoL}$ and E_v^* use the mass of produced ingot or cathode as the reference flow, i.e. the process output, and not the scrap input as a reference flow. This assumption will be used for the 3 fictitious examples so that the equation is simplified as follows:

$$e_{module\ D1} = (R_2 - R_1) \cdot (E_{recyclingEoL} - E_v^*) = 0{,}5 \cdot (E_{recyclinEoL} - E_v^*)$$

5. Calculation for 3 theoretical examples

The first example (Product "P1") considers the metal sheet case as described in the previous section, using a recycled content of 40% and an end of life recycling rate of 90%. The second example (Product "P2") considers a generic product, not necessarily a metal product, which is produced mostly from secondary materials (R_1 =80%) but which is not efficiently recycled in closed loop at end of life, i.e. R_2 = 40%. Finally, the third example (Product "P3") corresponds to a product made 80% of recycled material and which is recycled at 80% at end of life according to two scenarios, either in pure closed loop (scenario A) or in an open loop recycling with downcycling (scenario B).

Table I reports fictitious figures expressed in "Units of Indicator" [UoI] for the various processes listed for the previous simplified equations as well as the corresponding results for Module A1-A3, Module C and Module D. For Module C, only the sub-modules C3 and C4 play a differentiating role in the 2 scenarios of P3. Hence, only these 2 sub-modules are addressed in Table I

Table 1: equation parameters and [Unit of Indicators] for the 3 theoretical product examples

Parameters and process	Module A				Module C		Module D		
	R_1	E_v	$E_{recycled}$	E_{sheet}	C3	C4	R_2	$E_{recylingEoL}$	E_v^*
Unit	%	[UoI]	[UoI]	[UoI]	[UoI]	[UoI]	%	[UoI]	[UoI]
P1	40%	40	10	5	2	1	90%	10	40
P2	80%	40	10	5	2	3	40%	10	40
P3 - scenario A - closed loop	80%	30	20	0	4	1	80%	20	30
P3 - scenario B - open loop	80%	30	20	0	2	1	80%	5	10

*R_1 is not considered for the net flow calculation of module D as allowed in EN15804

**R_1 is considered for the net flow calculation of module D as recommended in ISO14044

P1 - Assuming values of 40 [UoI] for the primary production of 1 kg of ingot, 10 [UoI] for the production of recycled ingot from sorted scrap and 5 [UoI] for the transformation of 1 kg of ingot into sheet, the module A equation gives a result of 33 [UoI] for module A1 to A3 for 1 kg of metal sheet. Module C does not contribute significantly to the overall results. It is assumed that the scrap preparation of 0,95 kg of sorted scrap (module C3) contributes for 2 [UoI]. Landfilling contributes for 1 [UoI]. For the calculation of module D, similarly to the production phase, it is assumed that the recycling of sorted end of life scrap into 1 kg of ingot generates 10 [UoI] and the avoided primary production of 1 kg of metal ingot corresponds to 40 [UoI]. This provides a complementary result of -15 [UoI] for Module D reflecting the additional benefits resulting from the end of life recycling.

P2 –The same [UoI] figures are assumed as for P1, except for Module C, for which the contribution of landfilling is higher than for P1 considering the higher fraction going to landfilling. A value of 3 [UoI] is used for the landfilling impact. The Module A calculation provides 21 [UoI]. It is lower than for P1 due to the higher recycled content. The calculation of Module D provides a positive [UoI] due to a negative net flow of secondary materials entering Module D. The consumption of 40 % of recycled material generates then an additional impact of 12 [UoI] for module D.
Comparing P1 and P2 results, P2 appears as a better when using the recycled content approach, i.e. Module A + Module C, providing 26 [UoI] for P2 against 36 [UoI] for P1. However, from a full life cycle perspective which considers as well the additional benefits from end of life, the conclusions are reversed, i.e. 21 [UoI] for P1 against 36 [UoI] for P2. This shows the importance to consider Module D in the product assessment. It should be noted that EN15804 does not allow aggregation of results across modules. Hence, this aggregation is done for the sake of illustration and explanation but is not according to EN15804.

P3- For the sake of simplicity, E_{sheet} is not considered in this example (i.e. E_{sheet} = 0 [UoI]). For the closed loop case (scenario A), it is assumed that $E_{recycled}$ and $E_{recyclingEoL}$ are identical and correspond to 20 [UoI] while E_v and E_v^* are also the same processes and correspond both to 30 [UoI]. For module C3, i.e. preparation for recycling, a figure of 4 [UoI] is assumed.

For the open loop recycling with downcycling (scenario B), it can be assumed that ErecyclingEoL is less impacting than the closed loop case, i.e. a value of 5 [UoI] is used. Similarly, Ev* is also smaller since the substituted primary material is of lower quality/performances in case of downcycling than in case of closed loop recycling. A figure of 10 [UoI] is used for Ev*. For module C3, the preparation for recycling is less demanding than in case of closed loop recycling. Hence, 2 [UoI] is chosen for C3. For Module A, the calculation gives a figure of 22 [UoI]. For Module C, scenario A gives 5 [UoI] while the open loop with downcycling (scenario B) gives 2 [UoI]. Without considering Module D, the results for Modules A and C provide a lower impact to the open loop recycling with downcycling (scenario B) in comparison to the closed loop. In such a case, not considering Module D, will clearly lead to misleading choices which are against the most environmentally sound end of life practices.

In case of closed loop recycling (Scenario A), the module D is equal to 0 [UoI]. In absence of any recycled materials generated or consumed by the product system, a value of 0 [UoI] is indeed calculated for module D. In such a case, there is indeed no discrepancy between the recycled content and the end of recycling rate.

In case of open loop recycling (scenario B), it can be assumed that the secondary materials entering the system are not similar to those exiting the system. Hence, a net flow calculation via a direct deduction does not make sense. In such a case, the current formulation requires to calculate the net flows only for the secondary materials exiting the system. This means that the secondary materials entering the product system can be neglected in the calculation of Module D if its characteristics are significantly different from the characteristics of the secondary materials exiting the product system.

In the case of Scenario B-1, the entering flow of secondary materials has been neglected. This gives a benefit of - 4 [UoI] which results from a double crediting of the recycling benefits from the recycled content at production and from open loop recycling at end of life. From a calculation perspective, this open-loop recycling scenario B1 appears then as the most relevant for reducing the overall impact of the product life cycle while in reality, it is not the case, since the closed loop recycling provides better environmental results. The current lack of requirements to address all entering flows of secondary materials and fuels generate then results which can be misleading and which create discrimination against closed loop recycling vs. open loop.

In the case of scenario B-2, the calculation is corrected and the benefits from the recycled content are considered, leading to a result to +4 [UoI] for module D reflecting the effective downcycling at end of life. In other words, the product system consumes high quality secondary materials at production stage without generating them back at end of life. This second calculation shall be systematically used for Module D to properly reflect the additional contribution (benefits or burdens) of the end of life stage to the product life cycle assessment and to avoid misleading calculation wrongly promoting downcycling. The equation should then be adapted accordingly in any future revision of EN 15804.

6. Using datasets developed by the metal sector

Table 2 reports the LCI datasets which can be used in the context of EN15804 and building applications. Further explanations are then given for the 2 metal cases: Aluminium and steel.

Table 2. Aluminium and steel LCI datasets for use in EN15804

Module	Formula in EN 15804	Metal datasets corresponding to EN 15804 formula terms assuming 1kg sheet product	
		Aluminium	Steel
A	$M_{VM\,in} \cdot E_{VM\,in}$ + $M_{MR\,in} \cdot E_{MR\,after\,EoW\,in}$	R_1 x [wrought ingot from pre-consumer scrap or clean post-consumer scrap] + (1-R_1) x [primary ingot produced (or used) in Europe - cradle to gate] + [sheet produced from wrought ingot]	Aggregated cradle to gate LCI for 1kg steel sheet containing recycled and primary steel e.g. "Cold rolled coil" or "Continuous Hot Dip Galvanised coil"
D	$(M_{MR\,out} - M_{MR\,in})\left(E_{MR\,after\,EoW\,out} - E_{VMSub\,out} \cdot \frac{Q_{R\,out}}{Q_{Sub}}\right)$	(R_2-R_1) * ([ingot from post-consumer scrap] - [primary ingot produced (or used) in Europe - cradle to gate])	$(M_{MR\,out} - M_{MR\,in})$ * [Value of scrap LCI], i.e. LCI result using 100% scrap based EAF slab minus theoretical 100% primary slab.

6.1. Aluminium sheet

Every 5 years, *European Aluminium* develops average datasets representative for the European production or market. The latest datasets published in Feb 2018 refer to data collected for the year 2015 [8]. The datasets listed in Table 2 are included in this report, i.e.

- [primary ingot produced in Europe - cradle to gate] (A) corresponds to the production of 1 tonne of ingot from primary aluminium, i.e. from bauxite mining up to the sawn aluminium ingot ready for delivery. This dataset includes all the environmental aspects of the various process steps and raw materials used to deliver 1 tonne of sawn primary ingot produced by the European smelters.
- [primary ingot used in Europe - cradle to gate] (B) is similar to the previous dataset but considers as well the primary aluminium which is imported into Europe and which represent 49% of the primary aluminium used in Europe in 2015. Global data from the International Aluminium institute [14] have been used for modelling the primary aluminium produced outside Europe.

  If the use of average European LCI datasets is appropriate, these two datasets can be used for assessing E_v or E_v^*. The choice between both datasets should then be based on the sourcing of the primary aluminium. In case of evidence of domestic European production, the dataset (A) should be used. If not, the dataset (B) should be used.
- [sheet produced from wrought ingot] This dataset corresponds to the transformation of a sawn aluminium ingot into a sheet ready for delivery to the user. This dataset includes the recycling of the scrap and chips generated during the sheet production stage and corresponds to the production of 1 tonne of aluminium sheet. This dataset can be used to assess E_{sheet}
- [wrought ingot from pre-consumer scrap or clean post-consumer scrap] corresponds to the production of 1 tonne of recycled wrought ingot, i.e. slabs or billet, from process scrap or clean sorted post-consumer aluminium scrap like big aluminium pieces in the building sector or aluminium beverage cans collected through specific collection networks.
- [ingot from post-consumer scrap] corresponds to the production of 1 tonne of casting ingot from pre- or post-consumer scrap

6.2. Steel sheet

The World Steel Association, *worldsteel*, provide global and regional average data for up to 16 different semi-finished steel products [15]. The *worldsteel* modelling approach employs vertical averaging incorporating the slab and sheet production emissions specific to the individual product supply chains. For this reason, it is not necessary to split the data into slab and sheet, since the datasets already correspond to the result of:

$$(1 - R_1) \cdot E_v + R_1 \cdot \ E_{recycled} + E_{sheet}$$

The construction related sheet LCI products available, depending on the region, include: plate, hot rolled coil, cold rolled coil, hot dip galvanised, organic coated coil, and welded tube. Long products, such as sections and rebar are also available, similarly including further rolling and processing as for sheet production. The value for R1 is specific to the product supply chain and steel production process and provided in the datasets as a scrap input flow (external scrap). This excludes scrap recycled internally within the product supply chain and any re-melting losses, and so is no equivalent to the recycled content as such. The scrap input flow can be used to calculate the net scrap flow to avoid double accounting in Module D.

Due to the fact that all steel slab production includes some scrap, it is necessary to make a theoretical 100% primary slab without any scrap input. This has been modelled and calculated by worldsteel and is used with the corresponding 100% secondary slab to calculate the net environmental benefit of recycling 1kg of pre and post-consumer scrap, called the ['Value of scrap' LCI]. A yield factor is used to account for any scrap input or output that is lost during the re-melting due to the presence of non-target material in the scrap and metallic re-melting losses in e.g. fume dust. This means that the EN 15804 formula for Module D can be directly applied since on one side $(M_{MR\ out} - M_{MR\ in})$ corresponds to the next flow of scrap generated by the product system and on the other side $\left(E_{MR\ after\ EoW\ out} - E_{VMSub\ out.} \cdot \frac{Q_{R\ out}}{Q_{Sub}}\right)$ corresponds to ['Value of scrap' LCI],

i.e. = $yield \cdot \left(100\%\ secondary\ slab - 100\%\ theoretical\ primary\ slab \cdot \frac{1}{1}\right)$

Module D = $(M_{MR\ out} - M_{MR\ in})$ * ['Value of scrap' LCI]

7. Conclusion

In 2016, the European Commission requested an amendment to EN 15804 in order to ensure a convergence with the Environmental Footprint methodology, and in particular to make mandatory Modules C and D, which address the end of life stage. This development will bring renewed focus on recycling aspects of construction materials, which is an important aspect if the construction industry is to reduce waste, increase resource efficiency and become more circular. This paper shows the importance of considering the quantity and quality of recycling at end of life, and why the only focus on recycled content is insufficient. End of life recycling is not only relevant for metals, due to the increasing demand for materials and a limited supply of available secondary materials, but also other materials. The new proposed formula for Module D in the future amended EN 15804 has been applied to a series of 3 examples, to demonstrate the way both recycled content and end of life recycling are reconciled in a hybrid approach, thus ensuring a full picture of circularity over the lifecycle. The paper also highlights potential pitfalls in the interpretation of the wording of EN 15804, and so users of the standards should play particular attention to situations where net losses of valuable material resources from the system occur, or where changes in the quality of materials take place. This is important in order to avoiding double accounting recycling benefits at the beginning and end of the lifecycle, especially in open loop recycling situations. The paper also offers guidance to users in applying the available steel or aluminium average LCI datasets for the calculation of Modules A1-A3 and Module D.

Abstract. Increasing energy efficiency and related environmental performance improvements of buildings direct stronger focus on the environmental impacts related to building products. For product manufacturers, the provision of information in terms of environmental product declarations (EPD) is a market tool of continuously rising importance.
The increasing concern related to environmental and resource efficiency promotes the concept of circular economy, especially reuse and recycling procedures at the end-of-life (EoL) play an increasing role in decision making. Manufacturers are often unsure how to include late life cycle stages in their product declarations. At the same time users of the information are confused as to what provided information really refers to.
The concept of modular EoL-declarations with clearly identified and described scenarios aims to facilitate the inclusion of the full life cycle in EPDs based on reliable and realistic data. At the same time EoL-declarations promote the communication between the production and EoL-actors and enhance understanding of provided information, including judgements on potential demand and procedures for adaptation of provided information.

1. Introduction

Buildings account for 36% of global final energy consumption and nearly 40% of total carbon emissions [1] [2]. Construction and demolition waste accounts for 25 to 30% of all waste generated in the EU [3] an equally large share of the overall figures. The savings potential in the building sector is therefore considered to be high, according to government and industry.

In recent years, certification systems for sustainable buildings have been established, including DGNB (Deutsche Gesellschaft für Nachhaltiges Bauen e.V.) [4] and LEED (Leadership in Energy and Environmental Design) [5], providing a framework for improving sustainability in the construction sector. Within these certification schemes, a building Life Cycle Assessment (LCA) can be conducted as a means to evaluate the environmental performance of the building over its life cycle. To enable the architect or planer to calculate such a building LCA, it is essential to have access to environmental information for specific construction products. The concept of Environmental Product Declaration (EPD) in accordance with EN 15804 [6] has been established as an important instrument for declaring and communicating the environmental performance of the different building products in the context of a building LCA.

Furthermore, product manufacturers use EPDs in order to communicate environmental product information both internally and externally. With the increasing recognition of resource efficiency, end-of-life information is becoming more frequently requested and provided, leading to the clear demand to strengthen common practice in providing and applying such information.

2. Environmental Product Declaration (EPD)

An EPD is a document that communicates verifiable, accurate, non-misleading environmental information about products and their applications, thereby supporting scientifically based, fair choices and stimulating the potential for market-driven continuous environmental improvement. The results of a life cycle assessment (LCA) in accordance with ISO 14040/44 [7] [8] are declared in an EPD as impact (category) indicators, such as: global warming potential, acidification potential, primary energy and water consumption.

EPD information is expressed in life cycle stages and subdivided into information modules, which facilitates a coherent structure and expression of data packages throughout the life cycle of the product [6]. The modular structure groups significant life cycle stages into product stage (A1-A3), delivery and installation in the construction stage (A4-A5), use stage (B1-B7) and end of life stage (C1-C4). Additionally, benefits and loads from, for example, recycling or thermal treatment, can optionally be declared in module D. Figure 1 gives an overview of the stages and modules covered by an EPD according to EN15804 [6].

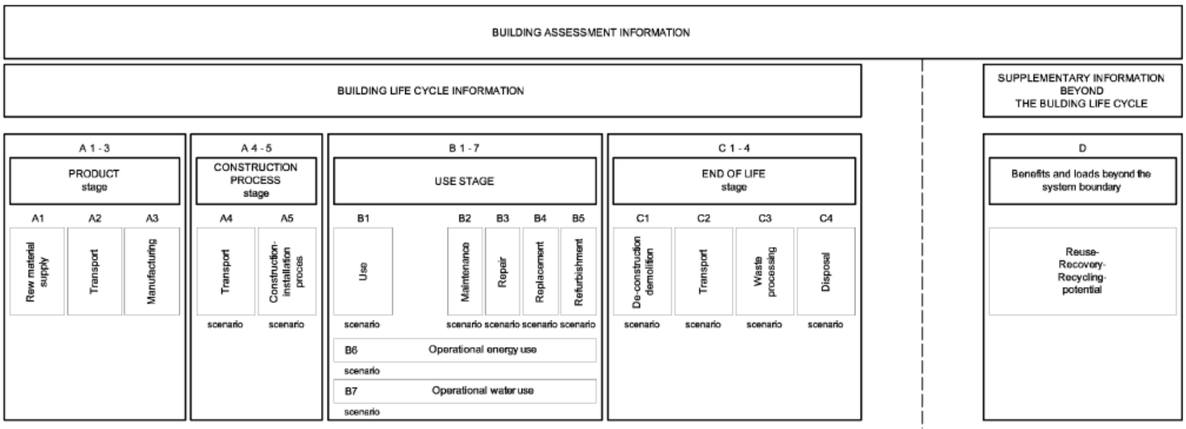

Figure 1 Life cycle stages and modules according to EN 15804

Today, most EPDs focus on the production stage (modules A1-A3 according to EN 15804 – "cradle to gate"); the subsequent modules are included less frequently. Frequently mentioned reasons for focusing on the initial life cycle stages include aspects such as the manufacturers direct involvement and responsibility through to the hesitance to include scenario-based information about later life cycle stages in a declaration for which the manufactures may be held liable. The declared environmental product performance may as well depend significantly on aspects well outside the influence of the manufacturer. Instead user-related aspects (e.g. frequency of product application) or contextual systems (e.g. changes in the energy supply system, or technologies being replaced in situations of changing demand) may have a significant or even decisive influence on the declared information. Consequently, the content of such an EPD may vary between scenarios.

While the loss of the generic value of the presented information may be considered a drawback, scenario-based information can also strengthen the quality of the information provided in an EPD, as the information may be adapted to case-specific boundary conditions, and scenario parameter variations may demonstrate the dependency and sensitivity of declared information to selected parameters.

3. Scenarios in Environmental Product Declarations

One way to declare the subsequent life cycle stages to A1-A3 in an EPD is to use a scenario. Scenarios support the calculation of information modules covering processes that deal with any one or all of the life cycle stages of the construction product, including the end-of-life. In order to define such a scenario, EN 15804 does not give further specifications but generally states that a scenario shall be realistic and representative of one of the most probable alternatives. Thus, currently it is the responsibility of the owner of an EPD to specify the scenario and declare these modules. To make informed decisions about scenarios, EPD owners need access to reliable and realistic data.

For the modules of the product stage (A1-A3) and installation (A4 - A5), manufacturers rely on their own data or generic data. Generic data describe processes that could, in principle, be traced back to the provision of raw materials and thus, for example, reflect the entire upstream chain of raw material or energy generation.

For the end-of-life, there are two processes/scenarios commonly included/described in EPDs: landfill and waste incineration (for production and post-consumer waste). For recycling, generic datasets for common recycling processes – e.g. steel or aluminum recycling – are available. But if a specific recycling process is to be declared in an EPD, then appropriate information for the recycling scenario must be available – often, this is not the case. In the context of circular economy and the promotion of recycling, it is important to close that gap and to enable manufacturers to address the complete life cycle in their declarations. Consequently, to enable manufacturers, they need to have access to robust data to develop reliable partly scenario-based EPDs. Such data, however, can only be obtained from the waste management and recycling industry. There is, thus, an information gap between the manufacturer at the beginning of the product's life cycle and the actors at the end-of-life of the building. The situation is complicated further by the necessity to identify substances and boundary conditions that might have an influence on the applicability or the efficiency of the processes involved in an end-of-life route such as the impurities or harmful components that might influence choice and applicability of an EoL route.

4. End-of-Life Declarations (EoLD)

With the aim of supporting the modelling of the entire life cycle in the context of a (real/true) circularity of buildings the research project: Resource efficient buildings - EPD for construction products: dismantling and recycling information (Module C and D) including hazardous substances funded by the German Federal Environment Agency (Umweltbundesamt, UBA) has started in 2017. Within this research project, the idea of an End-of-Life Declaration has been developed in order to close the information gap between manufacturer and the stakeholders at the end-of-life of the building.

An End-of-Life Declaration (EoLD) calls for the recycling and disposal industry to provide specific data in a form and format that can be integrated in a building product EPD according to EN 15804, which provides the modularity needed for the building LCA. In this way, all actors for production, use and disposal can be liaised. For waste collectors or recyclers, one benefit of declaring environmental information for the end-of-life procedure in an EoLD is the ability to present the environmental quality of their processes in a "readable" and EPD-compliant manner to the manufacturer. Recyclers can thus also describe the input conditions for the respective recycling process in terms of pollutants and impurities. Such information is essential for the correct choice of a scenario and can also be very helpful for producers by enabling the optimization of the product content in the context of better recyclability.

Within the research project, the format of the EoLD has been defined and aligned with the EPD format and content. The EoLD contains company specific, technical and LCA relevant information. It gives a description of the EoL route and the materials and conditions in which the material is accepted by the waste treatment companies. The LCA results are declared in the same systematic as in an EPD in order to link both documents in a consistent way.

The aim of the EoLD is mainly to promote information exchange between stakeholders over the life cycle of a product. By opening lines of communication during the creation of a product EoLD, actors are presented with opportunities to improve their stage of the product life cycle: from design to installation, disassembly, and waste treatment at the product end-of-life.

An EoLD should include a realistic selection of waste treatment at the end-of-life stage of a building or product, enabeling comparing recycling processes with landfill and incineration on the basis of reliable and specific information. To define the end-of-life treatment process for a product, producers must communicate with waste processors to find out which treatment processes are proven to be economically and technically feasible. On the other end, producers must decide, when defining an EoL scenario scope for a product, how the product is (designed/intended) to be installed and disassembled. Information about installation requirements for products, insofar as they enable the proposed EoL scenario, should be verified as realistic common scenarios.

Through the process of learning about how their products are, in practice, installed, maintained, disassembled, and processed at EoL, manufacturers gain valuable information for making improvements within their main sphere of influence: the product design phase. By exchanging information with a recycler, a manufacturer may learn how to improve product's recyclability, for example, regarding separability of materials, and can then make informed changes in the product design. The EoLD includes prerequisites for achieving high-quality recycling at the product EoL. Here, the planning and installation phases are significant. Manufacturers must provide targeted supporting information on the proper application and installation of products to enable the achievement of higher recycling rates.

For waste processors, the EoLD creation process presents the opportunity to learn about manufacturers' intentions for their products and, through access to LCA data and improved information exchange, to improve to their own processes. For example, as recycling companies learn more from the manufacturers about specific product properties and ingredients, they may be able to improve recycling rates by avoiding contamination and impurities, or by improving separability. Better understanding of the product may also lead to innovations in the recycling process. With strong communication pathways, recyclers can communicate with manufacturers about both established and new treatment processes in a way that meets the requirements of sustainable certification systems.

As EoLDs become established through the manufacturing industry, the EoL modules in EPDs will become much less sparse. And while, initially, the bulk of EoLDs will be issued by product manufacturers, once created, EoLDs can also provide a basis for associations or product TCs in international harmonization and standardization to establish reference scenarios for a product group. Based on robust EoLD data, such reference scenarios can then improve the comparability of EPDs. Over time, robust, reliable data on the environmental information about the end-of-life of construction products will become readily available. A larger dataset of EPDs covering the product end-of-life (/all periods of a product's life cycle) will provide reliable data to be used by planers on the building level.

5. Conclusion

As interest in improving the environmental performance of buildings continues to grow – and expand beyond energy efficiency – a stronger focus is directed towards environmental impacts related to building products. For product manufacturers, environmental product declarations (EPD) are a market tool of continuously rising importance, providing a way for producers to share information about the environmental impacts of their products.

The increasing concern related to environmental performance and resource efficiency promotes the concept of circular economy. Reuse and recycling procedures at the end-of-life (EoL) play an increasingly important role in decision making. Manufacturers, however, are often unsure how to include late life cycle stages in their product declarations. At the same time, users of the information are confused as to what provided information really refers to.

The concept of modular EoL-declarations with clearly identified and described scenarios aims to facilitate the inclusion of the full life cycle in EPDs based on reliable and realistic data. At the same time, EoL-declarations promote the communication between the production and EoL-actors and enhance understanding of provided information, including judgements on potential demand and procedures for adaptation of provided information.

While acknowledging that continued use or reuse of products is presumed to be a preferred option, the upcoming standards for environmental product declarations will require the inclusion of the complete life cycle, especially the inclusion of the end-of-life stages. The underlying research aims to identify a transparent procedure enabling actors along a product's life cycle to make well informed decisions, and to potentially adapt provided information to his or her current decision making context and the associated conception of reasonable scenarios for information relating to future situations.

Jane.anderson@open.ac.uk

Abstract. This paper identifies the need for Environmental Product Declarations (EPD) to provide End of Life (EoL) and Module D data for products for use in building level Life Cycle Assessment (LCA). Although the provision of data for EN 15804 Modules A4-D is not currently mandatory for EPD, many currently report some or all of these. This paper provides an overview of the existing reporting of the end of life (Modules C1-4) and Module D and the types of scenarios used in European EPD. Using examples from existing EPD for two product groups, this paper examines the variation in approaches to scenarios for Module C and D. It explores the difficulties brought by this variation and discusses benefits from using default national scenarios at end of life, but additionally considers the advantages of providing alternative EoL scenarios for products to promote the circular economy.

1. Introduction

Life cycle assessment (LCA), as defined in ISO 14044 (1) addresses "the environmental aspects and potential environmental impacts (e.g. use of resources and environmental consequences of releases) throughout a product's life cycle from raw material acquisition through production, use, end-of-life treatment, recycling and final disposal (i.e. cradle-to-grave)." For construction products, the European Standardisation body, CEN's Technical Committee TC350 responsible for Sustainable Construction has developed a framework and standards to address the assessment of environmental aspects and impacts for both products and construction works. The life cycle for construction works and for construction products are set out in the framework standard, (2) and used in the building level environmental assessment standard, (3) and the construction product level environmental assessment standard, (4).

This framework clearly separates the end of life stage from the other life cycle stages, and breaks it down into four information modules, C1 (deconstruction), C2 (transport to waste processing), C3 (waste processing for reuse, recovery and recycling), and C4 (Disposal). In addition, another module, Module D is included to show the benefits and loads beyond the system boundary from the net output of recovered material, fuel and energy from the product system.

This framework allows Environmental Product Declarations (EPD) as described in EN 15804 (CEN/TC 350, 2013) to provide information for the various life cycle stages and modules, and for this information to be used, if appropriate, within a building level assessment according to EN 15978 (CEN/TC350/WG1, 2007). EN 15804:2012+A1:2013 only requires the mandatory provision of data for Modules A1-A3 (covering cradle to gate for the product stage), other modules and stages are voluntary. The current amendment of this standard, EN 15804+FprA2:2019 (5) will require Module C and D to be provided for all products except a very small number of exceptions, however it does not describe any scenarios which should be assessed for products, other than the requirement already set out in EN 15804:2012+A1:2013, "A scenario shall be realistic and representative of one of the most probable alternatives." (CEN/TC 350, 2013, 6.3.8).

This paper builds on the work of Silvestre, Brito and Pinheiro (2014) (6) which demonstrated that EoL data provided in EPD can be an important source of data for decision-making at the end-of-life of building materials, especially to ascertain whether the minimization of waste flows, the maximization of their reuse or recycling operations, or the increase of the recycled content maximises their C2C environmental performance. At the time of their paper however, few EPD were available and they provided limited data on EoL scenarios. This paper demonstrates that many European product EPD now report some or all of the voluntary modules, including the end of life (C1-4) and beyond end of life (D). Using examples from existing EPD for two product groups, this paper examines the variation in approaches to scenarios for Modules C and D, and highlights some of the difficulties this causes. It discusses the benefits that can be gained from using default national scenarios at end of life, and also considers the advantages of providing alternative EoL scenarios for products to enable specific building LCAs. It also stresses the need for specific product scenarios at EoL to promote the circular economy within the manufacturing industry.

2. The purpose of EPD and use of data for Module C and module D data from EPD

2.1. Purpose of EPD and scenarios

EN 15804:2012+A1:2013 states "The purpose of an EPD in the construction sector is to provide the basis for assessing buildings and other construction works, and identifying those, which cause less stress to the environment.". EN 15804, which provides the core Product Category Rules (PCR) for construction product EPD, therefore states it has the objective to ensure:

- *"the provision of verifiable and consistent product related technical data or scenarios for the assessment of the environmental performance of buildings;".*

CEN TR16790:2017, the guidance document for EN 15804 describes the approach for scenarios,

> *"as soon as a construction product leaves the factory gate the assessment is based on scenarios and assumptions: the fate of the product in the building chain will depend on locations, types of transport, installation and constructing methodologies, building type, use of the building, maintenance, repair and waste handling. The manufacturer cannot control these processes completely. An assessment thus requires scenarios to be specified for each module, i.e. for modules A4, A5, all B-modules, all C-modules and for information module D."*

2.2. Purpose of EPD for Building Level Assessment

EN 15978, 8.1 describes how building level LCA assessment needs to evaluate the end of life of the building. "This requires the development and use of appropriate scenarios representing assumptions (or, where known, real information) that can be applied to models for construction, use, and end-of-life stages (modules A4 to C4) of the object of assessment. If information on module D is communicated in a building assessment, scenarios are required to be defined at the building level." As described in the TC 350 Framework, EPD to EN 15804 are the first source of LCA data for construction products to be used at the building level. EN 15978 8.1 states, "Information modules available from EPD shall be reviewed in order to determine if they are representative of the assessed building". This is reiterated in clause 10.2.3, *"Any scenarios incorporated in the EPD and/or other information used for the assessment should be checked for consistency with the scenarios for the building. Where differences occur, it is still possible to take consistent information from an EPD (e.g. cradle to gate information from a cradle to grave EPD) and apply other appropriate scenarios at the building level (e.g. gate to grave)."*

This means that if the building has been "designed for deconstruction" to minimise landfill and to maximise reuse at end of life, that EoL data provided in EPD should only be used if they are representative of this "design for deconstruction" approach; if the EPD provides EoL data based on a scenario for landfill or incineration without energy recovery for example, then it will not be representative of the assessed building and should not be used.

Similarly, if an EPD provides EoL data for Energy Recovery in C3 and its Module D shows the benefit of the exported electricity and heat in the UK with substituted UK grid mix, then this Module D data will not be representative for the end of life of a building located in France, where the French grid mix should be substituted if the product is used for Energy Recovery at end of life.

2.3. EPD for Product Comparison

For comparisons of EPD, EN 15804 states, "comparison of the environmental performance of construction products using the EPD information shall be based on the product's use in and its impacts on the building, and shall consider the complete life cycle (all information modules)."

As described above, products can therefore only be compared in a specific building context over the full life cycle. This means that data for the products end of life will need to be used, and will need to be representative of the chosen building context. It will therefore be necessary to ensure that end of life scenarios in particular reflect the same context – this does not mean that the end of life scenarios have to be the same however – they need to be equivalent; if the context is the typical building in the Netherlands, then it would be appropriate to reflect the typical Dutch end of life for different products – this could be recycling for metals and energy recovery for biomass for example.

3. The end of life stage

3.1. Benefits of assessing the end of life stage

The assessment of the end of life of the building (Modules C1-C4), and for Module D allows a number of mitigation strategies to be considered to reduce the impact of the building. This is described in Pomponi & Moncaster (2016) which classified various mitigation strategies (MS) found in the literature, including the following with direct relevance to Modules C1-C4 and Module D of EPD:

- MS1: use of materials with lower embodied energy and carbon;
- MS3: reduction, re-use and recovery of EE/EC intensive construction materials; and
- MS17: demolition and rebuild.

Many materials such as plastics or biogenic materials have high impacts at end of life as their feedstock carbon is emitted through incineration or transferred to future product systems. Other materials (e.g. reinforced concrete) can require recycling processes at the end of life to achieve the "end of waste" state meaning they have crossed the system boundary. The provision of data showing the impacts of end of life, allows the identification of products will lower life cycle impacts (MS1).

Provision of information in the EPD covering the impacts of reuse and/or recovery (Module C1-C4) and its potential benefits in the next product system (Module D) enables the reuse and recovery strategy (MS3) to be evaluated.

MS17 suggests that by demolishing existing buildings and rebuilding them with significantly increased energy efficiency we can make reductions in the whole life impacts of our built environment compared with refurbishment. The data provided in Modules C and D of EPD for products used in the building and EPD for new products can be used to assess refurbishment and redevelopment options and provide the information to assess the validity of this controversial proposal.

3.2. Assessment of end of life in Building Level studies

Despite the potential use of data from Modules C and D to mitigate the impacts of the built environment, these are seldom assessed in whole building LCAs. Wallhagen, Glaumann, & Malmqvist (2011) (7) point out that these stages are not addressed by Adalberth et al. (8), Chen et al. (9), Peuportier (10), Blengini (11) and Ortiz et al. (12). Silvestre, De Brito, & Pinheiro (13) also find that "*…the LCA results from more than 10 years of international research studies on the environmental impact of a building's external walls has shown that … just a third (21 out of 63) include the end-of-life of the building assembly.*"

This may be partly because end of life impacts are often considered small as for example found by Nemry et al. (2010) (14) though aggregating Module C and D together may have reduced the impact shown at end of life. Other studies show the impact of the EoL stage is greater. Pomponi, Moncaster, & De Wolf (2018) reviewed the assessment of five buildings undertaken by different consultants using different tools and found the impacts of the End of life module C averaged around 6 to 8% of the whole life carbon, but in some cases were as high as 15%.

It is also the case that the end of life stage varies in importance for different product types. For metals for example, the end of life stage is often assumed to have no impact, as the metal is assumed to reach the end of waste state on collection in C1. For masonry, many EPD only include collection as demolition rubble in C1 to be the end of waste state. However, for products such as those based on biomass or fossil feedstocks, the end of life stage can have significant impacts due to emission or transfer of feedstock carbon. The authors suggest that for buildings with higher proportions of bio-based products, the end of life stage impacts may be significantly greater than those provided in the literature above.

4. Reporting End of life in EPD

4.1. Approach to the Review of End of life Data in EPD

While reporting of Module C is not mandatory, many EPD from European EPD Programs do report Module C and D scenarios, as shown below. In some EPD Programs such as the French National EPD Program (15), it is a requirement to evaluate and report Module C as French EPD must cover cradle to grave.

The authors have reviewed over half (2464) of the EPD compliant with EN 15804 and registered by ECO Platform members (ECO Platform, 2018) over the period December 2018-January 2019. The study excludes all EPD from the IBU and EPD Norge Programs which are still being evaluated. 784 PEP EcoPassport EPD for electrical products used in buildings have also been excluded as although they are cradle to grave EPD, they do not report modules C1-C4 separately. The EPD were assessed and classified as to whether each module was “Reported” or “Not Reported”. If it was marked “not relevant” this was classified as “Not Reported”.

4.2. Results of the Analysis

The analysis showed that 72% of these EPDs report Module C1 (Demolition/deconstruction), 77% report Module C2 (Transport to waste processing), 76% report Module C3 (Recovery), 82% report module C4 (disposal) and 51% report Module D.

There was wide variation between EPD Programs in relation to reporting of end of life (EoL) modules (C3 and C4). For example, within the ITB Program in Poland, the DapHabitat Program in Portugal, EPD Global in Spain, EPD Danmark (Denmark) EPD Norge in Norway and EPD Ireland, less than 50% of all EPD provide EoL modules. However in RT EPD (Finland), MRPI (the Netherlands) and Bau EPD (Austria), over 75% provide EoL modules. The FDES and PEP Ecopassport programs (France) require all EPD to cover cradle to grave.

5. Analysis of declaration of Module C and Module D and scenarios for two product groups

5.1. Overview

A more detailed analysis was undertaken of the reporting and description of scenarios for two particular product/material groups, namely polystyrene insulation, including expanded and extruded polystyrene (EPS and XPS) insulation, and wood panel products, including medium density fibreboard (MDF), orientated strand board (OSB), particleboard and plywood. The end of life impacts of these product groups are likely to be significant due to the emission or transfer of feedstock carbon.

5.2. Classification of reporting of Modules:

For these EPD, the authors propose the classification of Module C1-C4 and Module D reporting as to whether modules were "**declared**" with an impact, declared with "**zero"** impact, "**not declared**" (MND), or declared "**not relevant**" (MNR).

5.3. Types of Scenario used in EPD

Additionally, the types of scenario declaration for module C1-C4 and Module D were analysed. The authors propose four separate types of scenarios used for gate to grave and Module D in EN 15804 EPD:

- **"100%"** scenario: where only one approach is reported for the module or modules in the EPD, eg 100% of the product is sent to landfill. These scenarios can also include consecutive processes, for example, where 100% of the product is used for energy recovery in C3 and then the incinerator ash is landfilled in C4, or where the waste is transported by road and then by sea to waste treatment.
- **"Mixed"** scenario: where a combination of two or more approaches is considered in a single scenario reported for the module in the EPD, with a proportion using each approach – e,g. 50% of the EoL product is sent to landfill (C4) and 50% used for energy recovery (C3), or 25% is sent to landfill (C4) and 75% sent to incineration without energy recovery (C4). These scenarios are often typical of a national situation;
- **"Multiple"** 100% scenarios: where two or more 100% scenarios are reported for the module in the EPD.
- **"Mixed+100%"** scenario: where a mixed scenario is reported for the module in the EPD together with 100% scenarios for the contributing approaches, as described in CEN/TR 15970 clause 6.3.8.

5.3.1. 100% scenarios: It should be noted that EN 15804, and more specifically the guidance document to the standard, CEN/TR 16970:2016 6.3.8(16), states that 100% scenarios should also be declared if a mixed scenario is provided:

> *"When different scenarios are developed for information modules C1-C4 the most relevant scenarios are provided as 100 % versions. For example when 20 % of a product is recycled, 50 % is incinerated and 30 % is deposited, scenarios for 100 % of incineration, 100 % of recycling and 100 % of deposition are declared. This allows the building assessor to choose and calculate the correct scenario on building level as actual waste management practices vary in different member states".*

5.4. Analysis of Description of Scenarios

The description of the scenarios provided in the EPD were also analysed considering the level of detail provided and the type of processes included in each module.

5.5. EPS and XPS Polystyrene Insulation

20 EPD from nine EPD programmes were identified and analysed under the product category "polystyrene insulation" and the results described in Table 1. Where several EPD for different but very similar specific products were produced using the same scenarios, only one was assessed.

10 EPD provided 100% scenarios, four provided two separate 100% scenarios and five EPD provided a "mixed" scenario. There were also some differences in the way in which EPD reporting a 100% scenario for C3 declared module C4 and vice versa. As Module C and Module D are intended to become mandatory requirements in EN15804+FprA2 then consistency in considering this situation would be useful.

Only four EPD declared C1, with 3 declaring the impact to be zero. 16 declared C2 with quite varied scenarios. Distances range from 10 km, 50 km, 200 km, and one Norwegian EPD used 1000 km by road to a recycling plant. For such a lightweight product as polystyrene insulation, it would be expected that the volume capacity might be considered in the transport scenarios, but few EPD mention it: two used

Table 1. Scenario data for Polystyrene Insulation EPD.

Product	Scenario type	Stated scenario for Module C1	Stated scenario for Module C2	Stated scenario for Module C3	Stated scenario for Module C4	Stated scenario for Module D	Programme/ Location of Manufacture
EPS	100%	Collection, no impact	10 km, 5% capacity	Energy recovery	MNR	Substitution exported energy	DK / DK
EPS	100%	Collection, no impact	10 km, 5% capacity	Energy recovery	MNR	Substitution exported energy	DK/ DK
EPS	100%	Deconstruction	Zero impact	Energy recovery	Zero impact	Substitution exported heat (district heat)	RT / FI
EPS	mixed	Collection, no impact	10 km	44% recycling, 53% energy recovery	2% landfill	Substitution exported heat + electricity and virgin product	EPD-Norge/ NO, SE
EPS	multiple 100%	MND	No info	Recycling	related disposal	Substitution of virgin product	EPD Italy/ IT
				Energy recovery	related disposal	Substitution of exported energy	
EPS	100%	Collection, no impact	25 km	Zero impact	Landfill	MND	Inies/ FR

a 5% capacity including empty returns, one 18% capacity and one 21%. Fuel consumption for the trucks was reported variously as 0.2 l/km, 0.38 l/km, 25 l/km, 0.173 l/tkm, 0.4 l/tkm, and 0.026 l/tkm for the large capacity trucks travelling 1000km.

There was a wide range of end of life options, including recycling, energy recovery in C3 and incineration with energy recovery in C4. 14 EPD declared Module D showing the benefit of energy and material recovery, though few stated what electricity or energy was substituted.

5.6. Wood panel products: OSB, MDF, particleboard/chipboard and plywood

Twenty five EPD from five EPD programs were considered within this product group and details of the modules reported and scenarios used are provided in Table 2. Again, there are a range of mixed, 100% and multiple 100% types of scenarios declared.As for polystyrene, very few declared C1. Reporting for C2 (transport to waste processing) was also varied with distances varying from 20 to 100 km. Although almost all EPD declaring end of life modelled use of the waste timber for energy, there was a big variation with some processing and using the waste for energy recovery in C3, some incinerating in C4, and some considering the use of secondary fuels in Module D with some also reporting processing in C3.

6. The Role of Product TCs and c-PCR

CEN/TR 16970:2016 (16) provides guidance to CEN Product Technical Committees on developing complementary PCR (c-PCR) to EN 15804. It says in the development of c-PCR, the following are considered, in 5.1.2, "inclusion of default scenarios related to a specific application of the product including guidance on:

i) The specific content of all information modules of the life cycle and information module D, for default scenarios;
ii) The definition of the end-of-waste status;
iii) The technical scenario information for all information modules of the product system and information module D".

It also states in 6.3.8, that "when different scenarios are developed for information modules C1-C4 the most relevant scenarios are provided as 100% versions. For example, when 20% of a product is recycled, 50% is incinerated and 30% is deposited, scenarios for 100% of 100% of incineration, 100% of recycling and 100% of deposition are declared. This allows the building assessor to choose and calculate the correct scenario on building level as actual waste management practices vary in different member states."

6.1. EoL scenarios in c-PCR in practice

Unfortunately, few of the c-PCR developed to align with EN 15804 provide detailed technical scenario information for the end of life and only one provides an assumption for the end-of-waste status if product specific information is not available. One states that geography will affect the EoL routes used.

6.1.1. EN 16783:2017 is the c-PCR for insulation. This does not provide any default scenarios or specific guidance on the End-of-Waste state for insulation products, but states in clause 6.3.4.5 that the products can be sorted and separated for recycling or for energy recovery and scenarios can vary with the application and with geographical location (17).

6.1.2. EN 16485:2013, the PCR for round and sawn timber (the raw material for use in board products), provides an assumption on the end of waste state for timber where product specific information is not available, which is after sorting and chipping for untreated timber, and gives some guidance on the types of process to include in modules C1-C4 for different end of life options depending on when the end of waste state is reached (18).

6.1.3. Other c-PCR: The c-PCR for Glass (EN 17074:2018, clause 9.8.4) states that "End-of-life scenarios and routes can vary according to national and regional legislation, de-construction schemes and requirements, collection and sorting schemes in place and end-of-life treatments available"(19). The c-PCR for concrete (EN 16757:2017) gives detailed technical scenarios for possible EoL options for concrete. It does state, as a note, that "The legal interpretation of End-of-Waste can differ significantly at national level. At some regions, crushed concrete stored indefinitely at demolition sites over long periods will revert to being waste. In such case, certainty over the legal End-of-Waste status is only confirmed when demand exists and a certain market is allocated and the crushed concrete is removed from site"(20). Again, this emphasises the differences that geography plays in determining EoL scenarios for EPD and highlights the difficulty in European c-PCR providing relevant default EoL scenarios when practice varies so widely geographically, due to differences in national and regional legislation, the recycling schemes in place and the EoL treatments available.

7. Discussion

7.1. Variation in reporting

The detailed analysis of end of life scenarios and reporting undertaken for this paper highlights the wide variation in end of life routes assumed within EPD. The authors are also concerned by possible errors in modelling or reporting of fuel consumption and vehicle capacity, differences in assumptions for transport distances, and the differences in the "end of waste state" used. The "end of waste state" can vary regionally as markets and demand may vary, the secondary material may not be commonly used in some regions and the legal definition of end of waste may also vary. But even for MDF EPD for the German Market, there is not consistency regarding the end of waste state – with one assuming the end of waste before chipping. Analysis shows these differences in scenarios also lead to differences in impact reported in Module C and Module D. The wide variation in scenarios also means that there is a general level of distrust with gate to grave data with many Building LCA tool providers telling the authors they do not use gate to grave data from EPD in their tools.

Provision of a national default scenario, such as that for the Netherlands (21) reduces the effort to produce gate to grave EPD data for that market as manufacturers and LCA practitioners do not need to individually research and develop representative end of life scenarios, and this is likely to be associated with reduced costs.

7.2. Insufficient description of scenarios

The authors note that many EPD provide insufficient information on scenarios for those using EPD for Building LCA to ensure "*Any scenarios incorporated in the EPD and/or other information used for the assessment should be checked for consistency with the scenarios for the building"* as suggested by EN 15978 10.2.3. If the type of heat or electricity substituted in Module D is not provided for example, then the module cannot be checked for consistency with building level scenarios for substitution.

7.3. Provision of multiple 100% scenarios

Very few of the EPD provided more than one 100% scenario for different end of life options, although there were several different end of life routes given across the product groups. EPD providing mixed scenarios did not provide any 100% scenarios for the individual processes despite the text in CEN/TR 16970:2016 6.3.8 recommending this. C-PCR also fail to recommend this option, although it would help to deal with the different EoL options available in different locations due to variations in legislation, recycling schemes and treatments available. Providing 100% scenarios for recycling, energy recovery, landfill and incineration (potentially with different end-of-waste states if relevant) gives an understanding of the different impacts of these end of life options and can be used for buildings currently being demolished, wherever they are, to assess the most advantageous options. Where 100% scenarios are reported for re-use and/or recycling in addition to energy recovery, they also enable use of the data for different building level scenarios, such as design for deconstruction, providing encouragement for the circular economy.

8. Conclusion

The authors have provided several new approaches to classifying the scenarios reported in EPD, and identified that a significant proportion of EN 15804 EPD already report Modules C1-C4 and Module D. However, the authors are concerned that their analysis of existing EPD has highlighted such wide variation in the modelling, description and reporting of these modules. With reporting of Module C and Module D likely to become mandatory for all EPD based on FprEN15804+A2:2019, the authors recommend that EPD programmes provide more guidance on modelling, description and reporting to ensure that EPD data can be checked for consistency with building level scenarios and used with confidence. It is also clear that Product TCs find it difficult to develop c-PCR with default EoL scenarios due to the geographical differences in real EoL routes. To address the differences in different locations, and encourage the circular economy, the authors also highlight the benefit for c-PCR and EPD of providing multiple 100% scenarios so the impact of different end of life options can be considered and circular economy approaches to building design can be evaluated in many locations. The authors also recommend that building level assessment schemes together with EPD program consider developing and publishing default national scenarios to enable consistent assessment for benchmarking.

Modelling options for module C and D: Experiences from 50 EPD for wood-based products in Norway

Tellnes L G F[1], Rønning A R[2]

[1] Research Scientist, Ostfold Research, Kråkerøy, Norway
[2] Senior Research Scientist, Ostfold Research, Kråkerøy, Norway

lars@ostfoldforskning.no

Abstract. Introducing the EN 15804 standard as a core PCR for building products included several specifications for LCA end-of-life and benefits beyond the life cycle. There are however several issues that the LCA practitioner need to interpret during the modelling and generic data needs to be adjusted for being representative and in accordance to EN 15804.The modelling of module C and D has been developed in three different stages during making 50 EPDs over several years. First the model was mainly based on generic data from ELCD database. The second was a statistics-based mix of different treatment options, where the substation of other energy sources in module D was a representative mix of district heating mix, electricity, coal in cement production, wood chips in wood industry and ELCD for exported waste. The third represented a 100 % scenario for energy recovery in municipal waste incineration and substituting statistical mix of electricity and district heating. The objective of the study is to present the experiences from developing and implementing the module C and D in the 50 EPD that where verified at EPD-Norway and discuss in relation to requirements in standards and usability in a building context.

1. Introduction

The environmental product declarations (EPD) for wood products was first introduced in 1996 for some generic products from the Nordic countries. The second generation wood EPDs came in 2009 and was based on the ISO 21930 (1). Several of these where representative for the most common products from the members of the Norwegian Wood Industry Federation. These EPDs was also third party verified and published through the Norwegian EPD Foundation. The use of EPD was however limited, but in 2012 the Norwegian Green Building council (NGBC) released a Norwegian adaption of building environmental certification scheme BREEAM. Known as BREEAM-NOR [2], it included credits for provided EPDs for the most used products and made a sudden increase in demand for EPDs. In 2013 the revision of product category rules (PCR) for wood products was released, NPCR015 [3], and was based on the EN 15804. The launch of BREEAM-NOR made EPDs requested for many more specific products, such as claddings, windows and engineered wood products.

Prior to EN 15804, end-of-life was assumed as energy recovery and that the emissions were allocated to the energy user. However, with EN 15804 it was required that emissions until end-of-waste state was included, but also optioned for including the benefits of energy recovery. The procedure was however not very specific, and the approach was improved in mainly three steps in making about 50 EPD over four years. The aim of this paper is to present this development in procedures with discussion to the relation to standards and practice.

2. Materials and methods

The review has focused on two main issues in modelling of end-of-life modelling:

- Development of scenarios
- Development of life cycle inventories for incineration of materials

2.1. Materials

Three EPDs are selected to represent the three stages of development in scenario modelling module C and D according to EN 15804 and NPCR015 [3]. The EPDs are listed in table 1.

Table 1. List of EPD that represent the different stages of developing the scenario model for module C and D

	Product	Year	EPD number	*Description*
First model	Pine moulding	2013	NEPD00232	Statistical mix of end-of-life treatment and generic data for benefits
Second model	Pine panelling	2015	NEPD-309-179	Statistical mix for end-of-life treatments and market mix of benefits
Third model	Cross laminated timber	2017	NEPD-1269-410	Most common end-of-life treatment and average benefit

One crucial aspect discovered over the years for EPD development was the LCI of incineration of resin in the wood products. This model was also developed in three different stages and EPDs representative for these are listed in table 2.

Table 2. List of EPD that represent the different stages of developing the LCI model for resin incineration in module C

	Product	Year	EPD number	*Description*
First model	Glulam beam	2014	NEPD00263	ELCD dataset for whole product
Second model	Standard glulam	2015	NEPD-336-222	Ecoinvent dataset for each material component
Third model	Glulam for custom projects	2018	NEPD-1577-605	Ecoinvent dataset adjusted to carbon content

2.1.1. Methods

The EPDs are reviewed based on the scenario information and the life cycle inventory is remodelled according to the writer's experiences. The exact LCI is however not publicly available.

3. Results and discussion

3.1. Scenario modelling

3.1.1. First model: Statistical mix of end-of-life treatment and generic data for benefits

The first model for end-of-life of pine moulding coated with paint. In the PCR applied, a reference was give to CEN/TR 15941 (2010) for the use of generic data. This states that generic data for scenarios in end-ofe-life stage should among others reflect: “today’s average practice an dmix of different end-of-life treatment of the product group in the location where the process takes place”. Hence, this was interpreted as that the Norwegian mix of treatment of wood waste should be used for the end-of-life modelling. The most recent statistics at the time of publishing the EPD was from the year 2011 and where about 91 % of wood waste was sent to incineration with energy recovery, 7 % to incineration without energy recovery and 2 % to landfilling.

The module D was based on generic data for energy substitution in ELCD datasets for wood incineration. The ELCD dataset had two versions, one with only emission from incineration and one with also the benefits of energy recovery. Hence, one dataset corresponded to C3 and the other to C3+D. In order to model module D, the first was subtracted to the second.

3.1.2. Second model: Statistical mix for end-of-life treatments and market mix of benefits

The mix of waste treatment was the same in the first and second model for C3, but the substitutions in module D was quite different and because of this also some differences in transport scenario, module C2. The new substitution model aimed at reflecting the current average substitution, hence taking into account that the wood was treated in both municipal incineration and industrial, in addition to a quite large export to Sweden. Based on several sources, a bottom-up approach was applied to estimate the amount to different treatments and what they substituted. The mix of treatment are listed in table 3.

Table 3. List mix of treatments in C3 and substitutions in module D

Treatment in C3	Share [%]	*Substitution*
Municipal incineration	25	District heating mix and electricity consumption mix
Cement plant	5	Heat from coal
Chipping to industrial fuel for sawmill and particleboard industry	10	Wood chip fuel
Pulp and paper industry	14	Heat from fuel oil
Export to Sweden	46	ELCD dataset substitution mix

3.1.3. Third model: Most common end-of-life treatment and average benefit

The third model was a result of more understanding of the EN 15804, but also more recent data understanding. The Norwegian EPD Foundation gathered LCA-practitioners from different research institutes in Norway to work together on a study to harmonize the scenarios in EPDs. This work revealed that EN 15804 requires to use one or more of the most common scenarios. Hence, the requirement for scenarios implies that it should not be a mix. The work also shows how disposal of ashes from incineration could be included in module C4 [4]. The situation in Norway had also changed and in statistics no wood waste was disposed in landfill or incinerated without energy recovery. The third model assumed then that municipal incineration with energy recovery was the one of the most common end-of-life treatments in Norway for waste wood. The amount of energy recovered was based on national statistics of district heating and which also included the amount of electricity generated. The substitution was the mix of heating sources in the district heating in Norway.

There are currently work on PCR in Norway, but also EN 15804 in Europe. The Norwegian PCR for wood products has included several reference scenarios that shall be include, but more can be included if relevant. For update of the EN 15804, it is included an informative appendix with formulas for calculating the module C and D. There is also a requirement to include module C, with some exceptions.

3.2. Inventory modelling for incineration of glulam

3.2.1. First model: ELCD dataset for whole product

European reference life cycle database (ELCD) was established by the European Commission's Joint Research Centre (JRC). It consists of LCI data on a system process type, which means that each dataset only includes elementary flows. This makes the dataset easier for exchange between different users, but not possible to adjust the data and quality control is difficult. The data for wood products incineration is representative for a European technology mix of incineration. For the waste composition, the products OSB and particleboard are mentioned. An example of LCI are performed as shown in table 4.

Table 4. Life cycle inventory from example of first model for module C3

Waste specification			
Name	Amount	Unit	Comment
C3, incineration glulam	1	m^3	
Outputs to technosphere. Waste and emissions to treatment			
Name	Amount	Unit	Comment
Waste incineration of wood products (OSB, particle board), EU-27	470	kg	Weight of product according to product standard

3.2.2. Second model: Ecoinvent dataset for each material component

In the second inventory model used for glulam, ecoinvent database was used instead of ELCD. Ecoinvent is available both as system and unit processes. The unit processes include technosphere flows, like energy use, transport, etc. In addition, the elementary flows are specific to the relevant activity and not aggregated as in system processes. The inventory for incineration of glulam was based on a dataset for untreated wood and one for incineration of polyurethane. Polyurethane was then chosen as a proxy for the resin, as it was also used for treatment of waste resin in manufacturing of glulam in an ecoinvent unit processes for glulam manufacturing. The total weight of the product was the same as in the first model, but divided between wood part and resin part. The LCI modelling is shown in table 5.

Table 5. Life cycle inventory from example of second model for module C3

Waste specification			
Name	Amount	Unit	Comment
C3, incineration glulam	1	p	per functional unit
Outputs to technosphere. Waste and emissions to treatment			
Name	Amount	Unit	Comment
Waste wood, untreated {CH} | treatment of, municipal incineration | Alloc Rec, S	461.22	kg	Wood weight
Waste polyurethane {CH} | treatment of, municipal incineration | Alloc Rec, S	8.78	kg	Resin weight

3.2.3. Third model: Ecoinvent dataset adjusted to carbon content

The third model is based on an update of the EPD in the second model. The company owning the EPD was interested in how they could reduce their carbon footprint and a contribution analysis was performed. The incineration of resin was found to be an important part of the life cycle greenhouse gas emissions and was therefore reviewed. The inventory for incineration was then adjusted to correct for the actual dry content of resin in the final product and the carbon content of the resin. The polyurethane

LCI has a carbon content of about 63 %, while melamine urea formaldehyde (MUF) resin has a carbon content of about 30 %. Hence, the carbon dioxide emissions from combustion of the resin is about half per kg. An simplified example of this inventory is shown in table 6.

Table 6. Life cycle inventory from example of third model for module C3

Waste specification			
Name	Amount	Unit	Comment
C3, incineration of glulam	1	p	per functional unit
Outputs to technosphere. Waste and emissions to treatment			
Name	Amount	Unit	Comment
Waste wood, untreated {CH}| treatment of, municipal incineration | Cut-off, S	375/(1-0,17408)	kg	Dry weight of wood, adjustment, LCI adjustment to dry
Waste polyurethane {Europe without Switzerland}| treatment of waste polyurethane, municipal incineration | Cut-off, S	4.85*0.5	kg	Dry weight of resin, adjustment to actual carbon content

The implication of the three models on the results on carbon is that the first model is actually not including the emissions from incineration of the resin in wood products. The second model overestimates these emissions of more than double when MUF resin is applied. The third model aims at modelling the emission as correctly as possible, but is more complicated to perform. The importance of the modelling to the total results are on a medium level for glulam, but for wood-based panels, like particleboard, these models would have a dominating effect on the total carbon footprint results. The modelling of the production of resin is usually based on specific data from the manufacturers of resin. In the future, it would be beneficial that all upstream LCI data for EPD also is supported with downstream specific LCI for waste treatment. At least for combustible materials.

The modelling of biogenic carbon has been another important issue with wood EPDs and in the future modelling of end-of-life scenarios and inventory of incineration it could have a crucial part. So far, biogenic carbon has been assumed by many of being climate neutral over the life cycle, as the end-of-life scenario of wood will lead to emission of the same amount of carbon dioxide as has been sequestrated during forest growth. Hence, as long as the climate impacts are not time-adjusted, the different approaches for biogenic carbon has the same climate impacts over the life cycle [5]. However, plans for establishing carbon capture and storage (CCS) in Norway at waste incinerator that treat a notable share of the wood waste will lead to new methodological challenges. A case study has been performed on this for treated wood and which leads to climate negative results over the life cycle [6]. This would probably lead to discussions as many believe that biogenic carbon is always neutral over the life cycle.

4. Conclusions

This study has presented modelling principles for modelling end-of-life practiced in a selection of EPDs published between 2014 and 2018. The modelling has been improved on a mainly three step development, both for scenario and for life cycle inventory. These experiences should be utilized in future development of EPD requirements in PCR, but is also in important message for the importance of transparency in LCI datasets in databases and during verification.

For PCR development, these experiences have been included in the revision of the PCR for wood products applied in Norway. The proposal for PCR now includes conservative reference scenarios for the end-of-waste scenario. For wood products, the end-of-life scenarios can be quite different dependent on the country. Hence, the references scenarios are separated between different markets.

For the LCI datasets applied, it is important that they are specific for each material composition of the product. The LCI data should also be available on a unit process type in both databases and during verification. Future methodological challenges will be climate negative situations when biogenic carbon will have final storage when CCS is practiced at end-of-life of wood products.

Abstract. Digitalization and digital technologies are buzzwords in today's building industry. Because of their promising opportunities to improve (among others) the sustainability footprint of the built environment, they have emerged as an important topic for policymakers, managers, and researchers. Yet, the debate is dominated by references to Building Information Modelling (BIM) and to the success of digital businesses in other industries; it thereby fails to consider other promising digital building technologies and ignores that—in the building industry—many digital technologies require alignment with buildings' physical components. For these reasons, it is unclear how the implications of digital transformation of the building industry for policy and business. In this paper, we develop a typology of digital building technologies, and categorize and assess 29 important building technologies. The substantive differences among different types of building technologies provide valuable insights into how digital building technologies affect the functioning, structure, and competition in the building industry and where digital building technologies offer opportunities to remedy the industry's sustainability footprint. Based on our findings, we offer recommendations to policy makers, companies, and researchers interested in digital building technologies.

1. Introduction

Until the late 1990s, digital technologies appeared as basic software or "the internet." This "first wave" of digital technologies allowed for simple levels of automation, analytics, and digital communication improving the efficiency of processes [1]. Yet, the digital technologies that concern people nowadays are part of a "second wave" of digital technologies of which Big Data analytics, cloud computing, Artificial Intelligence (AI), or the Internet of things (IoT) are only examples [2]. Some industries, such as retail or media, have already encountered the disruptive impact of the second wave of digitalization. New market players and business models have changed prevailing industry practices [3]. As these changes suggest, this "second wave" of digital technologies is a key enabler for disruptive innovations and the creation of new business models that not merely complement but fundamentally transforms how companies create, deliver, and capture value.

The building industry, too, has benefitted from digital technologies. In the past, digital technologies, such as e-mail, simulation software, or Enterprise-Resource-Planning (ERPs) systems have helped to adjust and improve existing processes. More recently, digital technologies of the second wave are also developed and adopted across the building industry and promise to transform prevailing processes and business models. This second digital transformation thus promises many opportunities to increase efficiency, productivity, and transparency across the building industry.

For business leaders and policymakers, understanding the digital transformation of the building industry is relevant for several reasons. The emergence of digital building technologies may change the competitive dynamics in the industry. Companies that successfully employ digital technologies may benefit from substantive efficiency gains that will allow them to offer similar services at lower prices. A company's IT capabilities may eventually determine whether it qualifies for joining building projects—digital technologies may thus emerge as the new entry barrier in the building industry. The enhanced transparency introduced by data-driven building technologies may oust companies that rely on opaque pricing and offer others opportunities to develop new business models.

The digital transformation also raises questions concerning the industry's labor market. In particular, trends in the area of prefabrication or robotics may drastically reduce the number of workplace in the building industry. Companies may need to transition from a large workforce of manual labor to a small one trained in handling IT or IT specialists. For policy, alleviating the industry's dependency on manual labor may lead to large-scale unemployment but may also offer a solution to the lack of skilled personnel—depending on the current situation of the labor market. Either way, policymakers will face questions of how to retrain the current and train the future workforce for a digital building industry.

The digital transformation of the building industry may also offer opportunities to policy makers to address sustainability and energy-related concerns associated with the building industry. Currently, the industry is one of the most energy-intensive ones with 40% of the primary energy consumption globally and about 36% of global CO_2 emissions [4]. Digital technologies offer several solutions to minimize the ecological footprint of the industry and help streamline processes across the entire building lifecycle in a more efficient, transparent, and safer way.

Yet significant barriers to digitalization remain. First, the adoption of new digital technologies in the building industry has been slower than in other industries. This is not necessarily surprising given the structural characteristics of the industry. Highly fragmented, with low margins, and low investments in R&D, building companies either have had no time (during construction booms) or no money (during building industry crises) to develop and adopt new technologies. Second, the current debate on digitalizing the building industry tends to focus on one digital technology, Building Information Modelling (BIM). A debate dominated by the promises of BIM not only risks neglecting the substantive challenges of successfully commercializing BIM solutions but, more importantly, risks neglecting other digital building technologies that may offer a more direct route to transforming the industry.

Third, the building industry differs from other industries affected by second wave digital technologies in one important aspect: the central role of the physical built environment. Successfully developing and commercializing second wave digital technologies is in itself challenging [5], integrating digital technologies with physical building components creates an additional complexity that has yet to be fully understood. A better understanding of how digital technologies will transform the building industry may thus provide important insights into other applications of digital technologies that require consideration of the physical world.

This article serves to develop a better understanding of the promises and pitfalls of digital trends in the building industry and is structured along two interrelated questions: What digital technologies influence the building industry and how will they transform the structure of the building industry?

2. Methodology

We focus on the intersection between digitalization and the building industry. We use the term *digitalization* to refer to the integration of digital technologies into everyday life [6]. Digital technologies are all technologies that comprise data or execute algorithms in digital form [1, 7]. The *building industry* refers to a specific segment of the construction industry, namely the one that includes all actors involved in, and activities related to, residential, commercial, and industrial buildings [8-10]. Thus, we consider digital building technologies as those applied by actors involved in activities related to, residential, commercial, and industrial buildings throughout the building's life cycle.

To address our research question we followed a three-step procedure. First, to identify digital technologies in the building industry, we conducted an exploratory literature review, complemented this review with expert interviews, and surveyed additional 20 industry experts asking them “What are the most important digital trends that have emerged in the building industry the in past years?” Through this process, we identified 29 digital building technologies frequently discussed in both the academic and practitioner literature.

Second, to understand the technological, managerial, and regulatory challenges associated with digital trends in the building industry, we distinguish *complementary* from *platform* technologies and *software-based* from *cyber-physical* digital building technologies [5, 11]. Whereas complementary technologies directly execute specific tasks without coordinating detached subsystems, platform technologies integrate multiple complementary technologies and peer-users via shared databases and standardized interfaces. Additionally, software-based technologies have no direct link to the physical infrastructure. In contrast, cyber-physical technologies [9] combine digital and physical properties and carry out specific tasks by either using digital data as input to execute a physical task, or generating digital data as output of a physical environment [11, 12].

Third, to provide insights into the technological features and implications for industry of digital trends in the building sector, we assessed each of the 29 digital technologies along five dimensions: two technology-related dimensions and three industry-related ones: (1) the maturity level of each digital building technology (i.e., technology in development, emerging technology, state-of-the art technology, or industry-wide standard); (2) the *general-purpose digital technologies* a building technology draws on (i.e., cloud computing, IoT, Big Data, AI, mobile technology, mixed reality, Blockchain); (3) the primary impact area (i.e., efficiency, productivity, safety, quality, transparency, convenience, sustainability); (4) the building life-cycle phase in which a technology is primarily applied (i.e., planning phase; construction phase; use/ operations phase, or end-of-life phase); and (5) the primary industry actors affected by a technology (i.e., investors, planning offices, architects, construction companies, suppliers, utilities, or end-customers).

To ensure the robustness of our findings we pre-tested all dimensions (including the labels and parameter values) for clarity and consistency, asked several experts to assess and code each technology along the five dimensions, and compared their answers for levels of agreement/ disagreement and discussed diverging perspectives to converge and agree on a common understanding of the dimensions.

3. Digital building technologies

Among the 29 digital building technologies, we find a variety of digital technologies currently penetrating the industry. Table 1 draws a typology of four distinct types of digital building technologies and categorizes the 29 digital building technologies. The specific digital building technologies differ markedly in technology- and industry-related aspects. We first provide an overview of the four types of digital building technologies and subsequently discuss important aspects for each type separately.

Software-based complementary technologies are apparently more mature than any other type of digital building technology. In fact, both types of complementary technologies have a lower variance in maturity levels between the technologies in each category, suggesting that technology development and commercialization of complementary technologies follows a more coherent pattern. In contrast, the high variance among platform technologies reflects the substantive challenges in developing and commercializing digital platform technologies. The four types also differ in how extensively they draw on general-purpose digital technologies. Software-based technologies only rarely draw on general-purpose digital technologies. In contrast, nearly all cyber-physical building technologies involve underlying digital technologies, in particular automation, IoT and cloud computing. These differences in technology-related factors directly translated into challenges associated with R&D and with successfully commercializing technologies. Software-based complementary technologies are comparably easy to develop and commercialize. Yet, as reflected in the reliance on general-purpose technologies, technological complexity increases with the shift from software-based technologies to cyber-physical technologies and from complementary to platform technologies.

Table 1. Types of Digital Building Technologies, incl. the number of technologies in each type.

	Complementary technologies	Platform technologies
Cyber-physical technologies	**Cyber-physical complementary technologies (#9)** (1) Laser scanning; (2) automated prefabrication; (3) radio tracking devices in operation; (4) on-site drones (construction) (5) on-site robotics (construction); (6) predictive maintenance; (7) 3D printing (on-site); (8) 3D printing (off-site); (9) augmented reality (operations)	**Cyber-physical platform technologies (#7)** (1) Cloud-based logistic platforms; (2) sensors/ monitoring building data; (3) building automation; (4) optimization of building functions; (5) smart-building systems; (6) connectivity of building to infrastructure; (7) automated building condition analysis
Software-based technologies	**Software-based complementary technologies (#5)** (1) Computer-aided design; (2) logistic management software; (3) parametric design; (4) building performance simulation; (5) virtual reality in design and planning	**Software-based platform technologies (#8)** (1) Digital documentation; (2) Enterprise-Resource Planning; (3) Closed BIM 3; (4) E-Business & tendering; (5) mobile technology in project coordination; (6) customer service automation; (7) block chain in project documentation; (8) open BIM

Regarding industry-related aspects, digital building technologies primarily improve transparency, quality, and productivity; and although their potential to improve energy- and sustainability of the built environment, these improvements occur only indirectly. Moreover, the impact of cyber-physical building technologies appears to be more evenly distributed than that of software-based building technologies. Moreover, whereas software-based platform technologies are applied across all building life-cycle phases, from planning to end-of-life, cyber-physical technologies are used almost exclusively during construction (complementary ones) and use (platform ones) phases. Relatedly, while architects mainly focus on software technologies, construction companies and planning offices deploy both software and cyber-physical technologies. Investors primarily use software-based platform technologies, while end-customers and utilities cyber-physical platform technologies.

Overall, digital trends in the building industry appear in a variety of technologies that differ in maturity levels, underlying general-purpose technologies, impact areas, building lifecycle phase and affected industry actors. As the following subchapters will show, distinguishing complementary from platform technologies and software-based from cyber physical ones helps outline important differences in the technological and managerial challenges associated with digital building technologies and understand the disruptive impact these technologies may have on the structure of the building industry.

3.1. Software-based complementary technologies

Software-based complementary technologies account for the highest maturity levels among all types of digital building technologies. Most technologies are state-of-the art technologies or have already become a standard across the industry. Software-based complementary technologies also account for a comparably low technological complexity as they do not rely on large database architectures and rarely draw on general-purpose digital technologies. For many years, R&D among software-based complementary technologies has been rather incremental as technology providers have primarily focused on developing updates, adding new features, and have only recently drawn on cloud services and developed platforms to connect complementary technologies (e.g., see Microsoft 365 [13]).

For technology providers, key success factors are a detailed understanding of the working processes in which their technology will be used and development of intuitive user experiences and design [14]. Key users in the building industry are architects and planning offices, occasionally construction companies, to facilitate the designing of buildings (elements) and to improve the process efficiency during planning and construction (e.g., facilitating transactions, supporting design, visualizing tasks). Because software-based complementary technologies are stand-alone and task-specific, they rarely require substantive changes to the organization and are thus easily implemented and do not require alignment with partners, suppliers, or customers. Moreover, the economic benefits are readily apparent and explain why these technologies are already widely applied in the building industry.

Yet, despite the maturity of software-based complementary technologies, many industry actors still lack the expertise in handling and using them [15]. The implementation of software-based complementary technologies requires adequate training of employees. Frequently, developers offer trainings to support the transformative process of implementing software in daily working routines. Ultimately, software-based complementary technologies help actors in the building industry develop first IT capabilities and are thus an important route for companies to remain competitive in the market.

3.2. Software-based platform technologies

In contrast, the maturity of software-based platform technologies varies substantially. Whereas some digital building technologies (e.g., ERPs) are already widely dispersed, others (e.g., block chain in project documentation) remain in development. Software-based platform technologies can be found in all life-cycle phases of a building and all industry actors are potential technology users. They primarily foster transparency, thus directly addressing a major barrier for modernization in the building industry.

Platform size primarily explains differences in technological complexity, market penetration, and experimentation with new general-purpose technologies. Complexity increases with volume and heterogeneity of data and users; the more users, the more attractive for technology developers to experiment with general-purpose technologies [16]. Additionally, software-based platform technologies offer opportunities to collect valuable data to generate additional revenue streams, and thus offer substantive indirect benefits to platform owners.

Yet, successfully commercializing software-based platform technologies is subject to network effects, i.e., the value for one peer in the network increases with the number of peers. These network effects are particularly strong in market place platforms and can lead to two problems: a “cold start” problem (i.e., early adopters enjoy only few benefits and have little incentives to join) and a winner-takes-all markets that while highly beneficial to platform developers pose risks to early adopters.

These challenges may also explain the rather reluctant and uncoordinated adoption of software-based platform technologies. Improvements in transparency may require adopters to disclose valuable information (e.g., sub-contractors, technical processes). Moreover, the new role of the network operators may also give substantive powers to individual companies. Finally, the competitive dynamics around software-based platform technologies, as for example among BIM solutions [17], may drastically change the building industry as increased transparency may oust certain industry actors and competences in handling platforms may qualify for joining building projects. Notwithstanding these barriers, software-based platform technologies are key to a more sustainable built environment. Not only do the offer direct contributions through increased transparency. More importantly, by digitalizing processes, structures, and plans, software-based platform technologies often constitute the first step towards enabling sustainability contribution of other digital building technologies.

3.3. Cyber-physical complementary technologies

Cyber-physical complementary technologies are highly sophisticated technologies as they are designed to intervene and adapt to a building’s physical properties [7]. These technologies frequently draw on general-purpose technologies (e.g., IoT, cloud computing, AI) to connect multiple devices and recognize their physical environment. Because of the technological complexity and the need to account for the physical built environment, developing such technologies involves substantive R&D investments.

Cyber-physical complementary technologies are mainly used during the construction phase by construction companies and suppliers. Users primarily benefit because from increasing productivity in the production and construction process, improving the quality of building components, and reducing the risk of accidents because dangerous tasks can be allocated to autonomously machines.

Yet, although many cyber-physical complementary technologies are technologically ready for the market, they still account for low market dispersion [18]. One barrier may related to the substantive upfront investment for the user. Other barriers include the challenges that users face when integrating cyber-physical complementary technologies into their operations as it requires significant adjustment to established operational processes and structures. Furthermore, overcoming the communication and skill gap between technology providers and users requires significant investments in training, re-training, and hiring efforts.

Notwithstanding these barriers, cyber-physical complementary technologies promise several opportunities for new market developments. For technology providers, they offer avenues for new business models, such as product-service systems (e.g., leasing contracts based on usage), data-driven services (e.g., analyze user behavior to improve safety and efficiency in processes), or financial models (e.g., leasing, co-financing, etc.).

Overall, although the industry has only reluctantly adopted cyber-physical complementary technologies, these technologies offer opportunities for new market players to transform the building industry through new business models. By shifting investment patterns and workforce composition, they may significantly disrupt the industry with technology developers gaining prominence while threating small and medium sized companies. Most importantly, cyber-physical complementary technologies offer significant sustainability contributions in a, thus far, labor-intensive and error-prone life-cycle stage (i.e., construction) and thus deserve particular attention from policymakers.

3.4. Cyber-physical platform technologies

Cyber-physical platform technologies, such as smart building systems, require substantive sensor technologies in and around building to coordinate user behavior with building components. They also heavily draw on general-purpose technology, such as cloud computing, IoT, and AI. R&D in cyber-physical platform technologies faces both the challenges of cyber-physical technologies and those of platform technologies. R&D challenges pertain to the real-time processing of data to and to the level of process automation and sensors necessary for cyber-physical platforms. Possibly for these challenges, they remain in development and are nowadays mainly used in large public and commercial buildings.

Technology developers of cyber-physical platform technologies usually maintain ownership over platforms. However, because of the technological complexity and substantive development costs, they strongly incentivize external technology providers to develop complementary technologies, both software-based and cyber-physical ones, compatible with their platform ecosystem. Clearly, as developers seek to reach a critical mass of users to join their platforms and to create a lock-in effect, competition among developers intensifies.

Cyber-physical platform technologies appear particularly attractive entry technologies for new market players from adjacent industries, in particular technology engineering companies with experience in IoT. In fact, many non-traditional industry players with stronger ties to other sectors, such as Siemens or WAGO, entered the building industry with cyber-physical platform technologies. Similarly, many technology component manufacturers begin digitalizing their components by equipping these with IoT sensors, APIs, and smart metering technologies. Thus, cyber-physical platform technologies traditionally serve as an entry point for new market players into the building industry.

This merging of building industry with companies from adjacent industries also lead to changes in existing business models. Cyber-physical platforms also produce different revenue models depending on the service type over the building lifecycle and offer opportunities to monetize data through additional services (e.g., energy optimization, predictive maintenance, and customer / tenants services).

Overall, cyber-physical platform technologies appear particularly valuable for more efficiently managing buildings during their use phase. These technologies offer opportunities for cost savings and new revenue streams. Yet, given the challenges associated with R&D, the severe competition for platform leadership, and their limited potential to realize efficiency and productivity gains during the planning and construction phase, it remains unclear if, and if so how, cyber-physical platforms may transform the building industry.

4. Discussion

The diversity of digital building technologies is immense and although most digital building technologies are still under development, they are already beginning to fundamentally change principles of the industry. Digital building technologies offer substantive opportunities to create positive impacts across the entire lifecycle of a building. Major impact areas of digital building technologies strongly vary within the four types of digital technologies, introduced in this paper. Undoubtedly, digital building technologies help address important energy and sustainability related factors in that they offer several paths to reducing energy and material consumption, increasing energy efficiency, reduce planning errors and facilitate retrofitting and demolishing of buildings and recycling or reuse of materials. However, business models of digital building technologies only rarely address energy- or sustainability-related concerns directly, as value propositions of the four types primarily tackle the areas productivity, efficiency, transparency, and convenience. Hence, most of the benefits to sustainability accrue indirectly as secondary effects. Business models that primarily promise contributions to sustainability and energy seem to struggle in succeeding. Thus, policymakers designing incentives to move towards a more sustainable built environment require an understanding of how primary (non-sustainability) benefits translate into secondary (sustainability) impacts. Thus, although digital building technologies offer several opportunities to move towards a sustainable built environment, designing policy instruments and business models to realize these opportunities remains challenging.

To better understand the promises and pitfalls of digital building technologies, we argue it is useful to distinguish four types of technologies: (1) software-based complementary technologies, (2) software-based platform technologies; (3) cyber physical complementary technologies; and (4) cyber physical platform technologies. This typology is valuable because it illustrates differences in adoption barriers, opportunities for new business models, and the transformative capacity of digital building technologies.

In particular, software-based platform technologies and cyber physical complementary technologies offer promising new business opportunities and may fundamentally disrupt the industry. Software based platform technologies do so by increasing transparency and inducing a stronger focus on the planning phase thereby shifting the traditional distribution of roles and responsibilities in the industry. By promising to reduce planning errors, software-based platform technologies offer vast secondary sustainability effects. They will also raise the entry barriers for traditional building companies while offering an attractive entry point for new industry players. Overall, software-based platform technologies may lead to a significant consolidation in the building industry.

In contrast, cyber physical complementary technologies, primarily applied during construction of buildings, promise significant improvements in productivity and safety, and, as a side-effect, reductions in resource and material consumption. Additionally, for design and aesthetic purposes, cyber physical complementary technologies offer many opportunities to provide large-scale customized buildings, thereby offering an attractive path towards a modular built environment. However, these major benefits come along with at least one major challenge for policymakers. The immediate automation of production and construction processes renders futile many traditional employments and occupations in the building industry. Prefabrication and on-site robotics may eventually replace many workplaces in the industry and shift demand for labor-intensive work to assisting, controlling, and supervising machines.

Thus, digital technologies in the building industry have important implications for business models and the industry structure. First, future business models draw more heavily on services and data analytics, especially in the case of cyber-physical technologies. Furthermore, owners of platform technologies may monetize platform-based market access for 3rd parties [19]. This shift will clearly change the business models of companies in the industry. Moreover, the deployment of platform technologies may disrupt the underlying structure of the building industry by developing stronger linkages to other, adjacent industries (e.g., energy, mobility) and by changing the composition of the building industry. Thus, digitalization will not only lead to more digital building technologies but also, more importantly, will help integrate buildings into a broader, cross-sectoral environment.

Second, the increasing concentration in market power and the changes in the skills necessary to continue participating in building projects should lead to a strong consolidation in the building industry. Larger corporations with the ability to establish platform technologies and to invest in cyber-physical capital will have an advantage over small and medium-sized companies (SMEs) with fewer resources. As a result, SMEs might not only lose market power but also be outdistanced in terms of experience with digital technologies. Thus, digitalization poses a severe challenge in particular to SMEs.

Third, digital building technologies will have a strong influence on the employment conditions and the labor market of the building industry. Especially cyber-physical technologies significantly reduce labor intensity of construction sites. On the other hand, skill requirements for the effective deployment of digital building technologies constantly increase. Digitalization of the building industry will thus most likely lead to a substantial reduction and upskilling of labor force in the building industry. This trend will challenge companies (e.g., construction companies) to find ways to smoothly transition from a company with many employees to one with only few, highly skilled ones. Additionally, given that the building industry is major employer for low-skilled jobs, the labor market effects of digital building technologies should be more pronounced in the building industry than in other industries. Thus, policymakers should not only consider how to support the digitalization of the building industry but should also devise approaches for absorbing the negative side effects on the labor market.

Abstract. Important amounts of construction and demolition wastes (CDW) are currently generated in several countries. Considering the correct management of this kind of residue, and the search for its noblest use, several studies have focused on the environmental potential impacts from CDW management. Life Cycle Assessment (LCA) is often used to investigate the potential environmental impacts over the life cycle of a product, thus becoming an important tool to support decision-making. CDW recycling process produces coarse, fine and mix aggregate as outputs, characterizing a multifunctional process. But, how CDW's LCA should be run, considering a circular and more sustainable built environment? Thus, the objective of this work is to explore the basic premises in proposing a product system for the CDW recycling process in Brazil. For this, data available in the literature on the recycling process in Brazil and in other countries support the definition of the product system. The complexity of this management option is explored, considering how the use of the recycled materials interfere in the scope, objective, unit function and other modelling choices, as well as reliability of CDW studies. Finally, the datasets provided by Ecoinvent are examined in order to promote debate on data adaptation, followed by remarks on the most appropriate choices on allocation in the CDW LCA. The cut-off system modelling associated with the new perspective on the avoided burden approach is concluded by the authors to be the most suitable for this waste recycling multifunctional processes. Understanding system models is key. When no inventory adaptation is intended, available inventory datasets are more advisable to be used when performing end of life scenarios only, once burdens differ according to countries management scenarios, as well as life cycle inventory approaches.

1. Introduction

The construction industry plays an important role in society. The processes of urban expansion or connection between cities demand the construction of buildings, residences, paving and urban maintenance, roads, train lines, among others.

The execution of engineering works requires the use of natural resources, such as coarse aggregates. Brazilian aggregate consumption in 2014 was 741 million tons, of which 302 million tons correspond to the consumption of natural coarse aggregates (NA), from 4.74 -19.1 mm. The potential per capita demand for aggregates for Brazil in 2014 was 3.7 tons, still lower than European Community (5.2 tons), USA (9 tons), China (12 tons) and Finland (17 tons). The Brazilian regions that consume the most natural aggregates are Southeast (47%) and Northeast (21%), followed by South (16%), Central West (9%) and North (7%) [1].

Associated with this large amount of natural resources extracted, there are potential environmental impacts that must be considered. The assessment of potential environmental impacts should serve as a basis for decision-making in actions to make building processes more sustainable.

The aggregates from construction, maintenance and/or demolition stages of construction works, called recycled aggregates (RA) from construction and demolition wastes (CDW), can be considered as potential surrogates for NA, observing their environmental viability, in addition to performance and costs.

The use of the Life Cycle Assessment (LCA) in a study of CDW recycling scenarios has gained attention, with growth in the number of publications in recent years [9] [21]. The definition of the product system in these studies, however, lack the application of concepts, such as allocation, multifunctionality of processes, system models and among others.

Thus, the objective of this paper is to explore the basic premises in proposing a product system for the CDW recycling process in Brazil. For this, data available in the literature on the recycling process in Brazil and in other countries support the definition of the product system. The system models proposed by Ecoinvent and background data available by the database are observed. Available data in the Ecoinvent are suggested as background data, considering the cut-off system modeling associated with the new perspective on the avoided burden approach, suitable for the multifunctional process.

2. Method

A literature review on the topics was conducted in other to add information into the product system definition, as well as system modeling choice to conduct LCA studies for CDW management. The first stage consists of a literature review on the existing research models. Secondly, an analysis of the CDW market in Brazil is presented as a case study. The product system is then defined. Finally, the datasets provided by Ecoinvent are examined in order to promote debate on data adaptation, followed by remarks on the most appropriate choices on system model and allocation in the CDW LCA.

3. Life Cycle Assessment and Construction and Demolition Waste

Bovea and Powell [21] showed growth in researches of LCA of CDW between 1999 and 2015, in consequence of European directives and ISO 14040 series standards. Yet, most CDW LCA studies present a lack of information about the system model adopted in the calculations, among others [22][23][24].

In a recent literature review [22], the authors identified a total of 91 published researches on LCA of CDW. Most of the reviewed researches focus on the cradle-to-grave analysis of buildings, considering the waste management into the EoL scenarios after demolition. Although the analysis are reasonable for EoL scenarios, there is a misinterpretation of the term “construction and demolition waste” management once most papers assess only demolition wastes. Moreover, the majority of the research papers assess the EoL for a variety of materials, as a result of the entire building demolition. The EoL inventory and processes are rarely detailed, however, several scenarios were assessed, as re-use, recycle, landfilling, incineration and composting for wood material.
Only 5% of the researches informed the life cycle inventory (LCI) analysis’ modeling approach. Considering that the recycling of CDW for RA production is a growing market for substitution of NA, the modeling approach could reflect a significant difference in the impact results, e.g. for natural resources depletion. Systems with high recycling rates have the choice of the system model adopted as a key factor [25].

Besides the studies, the treatment in waste management is strongly addressed in an update of the System Models carried out by one of the most worldwide used databases, Ecoinvent. In its version 3, in addition to the introduction of the Consequential approach, the attributional approach is presented in two system models, allocation at the point of substitution (APOS) and Cut-Off. In the cut-off model, for example, all intermediate exchanges (i.e., exchanges within the technosphere) are classified into either “allocatable by-products”, “recyclable materials” or “wastes”. The classification is based on the expert judgment of an exchange’s value, use potential, and predicted fate [25][26]. Depending on this classification, byproducts (i.e., products that are not the reference flow) in multi-functional activities are handled differently [25][27][28][29][30].

4. Brazilian CDW Market

The literature review showed that most of the LCA application to CDW management is connected to the building's LCA. However, the market for this kind of waste still developing and information is needed to support decisions related to CDW recycling.

4.1. Source and composition of the Brazilian CDW

CDW is a generic term that defines the waste generated by the economic activities involving the construction, maintenance, demolition and deconstruction of buildings and civil works [2]. The CDW can be generated in activities like construction and demolition of buildings and infrastructures, roads and their maintenance, disaster debris, among others. Data available from Brazil suggest a higher generation of new reforms and repairs, followed by new constructions, reaching 76% and 67%, respectively, of the total CDW in some important Brazilian cities [3][4][5][6][7]. According to the same sources, another significant source of CDW in Brazil is demolition, although this does not represent 50% of the CDW in any evaluated city.

In a previous work [9], a systematic review identified that in the average composition of Brazilian CDW, the most representative materials are concrete, ceramics and mortar (Figure 1). However, the amount (in %) of each material may vary considerably.

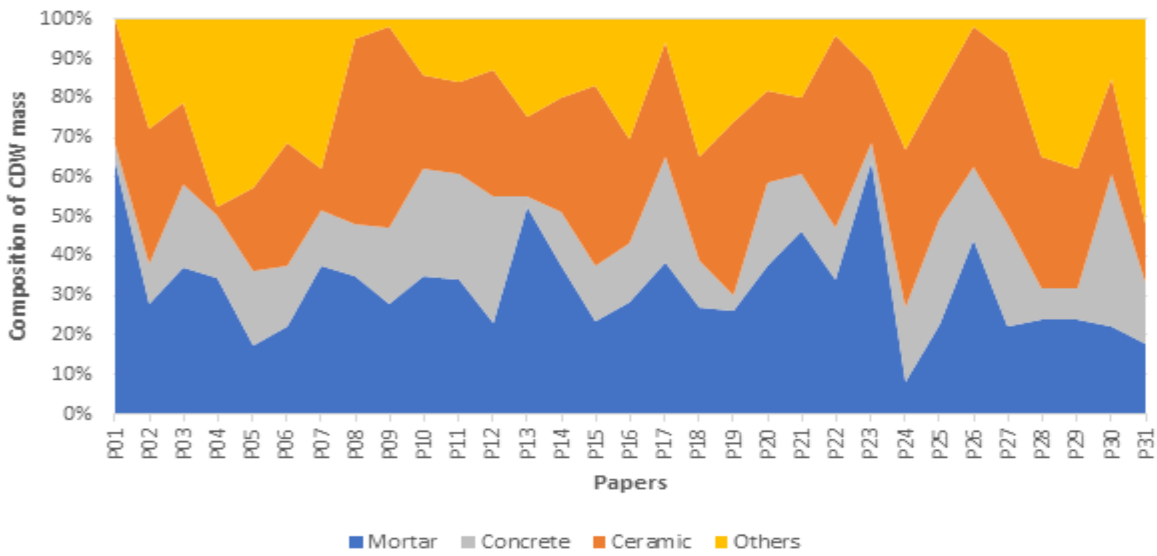

Figure 1. The composition of Brazilian CDW from 31 papers published available in a systematic review realized [9].

4.2. Future use and RA performance

RA is a coarse material derived from the beneficiation of CDW. The use of RA in concrete has still some technical limitations since their performance varies depending on the source material and its properties, such as compressive strength, shape, abrasion resistance, presence of cement incompatible materials, among others. Associated to this, there is a low level of confidence on the mechanical performance of the concrete with RA when compared to the concrete composed by NA, a commonly used material with known properties.

Although concrete applications are the noblest, the use of RA as sub-base materials for roads, backfilling and maintenance for unpaved roads, and higher grade applications (e.g. aggregate for new structural and non-structural aggregate) also has a high potential. However, assuming that the product complies with high-quality standards, the use of RA in structural concrete manufacture is widely accepted in the scientific community as an alternative to replace NA [10][11][12][13].

According to Gálvez-Martos et al. [15], RA from mixed wastes, usually with a minimum of 50% concrete content, can be used for buildings and other civil works, for non-structural concrete.

Cabral [11] generated a series of models to simulate properties such as compressive strength (fc) and demonstrated that the partial replacement of NA by RA can achieve the same compressive strength of concrete composed in 100% of NA, when adjusting water/cement ratios.

Figure 2 shows the main impediments in the reuse of the Brazilian CDW, mainly related to composition and quality, available technology and market of RA. Positive issues that need to be highlighted for the purpose of expanding recycling of Brazilian RCDs are also described in the same figure.

STRENGHTS	WEAKNESSES
❑ Reuse of an inert material; ❑ Reduction of landfill / uneven disposal; ❑ Reduction of natural resource consumption (NA); ❑ National Policy on Solid Waste; ❑ Seek for nobler uses; ❑ New marking opportunity.	❑ Residue of very diverse composition; ❑ Existence of impurities of other materials with the CDW; ❑ Poor quality of the material; ❑ Unknown performance; ❑ High NA availability in most regions; ❑ Low-tech recycling plants; ❑ Lack of established market; ❑ Distance of collection/delivery *vz.* distance from NA mines.

Figure 2. Strengths and weaknesses related to CDW recycling in Brazil, based on [7][12][15][16][17][18][19].

4.3. Growth and economic representativeness of CDW in Brazil

There is no consolidated information available on the CDW market or its economic representativeness in Brazil. In 2014, construction consumed 811 million tons of cement and natural aggregates [1], thus considering the generation of the residues only in the construction phase, an important market can be exploited. In addition to these values, we must consider the waste generated in renovations or demolitions, the main CDW generators in Brazil [3][4][5][6][7].

According to Brazilian Association of Public Cleaning and Special Waste Companies - ABRELPE [20], the Brazilian municipalities collected about 45 million tons of CDW in 2017, an average of 123 thousand tons of CDW per day or 600 g.person-day. Although the RA market is not yet exploited, there are still some challenges to overcome. The latest sectoral research by the Brazilian Association for the Recycling of Civil Construction and Demolition Waste [17] shows an optimistic perspective based on the capacity of treatment plants in operation. Over 52% of plants have a nominal capacity to produce up to 3000m^3/month, and another 31% over 10,000m^3/month. Still, until 2015, only 11% of those operated with full production. At the time, 93 plants were producing around 431,500 m^3 of RA per month, while the total installed capacity was 958,000 m^3. Moreover, the research also showed that RA price is up to R$20.00 per m-3 (around US$ 5 per m-3).

Considering the total generation [17] and the maximum total production capacity of the mills [20], it is possible to infer that only 0.5% of the total CDW generated per year in Brazil is recycled, the other 99.5 % is mainly destined for landfill. Thus, the installed capacity of CDW recycling plants is underappreciated but still much below CDW availability.

In 2009, Miranda et al. [7] have already identified the basic structure available in the Brazilian recycling plants: loader or backhoe, vibrator feeder, conveyor belt, jaw crusher or impact, permanent magnetic separator or electromagnet, and vibrating screen. In this way, the material is comminuted and separated by size without any quest to improve its quality. Thus, the final product carries characteristics equal to the input material.

5. Proposal of Brazilian CDW product system and modeling approach

The results from the Literature review are summarized in the proposed product system for the Brazilian market (figure 3). The figure shows the potential input wastes according to Brazilian classification and the path to be followed by the waste until the output for the recycled products, using the waste concrete gravel as the desired RA output. The dotted line in the system represents by-products. The dashed line that separate flows represent the change on waste management responsibility (from construction managers to recycling plants' managers), also representing a monetary change between stakeholders (the waste disposal or recycling services). The authors suggest that to avoid misinterpretations on the allocation for recycling product, when the recycling processes depend upon a tertiary service, the recycling process should be treated separately from the construction and demolition process, and to the future use, and only further connected to them.

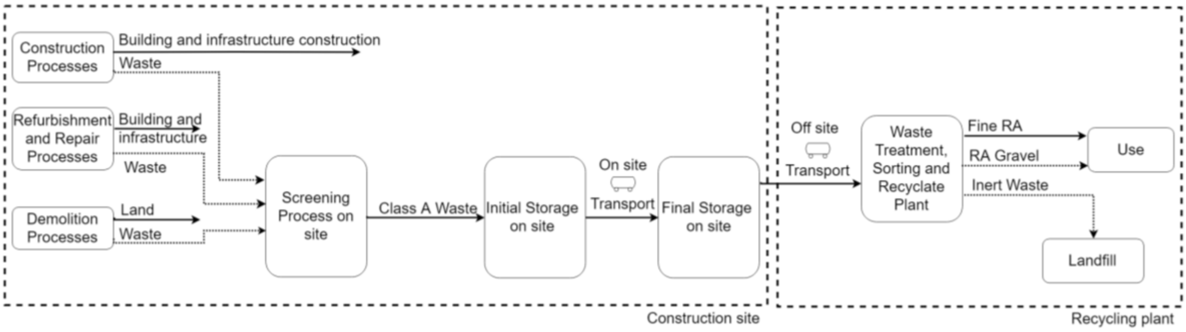

Figure 3. The potential input wastes according to Brazilian classification and the path to be followed by the waste until the output for the recycled products, using the waste concrete gravel as the desired RA output.

From there, the questions that arise are: how to allocate environmental impacts, from an LCA perspective, in this system? Should burdens from waste management be allocated to waste provider, or to the disposable and recycling services? And how to represent avoided burdens from recycling to the consumers of the recycled materials? These questions concerned the following discussion of approach and decision while modeling an LCA on CDW management. As well as the definition of the proposed product system for the Brazilian CDW recycling scenario, the definition of the system model and allocation should be considered since it is a multifunctional process.

5.1. The Ecoinvent® database and the CDW EoL

The Ecoinvent database provides data, generally generic and average data, that can serve as a background in defining or adapting datasets. The dataset regarding the recycling of CDW, for example, has its origin in Switzerland. According to the "Life Cycle Inventories of Waste Treatment Services" report from Ecoinvent® [31], there are three main disposals/recycling of CDW options in Swiss, direct recycling, partial recycling after sorting, and direct final disposal without recycling - represented in the Figure 4 as "A", "B" and "C", respectively.

The inventory distinguishes the construction materials according to the recyclability, for example, those destined for recycling and those destined for disposal in a landfill. No distinction is made between different building phases source of wastes (construction, refurbishment, and repair or demolition), and all datasets consider the same demolition energy within the system boundaries. Thus, CDW is only originated from the demolition stage, diverging from the Brazilian reality.

Following the methodology provided by Ecoinvent® [31], no bonus or burden compensation are given for recycling material, on the versions preview to v. 3. No partial allocation of burdens from recycling processes to the first product and recycled products were made. Instead, the system boundary for both "A" and "B" disposal options does not include the recycling process, but includes sorting plants and the disposal of non-recyclable material. In this sense, waste concrete gravel, for example, does not include the recycling plant burdens, once the data "cut-off attributes all further processes (transport, sorting, recycling, etc.) to the recycled product consumer and not to the first user of the (raw) material" allowing, in this way, to conclude that the data is directed towards the end of life of the building.

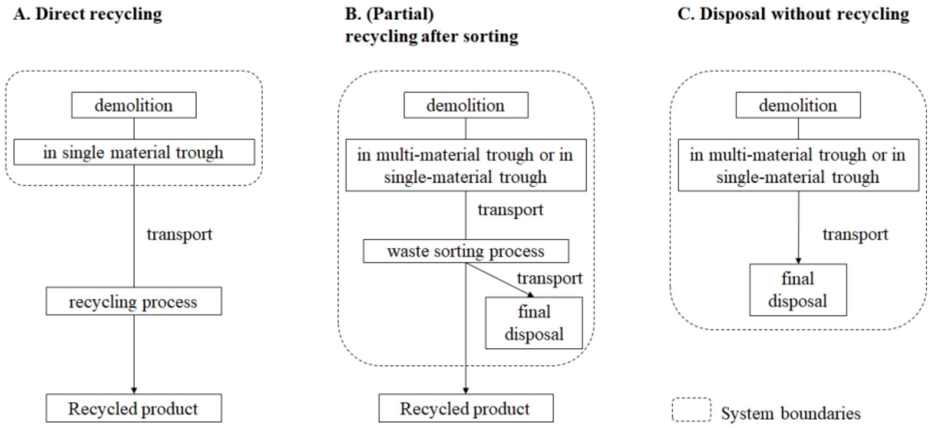

Figure 4. System boundaries of the three types of CDW disposal options according to Doka [31].

5.2. A new perspective in LCA of CDW management

According to Baumann and Tillman [32] the allocation problem happens in three basic cases: (I) when processes result in several products, meaning multi-outputs; (II) waste treatment processes that have different input sources, meaning multi-inputs; and (III) open loop recycling, meaning that a product is recycled into a different product, which implies that they share common activities, as the extraction of the virgin materials. The allocation can be avoided in the two first cases by detailing the model, but it is not true for the third case. Baumann and Tillman (2004) indicate the procedure to be adopted is either allocation through partitioning or system expansion. Partitioning would be applicable to traditional attributional LCAs, as the system expansions would work better to LCAs modeling effects of changes (consequential).

In the case presented on CDW recycling market in Brazil, the three allocation problems are observed, due to multi-inputs (construction, demolition, refurbishment, etc.), multi-outputs (different class of residues), and to the fact that the recycled products as concrete gravel have an open loop recycling process.

Also, the replacement of NA by RA is not expressive in the Brazilian market due to the lack of offer (low recycling content rates). Thus, the consequential approach based on Ecoinvents datasets wouldn't be appropriated in this case, once it would take a long time or an extreme change in CDW management policies so that the replacement affects NA market. In this last case, the consequential approach would feature the potential effects of RA use in the new constructions. Moreover, a system expansion would be needed, and the other materials recycled included as by-products in the same process, which is not integrated into the Ecoinvent consequential datasets.

That being agreed, the attributional approach would then be used with the need for an additional allocation procedure. Among the literature, Saade [33] presents a new approach to the decision-making process by the co-product user industry. Some factors contributed to the definition of this new approach, such as: the inadequacy associated with the use of the most common allocation criteria (mass and economic value), where the scarcity of virgin raw material is replaced by the co-product and benefit of the recycling of a co-product to the detriment of raw material consumption; the avoided impact approach, as typically adopted, fails to distribute the benefit fairly, since the environmental burdens that cease to exist with the replacement of virgin raw material by the co-product are reduced in their entirety from the multifunctional process which generated the co-product without considering, for example, the impacts associated with the processing of the co-product, avoided loads (eg end-of-life) and other results for co-product reuse. The author then proposes an alternative manner of calculating the avoided impact. This proposed approach consists of adding or subtracting from the avoided impact associated with the replaced product, all potential loads caused and/or avoided by the replacement. The net avoided impact is then the avoided impacts from the substituted product (value given by conventional allocation), minus the impacts associated with the processing of the by-product or waste, and other burdens from the recycled material life-cycle until its uses (such as transport), plus the impacts associated with the business as usual (BaU) final disposal of the waste [33]. Thus, it is possible to evaluate the environmental viability of the recycling process.

In the case of CDWs, the use of RA minimizes the potential impacts of NA extraction that is not extracted. Then, first the environmental load of the amount of NA that can be substituted by the RA in the assessment inventory should be considered as negative inputs. Secondly, there are impacts through the CDW beneficiation process, mainly related to transportation of waste and distribution of the recycled material, and electricity consumption for the comminution process. Those would be considered as positive inputs. Similarly, within the approach suggested by Saade [33], are considered the negative input the not disposing of the waste. In this case, BaU scenario would be the landfilling, and the recycling or reuse of the material would also represent avoided burdens.

6. Final remarks

According to the system resulted from the literature review, the background databases and literature reference may be used for analysis with some regards.

The first important issues to pay attention is the objective of the analysis and boundary of the system to be analysed. The review made in this study, as well as the guidelines for calculation method on assessment of the environmental performance of buildings in the BS EN 15978:2011, might suggest the differentiation of two types of analysis regarding the CDW: the EoL scenario for construction demolition, and CDW recycling and reuse analysis. Both are not mutually exclusive. One may carry an analysis of EoL scenario for one building and include the recycling and reuse avoided burdens (Module D, according to EN 15978). However, the analysis does not exemplify the market for recycled construction materials, once it would be representing only that demolition waste portion of the market. For analysis considering the recycled materials, the origin and composition are meaningful for the inventory of sorting and recycling process, and the intended use is critical regarding the rates of recycled content use.

Regarding Ecoinvent® datasets, some inputs need to be removed during inventory adaptation because they are not part of the analysis by the system model and product system suggested for the Brazilian scenario. Considering the recycling market, the construction waste burdens would be spared. As previously discussed, in developing countries these burdens could be significant, due especially to the transport of waste. Adjustments of the current data available are necessary in order to reflect the scenario of the CDW Brazilian recycling management and plants. Following the discussion made, these datasets are more advisable to be used when performing EoL scenarios only. RA, for example, is not a co-product of construction, however, the avoided burdens should be accounted when performing new constructions or materials LCA with recycled content. Local inventories should be used when analysing these avoided burdens.

The characteristics adopted by the systems models currently available in the Ecoinvent® database suggest that the adoption of the cut-off system is the most appropriate, and it is possible to combine this system model with the new approach proposed by Saade [33] in order to consider the potential impacts avoided serving as an incentive to the recycling process. With such integrated modelling, all life-cycle process of waste recycling is added to the environmental avoided impacts. The integrated modelling can then represent a better approach to the realistic benefits of recycling.

The identification and availability of information on the representation of CDW recycling in the Brazilian economic scenario may, together with the inventory of other information, corroborate with the elaboration of market data for Brazil.

Abstract. In the upcoming decades, cement production growth is expected to exceed the increase in availability of clinker substitutes. Increased clinker replacement rates in cement and use of alternatives fuels were pointed out as the main alternatives for reducing emissions of the national cement industry, whilst increasing cement production in 2050. Consequential life cycle assessment (CLCA) offers a framework to capture environmental consequences from demand alterations. Modelling the cement production and markets involved is however challenging, given conceptual (only unconstrained markets are considered) and practical modelling limitations (e.g. model granularity compatible with CLCA interests). This paper refers to an ongoing work and adopts a two-stage approach to discuss the effects of the change on the average cement production process in Brazil. We first performed a CLCA without formal affected market identification to estimate the potential environmental impacts of the technology change proposed in the Brazilian Cement Technology Roadmap. Secondly, we used a Computable General Equilibrium (CGE) Model of the Brazilian economy to (more) realistically foresee short-term effects induced by such change. The CGE model comprises 102 economic activities, including cement production and its production chain. Our results indicate that (i) increasing the proportion of calcined clay and limestone filler as clinker partial substitutes and (ii) excluding charcoal from the fuel mix composition at the kiln would impact all economic sectors. Our preliminary findings suggest that the increased efficiency in cement production would create some rebound effect that would not invalidate the emission benefits from displacing energy and virgin materials. Additional impact categories and consequences in other economic sectors should be further investigated.

1. Introduction

The recovery of the Brazilian economy from its current recession, and subsequent GDP growth plus the infrastructure and housing deficit should drive up cement demand steadily from 2020 to 2040. According to the Cement Technology Roadmap for Brazil [1], the production is expected to reach its peak in 2045, should it follow a high- (170Mt) or a low-demand variant (127 Mt), considered more realistic. Such long-term growth poses a considerable challenge to the Brazilian cement sector in terms of energy demand and CO_2 emissions.

The cement manufacturing industry is one of the five most energy intensive sectors in the world. Typically, 30% to 40% of the direct CO_2 emissions result from burning a mix of fuels, whilst 60% to 70% are produced by the chemical reaction that converts limestone into calcium oxide (calcination) to form Portland clinker. Additional indirect 5% of CO_2 emissions result from electrical consumption by the industrial plant. Whilst the calcination contribution (63%) and the burning of fuels (36%) are within world average emission ranges, indirect emission from electricity consumption in Brazil is only about 1%, due to its distinguished, highly renewable (>70%), electricity matrix.

In 2014, the Brazilian cement industry utilized 1.5 million tons of waste (8%) and biomass (7%). At the current level of thermal substitution, the remaining 85% of the fuel mix is fossil-based, mostly petroleum coke (petcoke). These figures show potential for increased use of biomass and waste - including municipal solid waste - as fuel, given the favorable characteristics cement kilns offer to coprocessing - i.e. combined operation of manufacturing cement together with the burning of waste – favoring impact reduction from otherwise inadequate disposal of waste in nature [1].

Simulated contribution of non-renewable fossil fuels in cement production could diminish from 85% to 45%, due to increased share of waste and biomass in the fuel mix. Decrease in the projected thermal and electrical intensity would become more noticeable after replacement of obsolete equipment by 2030 and reach 3,2 GJ/t of clinker (92 kWh/t of cement) by 2050 [1].

The Brazilian raw material has higher magnesium carbonate content and, therefore, higher calcination factor than the world average. Still, the Brazilian cement industry has one of the lowest specific CO_2 emission levels in the world, due to mitigation actions implemented over recent decades, such as use of alternative fuels and clinker substitutes. Blast furnace slag (bfs) and fly ash have been used as additives to Portland cement for decades.

In 2014, more than 95% of granulated bfs produced in the country was consumed by the cement industry [1]. However, increased use of bfs by the cement industry is challenged, in the short and medium term, by the lower growth in supply in relation to the increase in cement production, due to the rising global competition faced by the national steel industry; and in the long term by the evolution of technological processes, with a lower production of slag per ton of pig iron produced. Fly ash shows a similar trend, due to lower investments in coal-burning thermoelectric plants, decarbonization of the Brazilian electric grid, and low utilization factor of thermoelectric plants, which was around 50% in 2013 [1].

Considering the constrained supply of the major clinker substitutes used today (bfs and fly ash) and the increased demand for cement in the long run, the Roadmap BR projected decreases in the clinker factor (proportion clinker/cement) based on increased proportions of limestone filler and calcined clay as clinker alternatives. Practical implementation of such measures still faces technical, economic and legislative limitations created by e.g. different applications of the final product, environmental regulations and technical standards, local availability of raw materials, logistics complexity and costs, contractual difficulties to ensure waste supply, and challenging performance (calorific power, high moisture and concentration of chlorine or other detrimental substances) [1]. Nevertheless, these assumptions formed the basis of our assessment.

Consequential LCA (CLCA) modelling aims at identifying the study boundaries to encompass likely consequences of an action or decision [3]. While attributional life cycle assessment focuses on describing the environmentally relevant impacts of the activities that contribute to a specific property of a product or process, consequential assessment describes how environmentally relevant impacts will, or could, change in response to the studied action or decision [5]. Attributional and consequential modelling are therefore intended to answer different questions [3]. Attributional LCI aims at answering "how are environmentally relevant things (pollutants, resources, and exchanges among processes) flowing within the chosen temporal window?" whereas Consequential LCI aims at answering "how will flows change in response to decisions"? [6].

Ultimately, the differences between attributional and consequential LCA are the result of the choices made in the Goal and Scope Definition phase of the general LCA process [5]. In order to incorporate possible consequences, CLCA models include additional economic data like marginal production costs, elasticity of supply and demand etc [4].

In CLCA, the system boundaries are defined to include the activities that change as a consequence of a small change in the demand for the studied products. To understand the potential consequences of a decision that involves the substitution of one product with another, the differences between the alternative product systems - that have the same output, fulfil the same performance requirements, i.e., have the same functional unit - are modelled [5]. Prox and Curran [5] explain the step-wise procedure originally proposed by Weidema et al. [7], which consists of: Step 1 – describing the product by its properties; Step 2 – identifying market boundaries; Step 3 – identifying product alternatives; Step 4 – defining the functional unit; and Step 5 – determining reference flows for alternatives.

The functional unit is the service delivered by the product system (i.e. it represents the meeting of the demand for an additional unit of the product under study), which provides a reference for inputs and outputs to be related. The choice of functional unit should reflect the quantity, properties, and duration of the product/service of interest. And ensure same functionality for the alternatives compared. Where it represents the meeting of the demand for an additional unit of the product under study, the functional unit does not displace any marginal product [2].

The system boundary definition determines which processes are to be included (or not) in the assessment. CLCA only considers ‘unconstrained markets’, that is, those represented by determining products. A determining product is defined as a product for which demand is directly linked to its production. Contrastingly, a co-product is said to be dependent when demand for it has no influence on its production. Such ‘constrained markets’ are excluded from the CLCA system boundary. Also, CLCA should only include the activities that change as a response to an additional demand for the functional unit, and the corresponding marginal effects, i.e. the effects that take place *in addition to* what would have happened without an increased demand for the functional unit (*ceteris paribus* principle), displacing e.g. marginal virgin materials and energy flows [2].

This paper aims at assessing the environmental consequences of the proposed change for the cement production technology in Brazil, by identifying the reference flows for alternative energy and virgin materials whilst offering wider consideration of reflections on other productive sectors. Our baseline was the production system in 2014, modified by incorporating fuel mix and cement composition projected by the Roadmap BR for 2050.

2. Method

We followed a two-stage approach to discuss the effects of the change on the average cement production process in Brazil. We first perform a CLCA without formal affected market identification to estimate the potential environmental impacts of the predicted change by solely using data published in the Roadmap BR [1]. Secondly, we used a general equilibrium model of the Brazilian economy (Section 2.5) to (more) realistically foresee which short-term effects are induced by this change.

Our CLCA was conducted following the ISO standards. First, the goal and scope of the study are outlined, to set the context for the study and ensure that the outcome is consistent with its objectives. The adopted functional unit provides a reference for inputs and outputs to be related. The corresponding system boundary is described separately below. SimaPro 8.5 supported the assessment. The inventory that reflects the studied system is composed by primary data for the clinker production (foreground), and secondary data from the Ecoinvent v3.4 database adapted to the Brazilian energy mix (background). Finally, the environmental implications were reviewed in the impact assessment step using CML-IA baseline v3.05, and the results were interpreted and iteratively revised.

The goal of our CLCA was to estimate the potential environmental impacts of the decision to implement two major technology changes in the Brazilian cement production process projected for 2050 described in the Roadmap BR [1]: change in cement composition (route 1) and change in the fuel mix used (technology route 2), relatively to cement production as per 2014 (baseline).

Key to defining the scope of CLCA is an endeavour to foresee what changes are induced by implementing the decision under assessment. The geographical scope of this assessment is Brazil, which defines the related legislative, political, and market contexts important to determine the marginal processes and technologies affected by the changes in demand analysed. The technological scope refers to cement production as per 2014 (baseline) and the same production capacity but after the technology changes considered. The temporal scope of the assessment is 2014-2050. Long term, investment-intensive route 3 (carbon capture and utilization or storage - CCUS) is not included in this study. Therefore, the time horizon refers to short term marginal effects (‘operational margin’). This means that existing capacity can absorb the shocks of changes in demand for the functional unit and only changes in the utilization of existing production capacity are considered.

Table 1 summarizes characteristics of clinker and cement production as per 2014 (baseline) and after technology changes projected for 2050.

Table 1 - Characteristics of cement production as per 2014 (baseline) and after technology changes projected for 2050 [1]. Determining and dependent products as indicated.

1 t of (average) cement 2014 (baseline) Inputs	**1 t of (average) cement 2050 Inputs**
3,5% gypsum 1% other	3,5 % gypsum 2% other (+1%)
14% ggbfs (dependent) 3% fly ash (dependent) **3% calcined clay (determining)** **8% limestone filler (determining)** **68% clinker (determining)**	11% ggbfs (-3%) (dependent) 2,3% fly ash (-0,7%) (dependent) **4% calcined clay (+1%) (determining)** **25% limestone filler (+17%) (determining)** **52% clinker (-16%) (determining)**
Fuel mix clinker (3,5 GJ) **6% charcoal (determining)** 85% petcoke (dependent) 0,7% agricultural waste (dependent) 4,6% scrap tires (dependent) 3,5% industrial blend waste (dependent)	**Fuel mix clinker (3,22 GJ)** **0 charcoal (-0,21 GJ) (determining)** 45% petcoke (-40%) (dependent) 3,7% agricultural waste (+3%) (dependent) 5,1% scrap tires (+0,5%) (dependent) 4% industrial blend waste (+0,5%) (dependent) 7,4% sewage sludge (+7,4%) (dependent) 17,4% non-hazardous waste (+17,4%) (dependent) 17,3% municipal solid waste (+17,3%) (dependent)
113 kWh average electricity demand	92 kWh average electricity demand (-21 kWh)

The defined functional unit for this study is 1 ton of (average) Roadmap BR cement technology projected for 2050. Figure 1 shows the CLCA System boundary used in this study. Only determining products from the fuel mix (charcoal) and from the clinker substitute palette (limestone and clay) were computed within the system boundary. Displaced virgin materials refer to flows suppressed by increased shares of calcined clay and limestone filler to reduce clinker content. Displaced energy and electricity refer to the removal of charcoal from the fuel mix and increased technology efficiency in cement manufacturing.

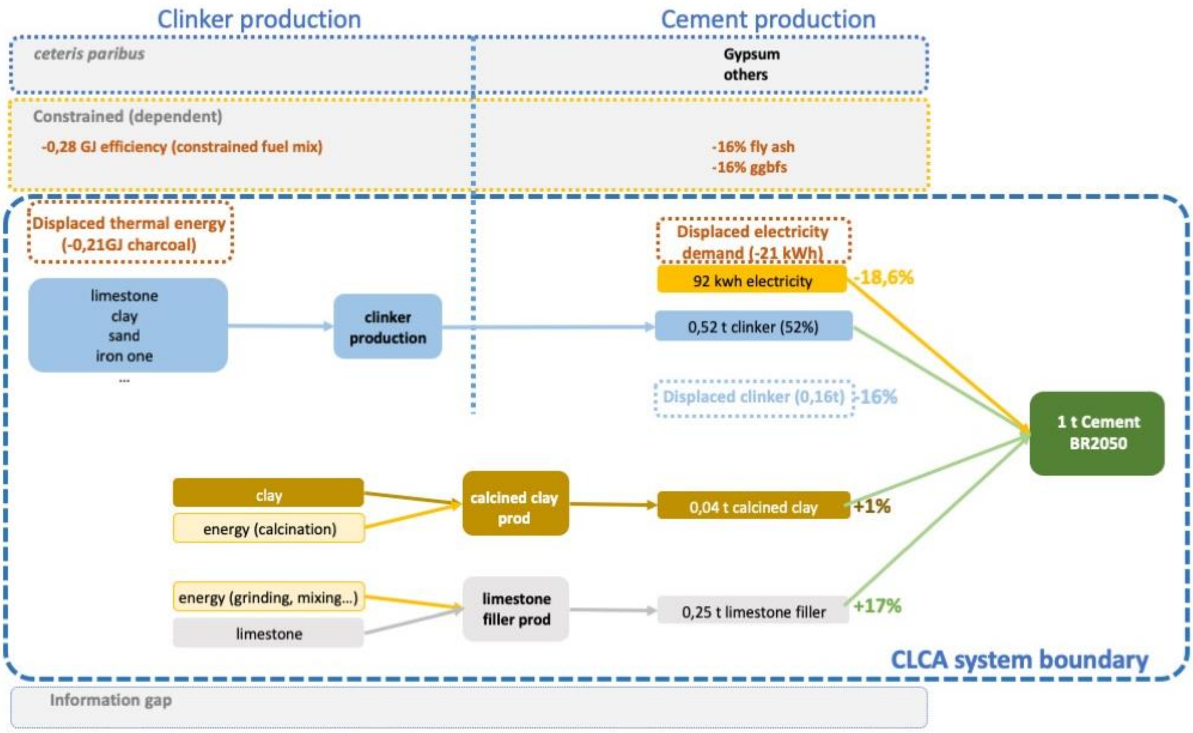

Figure 1 – CLCA System boundary used in this study showing displaced energy (thermal and electricity) and materials (clinker) and added inputs (calcined clay and limestone filler). All dependent products (constrained markets) are excluded.

2.1. Economic modelling

A Computable General Equilibrium (CGE) model enables to capture the consequences that a technological change from one single sector has on the output level of all other sectors of a given economy. For didactic purposes, Figure 2 illustrates a simplified (two-sector) economy according with the CGE model used in this paper.

In the domestic economy, the production level (XDj) of each sector (j) will combine an aggregate of inputs from the intermediate consumption (IC, e.g. X_{11} and X_{21} for sector 1, in Figure 2) with value added (VA) through a Leontief function, which requires inputs in constant proportions. The value added (VA) in each sector combines the capital (Kj) and labor (Lj) factors through a Constant Elasticity of Substitution (CES) function, which allows the substitution between the capital (Kj) and labor (Lj) factors whenever their relative prices change; whilst the intermediate consumption (IC) from a sector (j) refers to the use of inputs in a constant proportion (Leontief Function) and each of these inputs is in its turn a combination of domestic (XDDj) and imported (Mj) inputs..

The proportion of the production level (XDj) that stays in the domestic market (XDDj) or is exported (Ej) is defined by a 'constant elasticity of transformation' (CET) function, which considers the changes in the product's relative prices in the international and domestic markets. The domestic production of product j (XDDj) is then combined with that product imports (Mj) through an Armington function, which considers the product's relative prices in the domestic and international markets. The resulting sector supply of product j in the domestic economy (Xj) feeds the intermediate consumption (IC) and the final demand (FD), the latter composed of household consumption (C), government consumption (GC) and investments (I), essentially in civil construction and capital goods.

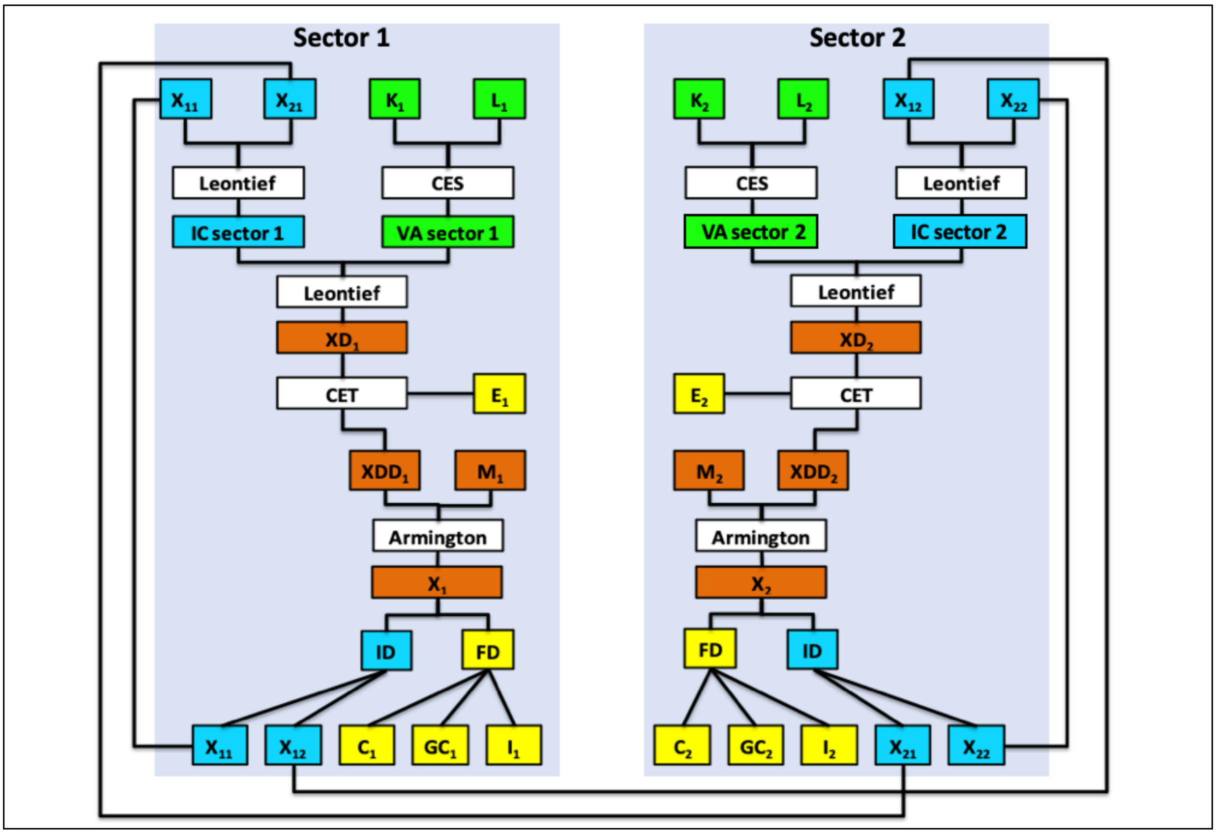

Figure 2 – CGE model used in this study illustrated for a two-sector economy. Blue boxes represent the products and services' intermediated consumed (IC). Green boxes show the primary production factors: labor (L_j), capital (K_j), the elements of VA, the value added. Production (CES, Leontief and Armington) and transformation (CET) functions are shown in the white boxes. The brown boxes stand for the sector supply of products: X_j is the supply in the domestic economy, composed of the product's domestic market, XDD_j (production level XD_j minus exports E_j), and its imported share, M_j. Finally, the yellow boxes consist on the final demand products of the economy: E_j is the exported proportion of the product; C_j and GC_j are respectively the household and the government consumption; and I_j represents the investments.

This CGE model is built upon some classical assumptions: (i) the supply of each good and each factor of production (capital and labor) is equal to its demand - clear markets; (ii) each activity operates at zero economic profit (each sector operates in a perfect competition market, such that one sector's revenues are equal to all of its costs, including remuneration over the capital factor); (iii) families maximize their utility in the consumption of goods, subject to the restriction of their income subtracted from their savings; (iv) firms seek to minimize their cost for a given level of production, subject to their technological constraints; (v) the government spends its revenue (taxes collection) on the provision of public services, social security expenditures and savings formation; (vi) it is assumed that all investment is financed by savings; (vii) savings are made up of external savings from government and households; (viii) external saving is given by the inverse of the trade balance, which is the difference between exports and imports.

The functions of demand for capital and labor in each sector of the domestic economy derive from the CES function that combines these two factors to result in value added. For each product, the demand function of household consumption results from the utility function LES (Linear Expenditure System). The investment demand function for each product is a Cobb-Douglas type, in which the share of expenses with each product is constant. Finally, the supply of public services results also from a Cobb-Douglas function: in this case, spending on each service is constant relative to government's collection.

The database used in the CGE model refers to the Brazilian National Accounts [9] for the baseline year (2014). An Input-Output Matrix was estimated from the National Accounts data using the method proposed by [8]. A 102-sector input matrix was then derived to determine the intermediate consumption. For this paper purposes, it was necessary to disaggregate the sectors of cement, clay and limestone production. Information for these activities were obtained from National Union of the Cement Industry – SNIC, and the Annual Industrial Production published by the Brazilian Institute of Geography and Statistics – IBGE [10].

3. Results and discussion

3.1. CLCA outcomes

To estimate the changes in material and energy flows resulting from the proposed technology changes in cement production, the environmental impacts were calculated relatively to the reference unit – 1 t of cement (modified technology), as shown in Table 2.

Table 2 - Material and energy flows considered and respective original Ecoinvent dataset/process. Dataset for clinker was modified based on primary data collected; dataset for calcined clay was developed based on primary data. Remaining (secondary) datasets were modified to account for the Brazilian conditions.

Ecoinvent Dataset/Process modified	Quantity	Unit
Clinker {RoW}| production | Conseq, U	-1,60E-01	t
Charcoal {GLO}| production | Conseq, U	-1,46E-03	t
Electricity, medium voltage {BR}| market for | Conseq, U	-2,10E+01	kWh
Limestone, crushed, for mill {RoW}| production | Conseq, U	+1,70E-01	t
Calcined clay	+1,00E-02	t

The amount of clinker substituted (i.e. avoided) and corresponding quantities of its substitutes - limestone filler and calcined clay - were defined by the cement production changes proposed by the Roadmap BR [1], as indicated in the CLCA system boundary (Figure 1). The modified manufacturing process is more energy-efficient, due to combined decrease in electricity demand (from 113 to 92 kWh/t cement) and in thermal needs. No prospective scenarios regarding alterations on the Brazilian electricity grid until 2050 were predicted. In view of CLCA methodology, charcoal was the only thermal energy source analysed. Of the total 0.28 GJ reduction, 0.21 GJ result from suppressing charcoal from the fuel mix. Its corresponding mass is presented based on a calorific value of 23 MJ/kg.

The datasets used were minimally modified for adherence to the Brazilian reality; hence, electricity and water inputs were altered to Brazilian data. Clinker and calcined clay production datasets were formulated using Brazilian average information, incorporated in novel datasets already delivered to Ecoinvent and to be published in version 3.6. The cement composition proportions used in the dataset (and actual displaced materials) refer to collected data in 2017 for Portland cement CP V – similar to European CEM I, whereas the Roadmap BR used weighted average of all produced cement types. This will be refined as this work progresses.

Results for the CLCA are presented in Figure 3 for different impact categories. The substitution of clinker reduces environmental burdens due to materials involved in its composition and energy required in process such as calcination, grinding and mixing. Incorporating limestone filler and calcined clay as substitutes indeed adds in impacts, but the net impact in each category is always reduced.

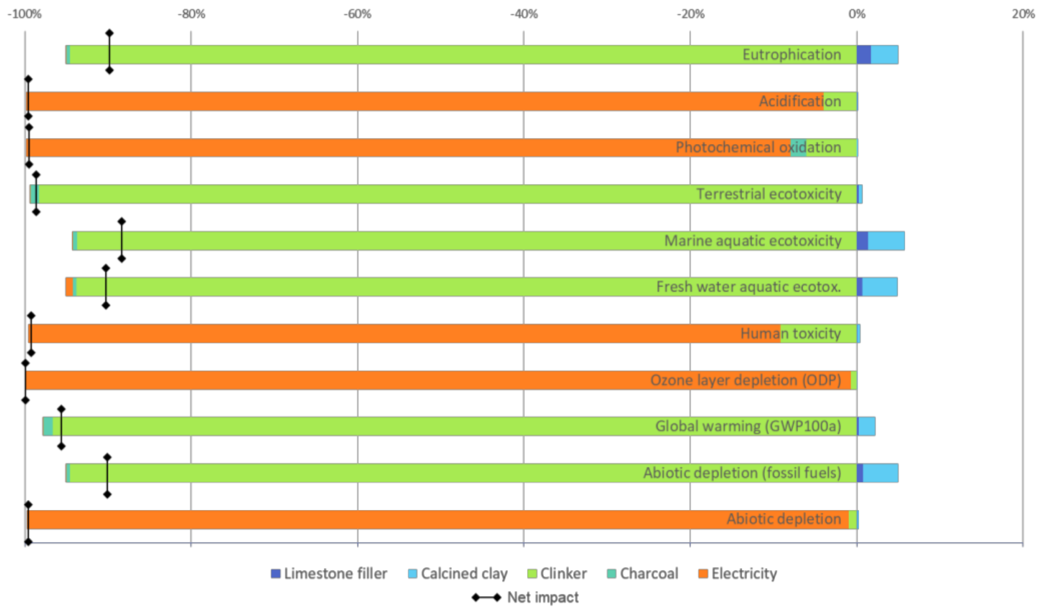

Figure 3 – CLCA results for altered energy and material flows relatively to the 2014 baseline (vertical line at 0%). Bars at the negative (left) side of the horizontal axis indicate impacts reduced.

3.2. Affected sectors and changes in production levels

From the equilibrium observed for the Brazilian economy of 2014, in the CGE model, exogenous changes were made in the participation of clay, limestone and charcoal in the cement production, consistently with

Table 1. These changes lead to a new economic equilibrium captured by the model. The industry-proposed changes modelled for cement production technology would enhance its economic efficiency and reduce cement's production cost, which would in turn reduce the product's price, and ultimately increase its demand and production. The technological change in the cement sector trigger changes in prices and ultimately in the production levels of all 102 sectors of the economy. For simplicity, Table 3 list is truncated to show only the sectors with the highest increments or reductions in production level.

Table 3 - Sectors with the highest production level increments or reductions after applying the cement technology change

Sector	**Change in production level**
Cement	+0.0714%
Pulp and Mechanical Pulp Manufacturing	+0.0268%
Construction	+0,.0233%
Other non-metallic mineral products	+0.0227%
Paints, varnishes, enamels and lacquers	+0.0119%
Manufacture of petrochemical Diesel	-0.0046%
Clay	-0.0310%
Pesticides	-0.0445%
Fertilizers	-0.0457%
Forestry	-1.1324%

The economic model assumes that inputs are used in constant proportions. Therefore, the additional demand for cement propagates activity increments across 81 economic sectors, whilst the remaining 20 sectors would reduce activity. The cement sector obviously shows the highest increase in production for being directly affected by its cost reduction, but it also directly stimulates e.g. production in the pulp

manufacturing (paper bags) and the construction sectors, besides the general increase in the whole economic activity. The highest reduction in the forestry sector production level stems from the suppression of charcoal as a thermal energy source in the revised cement production technology. Fertilizers and pesticides demand decrease accordingly. Reduction in clay production level consistently reflects the decreased flow of clay and slightly increased activity in the limestone sector (+ 0.00141%) in the revised cement composition.
Due to the cement cost matrix, the reduction of clay (overall input mass balance ~ -15%) and increase of limestone (overall input mass balance ~ +1%) reduced input costs by about 1.91%. The cost reduction reduces the cement price, which allows for the reported increase in demand and consequently in production. As the share of limestone in the cost of cement is much higher than that of clay, reduced expenditure on inputs affected proportionally little the final cement price. The emission balance would be positive but, from the economic perspective, the 0.07% increase in cement sector activity depicts a rebound effect, that is an increase in production level (and corresponding emissions and impacts) resulting from a technology change envisioned to decrease specific emissions (per t). This aspect shall be further investigated and characterized.

4. Final remarks

This simplified consequential LCA performed were based on the predictions brought forth by the Cement Production Roadmap Brazil, and showed that the two possible routes for impact minimization do not backfire: not only is the carbon intensity within the sector significantly reduced, all other assessed impact categories presented net reductions of at least 80%. The global equilibrium model, on its turn, showed that all 102 economic sectors are quantitatively affected by the predicted changes, with marginal increased or decreased production levels. We are currently working on the integration of the equilibrium model output with LCA tools to quantify the mentioned difference.

As with any LCAs in countries lacking a national inventory, our study was sometimes hindered by the absence of representative data. We attempted to limit this issue with dataset adaptation to best represent the national production scenario. Moreover, no prospective modelling of the electricity grid in 2050 was assessed. With the current worldwide trend to decarbonize electricity mixes, one could argue that the avoided impact in the next decades would be lower. Still, for GWP, the major benefit comes from clinker reduction, so conclusions would not have been deeply altered from a GHG emissions perspective.

Consequential LCAs are usually coupled with the step-wise procedure approach to identify the markets affected by a predicted change in demand, as briefly discussed in section 1. Our modelling relied on predictions already developed by the cited technology roadmap, assuming composition changes (and their quantities) according to specific sectorial information. These approaches involve subjective assumptions but facilitate the exploration of CLCA’s more sophisticated concept without increasing data collection complexity. The ease of application is however hindered by a biased perception of the economic sector’s response. Our paper, albeit only exploring the output of an equilibrium model without its full connection to LCA modelling, already shows how the demand change unfolds into the whole Brazilian economy. This is an ongoing work and additional impact categories and consequences in other economic sectors will be further investigated.

Abstract. Wood products are gaining interest in the building sector, due to their potential in sequestering greenhouse gas emissions. However, increasing wood materials use in the built market can have unforeseen changes in the material supply chains. Consequential Life Cycle Assessment (CLCA) allows the assessment of changes in material supply chain. To quantify and link those consequences, the affected physical flows need to be estimated. Material Flow Analysis (MFA) can bring to CLCA modelling more representative and quantitative information than the commonly used hypothesis in consequential modelling. Indeed, MFA considers physical constraints (technology performances and material availability), in addition to account for mass balance. The main objective of this presentation is to illustrate how such consistency is added to CLCA through an MFA of wood products in non-residential (NR) buildings in the province of Québec (Canada). Wood flows are tracked to identify their end-use markets and trends in consumption. To overcome the lack of data and bring insights on the sector's dynamics, such as stock variations and potential discarded flows that supply recycling markets, residence time model and also extrapolation and correlation between physical and economic parameters are used. Results show how flows can increase in the market before reaching their physical constraints, such as the available wood stock in the forest. These insights will significantly enhance the data collection for CLCA. In conclusion, the MFA brings support to CLCA by proposing a framework to model changes in the construction market.

1. Introduction

The consequential approach aims at modelling environmental impacts of the changes in the market due to a decision. Several methods exist to identify these changes [1]–[3], which all require an understanding of the market and flows. Indeed, the affected flows in the market depend on their expected sensitivity to the changes. But this requires different hypotheses on the state of the market before and during the changes. However, such characterization of the market is still a challenge for the development of consequential methodology in LCA. Indeed, for long-term assessments, assuming constant technological data is not sufficient, and data projection is required to build consistent prospective scenarios [2].

Recently, the consequential LCA approach started to be combined with the Material Flow Analysis (MFA) method, in order to build a system-wide inventory of flows associated to a given economic sector. Indeed, using MFA allows to track physical flows in the economy throughout their life cycle, including the end of life and exports [4]–[11]. Several studies showed MFA inflows and outflows (such as raw materials, finished products, old scraps, residues, and recycled materials) can provide information about both the dependence of a regional economy to some resource and its resource recovery potential [12]. Moreover, this tool brings insight into the dynamic flows of a sector. It helps to assess how important the market under study is regarding all the market and its physical constraints.

The MFA is a transparent tool that brings insight into the sector's dynamics. The Québec province is a good example because a political initiative projects to increase the use of wood in the NR buildings and no consistent and homogeneous accounts for engineering wood products (EWP) life cycle exist. The aim of this paper is to evaluate the state of the wood structural market for Non-Residential (NR) buildings by performing a material flow analysis of the EWP in the non-residential wood building sector. We then project scenarios to evaluate the potential consequences related to the growing EWP use. Dynamic MFA is expected to help in identifying and generating consistent flow and to capture trends in the market.

2. Method

The Quebec region is the geographical boundary of the NR building sector. The temporal boundary of the sawnwood demand, for the structure of new NR buildings, includes the 2010-2050 period. The system contains the stages of domestic harvesting, transforming (1st and 2nd), manufacturing of structural products, and using those products. These stages consider the softwood structural products which can represent cross-laminated timber, glued-laminated timber, or roof frame. The material losses from the first transformation are included.

The methodology to quantify the wood in the NR building structures is a top-down approach. Firstly, it defines the building sector at an aggregated level, with in our case, the value of the building permits. Secondly, to disaggregate this sector and get an amount of wood, we combined several parameters such as the share of the structure in the building cost, the price of a wood structure and the share of the building containing a wood structure. To match numerous inconsistent databases, the data reconciliation method in the MFA tool is performed with STAN software [13].

2.1. Quantifying the wood

The estimation of wood in the NR construction market (equation 1) implies several parameters extracted and adapted from Geskin Conseil [14]. The following equation presents the used parameters:

$$\frac{BP\ (\$) * \mathrm{SCs}\ (\%) * \mathrm{WBs}\ (\%)}{WSp\ (\frac{\$}{\mathrm{m}^3})} \quad (1)$$

The first parameter ***BP*** is the value of building permits. It can represent the spending and the size of the NR construction market at an aggregated level. Indeed, building permit data are used as a leading indicator for the construction industry since getting a building permit is one of the first steps in the construction process and is a major input of expenditures by companies and governments to build buildings [[15]–[17]]. However, the values ($) of the building permits are disaggregated to consider the value of the new building constructions among all the types of work such as improvements, conversion, addition. The scenarios only consider the building permits for new buildings with two scenarios (a maximum and a minimum).

Among the value of a building, the share (%) of the structural cost ***SCs*** (material and installation) in the total building cost (associated with the building permit) is necessary to consider the structure. We determined this share with several case studies from public [18] and confidential review (on behalf of the Ministry of Forests, Wildlife and Parks) [19] on the NR buildings whose structure is made of wood. The case studies of the confidential report are selected from a collection of hundred wooden buildings to meet the needs of ensuring the representativeness of the Québec public building context and to guarantee a coherence of the whole despite the many uses of wood for construction. The criteria consider the year of construction, the 100% wood structure, the building classification (recreation, sport, culture, education, health, offices and warehouses), the diversity of building vocations and the potential reproducibility of the project [19].

In order to convert the dollar values into the amount of wood, we introduced ***WSp*** the price of installed wood structure ($/$m^3$) in the estimation. This is important to consider this price instead of the one of softwood lumber because the wood products are gaining value throughout the transformation chain from the sawmill to the building, which increases the price per cubic meter. Therefore, we avoided overestimation of the wood cubic meter installed in the NR buildings.

Finally, some buildings have a wood structure, not all. Therefore, we applied the coefficient ***WBs*** to consider the share of buildings using wood. It is this share which drives the modelling of wood consumption in NR buildings. Currently, around 28% of new NR buildings (4 stories and less) are using wood structure according to a survey (on behalf of cecobois) conducted with engineers and architects [20].

2.2. Projecting the quantification of the wood

We estimated a minimum and a maximum scenario of potential wood use in NR structure until 2050, according to the minimal and maximal parameters' values. The 2050 as a long-term horizon is set because of the estimated growing population after 2050 [21], suggesting there will be still a need for construction. Moreover, depending on the current market volume, a short-term analysis would not reflect consistent and significant effect because of the inertia of the market and the barriers. For future work, the buildings have a long lifetime (more than 50) and the future discarded flows of buildings would start to appear after these 50 years. This will involve a future secondary wood resource supply. The respective estimations of parameters are described below. The projection is made for each year in order to track changes between the starting calculation date (i.e. the time of the starting decision or change) and the final state. The idea is to follow the flows to understand if there might be intermediaries' consequences during the change modelling.

2.2.1. Demand of wood in the NR buildings

The expected competitive trends are helpful to identify the most sensitive suppliers to a change [22], [23]. In that sense, future trends in the market are required and each parameter must be predicted to simulate the increasing use of EWP in non-residential construction. Predictions of the concerned parameters are not available with enough information. So, it is essential to remind that a prediction remains highly uncertain. Such uncertainty will be part of our future work. Following, we present assumptions of the parameter's predictions concerning the building permits, the softwood lumber price and the share of NR building with wood structure. We assumed a constant evolution of the share of structural cost in the total building cost. This assumption implies that structural cost and building cost are linearly dependent.

To project the building permit, we assumed it to follow the existing population projection [21]. The observed strong correlation (R^2>0.8) between the total building permits and the population of Québec (figure 1) was the reason for this assumption.

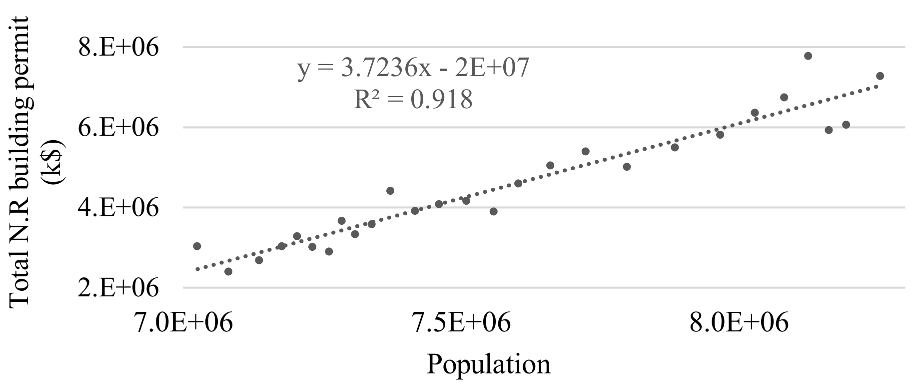

Figure 1. Correlation between building permits [17] and population [24] in Québec (1991-2017).

The following figures present the projections we made for the share of new NR buildings with wood structure (***WBs*** - figure 2) and the cubic meter price of the softwood lumber (linked to the ***WSp*** - figure 3). In the NR building structures, wood usage is an emerging market and no historical data are existing in the context of Québec. Therefore, we considered a prospective approach to model the increase of wood in the NR buildings. The projection of the potential share of building with wood structure is assumed to follow an S-shaped curve because the developments of EWP for building structure are not obvious linear process [25]. Indeed, when the first projects are successfully achieved and when the concerned public approves its technological breakthroughs, its development may follow a typical logistic S-growth [26].

Concerning the price projection, it follows the past trend of the average of the softwood lumber's prices (adapted from FEA - Forest Economic Advisors [27]). The minimum and maximum projection considered the historical minimum and maximum values which are projected following the trend of the average. This does not provide with precise figures but shows the price variability. As mentioned in subsection *2.1.,* the cubic meter price of the installed wood structure is considered in the modelling instead of the lumber cubic price. To do this, we applied a coefficient to represent the added value of the engineered wood product compared to lumber.

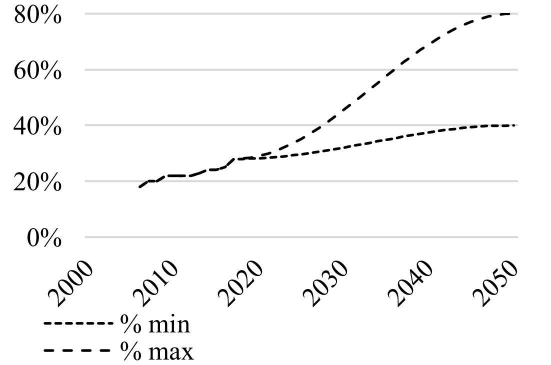

Figure 2. Projection of the potential share of the buildings with wood structure - WBs.

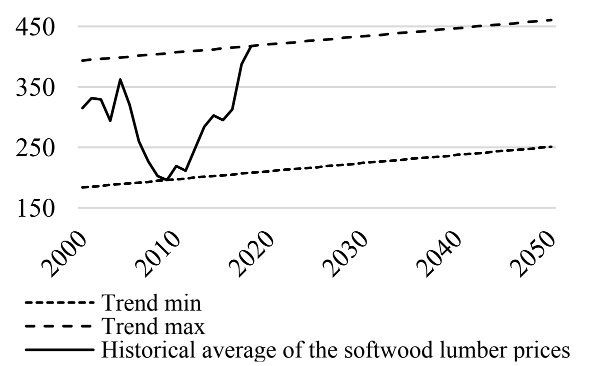

Figure 3. Projection of the softwood lumbers prices ($\$/m^3$).

2.2.2. The wood supply chain

The modelling of the increasing wood demand drives the wood product flows throughout the supply chain (from the buildings to the forest). Therefore, to estimate the amount of wood resource, we investigated the wood supply chain. It is at the sawmill, when roundwood is processed into standard lumbers, that there is the higher loss of matter. Historical statistics gave the improvement trend of each sawmill yield for each output such as the lumbers, the wood barks, the chips and the sawdust per cubic meter of roundwood.

Projecting this improvement trend with a retrospective approach allows representing the sawmills' efforts to reduce co-products production (wood barks, chips, and sawdust) and increase efficiency. Indeed, those efforts include the use of thinner saws that reduce the cutting thickness, the use of optimized multi-saw slitting machines - straight sawing and curve sawing - and the recovery of parts during trimming to transform them into smaller parts [28]. We assumed the current trend will continue because changes are gradually as long as sawmills are improving their equipment. But this implies sawmills can invest thanks to the growing market. However, this reduction cannot be infinite. To do so, we constrained the reduction with an asymptotic limit of each yield according to the minimum values available in the statistics databases [29], except for the barks we supposed constant. Therefore, we projected the yields until their respective limit. But it is also important to notice that the number of lumbers and by-products must verify the material balance with roundwood as long as the yields are decreasing. So, if the yield of lumbers per roundwood reaches its limit before one of the co-products, the sum of the three co-products yields per roundwood cannot decrease anymore even if their respective assumed limits are not reached.

In order to evaluate the wood demand effect for NR building sector related to other sectors, we introduced the wood consumption of the other final uses in accordance with the material balance between the lumber imports, exports, and sawmill productions.

3. Results

The results relate to the estimated amount of wood products for the new NR building structures and the amount of roundwood which is required for this sector as well the others.

3.1. Wood in new NR structures

The following figure displays the two scenarios of the wood quantity for new NR building structures. We built these scenarios regarding the different uncertainties of the main parameters presented above.

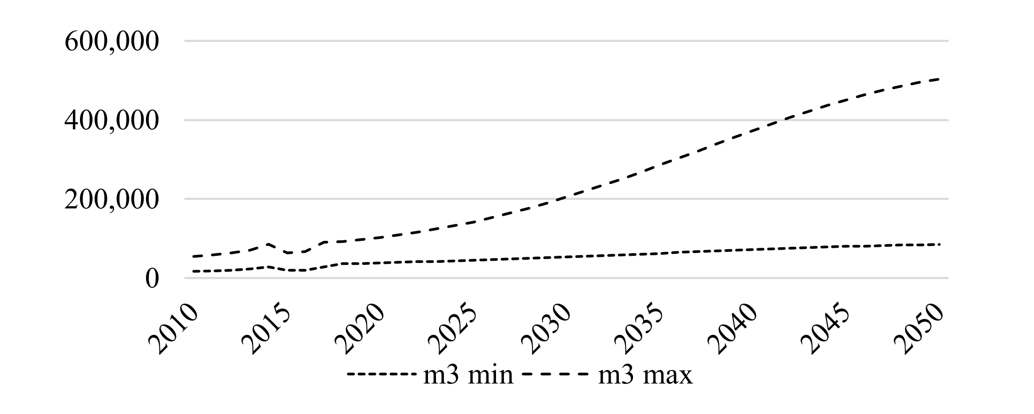

Figure 4. Estimation of wood products (m^3) in the structure of new NR buildings in Québec.

The minimum scenario follows an S-shaped curve, but the target of the ***WBs*** is so small that it seems to follow the trend. This scenario shows a negligible quantity because it also considers the maximum cubic meter price of installed wood in the structure. There is consistency in the sense that the more wood is expensive, the less it may be used. However, the price is not related to other endogenous parameters such as the availability of the resource.

3.2. Softwood roundwood harvesting

The importance of the additional softwood roundwood demand regarding the other domestic markets is illustrated in this section. The obtained results depict the additional demand for wood for NR building structures may be unconstrained by the resource availability if harvesting for other end-uses is constant. We also notice if the additional demand remains negligible and other end-use markets are constant, then the consequences of the decision may only occur in the investigated sector. This will imply to consider competition between structural material. Figure 5 shows the historical harvesting of softwood and resource availability in public and private forest in Québec [30] and the projections made. As shown in figure 5, even if the additional demand is negligible, considering the trend of other sectors will result in a constrained resource before reaching the expected time horizon.

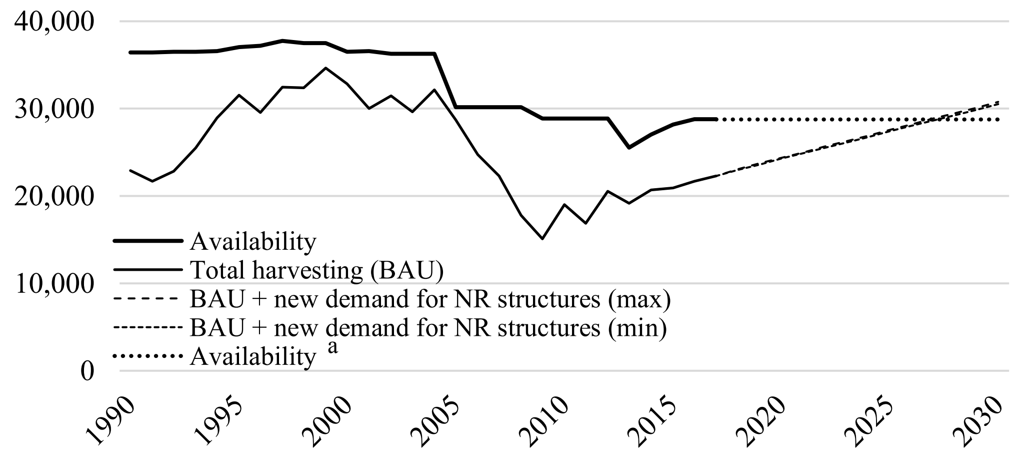

Figure 5. Total domestic softwood harvesting for NR building and others projected end-uses (‘000m^3). [a] Considering constant availability

The MFA allowed indicating the softwood lumber exportations [31] accounted for around 50% of the total harvesting in the 10 past years. This mainly drives the past harvesting trend implying that exportations may constrain the development of the NR wood products in term of resources availability. With the MFA in the wood supply chain, it is also possible to investigate the effects of additional sawmill by-products by assessing their potential demand for end-use markets (e.g. pulp, paper, cardboard, veneers, plywood, and panels, or Cogeneration and Energy Products).

4. Discussion

We presented a method to account for material in the emerging market of NR wood structure. Secondly, we investigated the dynamic wood flows in the supply chain to understand the effect of additional demand.

Regarding the account of material in the emerging market of NR wood structure, the parameter of the added value is specific to the wood buildings sector. Indeed, it allows considering the value which is added to wood during the EWP processing between the sawmill and the construction of the buildings. However, the lumber price is a dynamic and endogenous parameter and the added value is linearly dependent on it. By the end, the equation (1) respects the fact that, if the wood price is skyrocketing then it can deter timber harvesting. It results in an amount tending to zero. But there is a limitation here. The wood harvesting modelling does not consider the relationship between the resources price and its availability in the regional forest. In addition to that, the new buildings may not only include the structure but also the envelope which can possibly use wood. This additional demand for NR buildings is missing in this flow accounting. The quantity estimation is important to model representative additional harvesting regarding the potential of the emerging market to grow.

The results show how and when the limit in the resource availability can be reached depending on the assumption of all markets using the same resource. According to the assumptions, it does not appear relevant to look for consequences that will occur in the current supply chain because the wood quantity for NR building seems to remain negligible compared to others. One of the main sources of uncertainty in such studies concerns the evolution of the NR market related to others which use the same resources. It is an issue because both will contribute to reaching the limit.

Our research shows how MFA helps to identify EWP flows in the Québec non-residential buildings. This MFA provides a snapshot of the EWP use across years and considers trends. The estimation of wood quantity is related to the price, the population growth and the spending of the sector. It is important to underline that dynamic material flow analysis mainly consider the material intensity per square meter and statistical data on the total floor area put in place or the material intensity per capita and the population of the country to estimate the material demand. Therefore, the presented methodology to estimate the quantity of wood should be compared to other methods using these parameters. Also, in the following work, system boundaries should be expended to understand the effects of EWP demand on the other structural materials as well as the effects of the stock accumulation on future discarded material.

To make the MFA less uncertain, we would need the share of the materials in the building archetypes and the distribution of those archetypes. But for an emerging market, dealing with a lack of data is obvious (non-existent or confidential). Also, as an emerging market, the price of the structure per cubic meter (WSp - $/m3) and the share of the structural cost among the building permit value (SCs - %) may be overestimated compared to a well-established future market. Concerning the wood products, we only considered the softwood sawnwoods, which are the raw products for structure products such as cross-laminated timber, glued-laminated timber or roof frame. As a consequence, the roundwood harvesting is overestimated because the sawnwood processing implies around 40% of material losses as barks, chips, and sawdust. If we considered a share for structural panels, such as oriented strand boards and laminated veneer lumbers, the processing yield would be less because all the roundwood (excepted the barks) is either destroyed as strands or laminated as laminated veneers. To overcome this bias, the share between the sawnwood products and other structural panels would help to disaggregate the cubic meter of the installed wood structure. This would imply one yield for the softwood sawnwoods and another one for the panels made of softwood and hardwood. As a consequence, the total and softwood harvesting would be less.

By tracking material flows of a sector, MFA supplies the CLCA modelling with a framework for several purposes. It identifies physical flows directly affected by a decision and models their trend. The dynamic MFA is a tool that brings insight into the evolution of a given economic sector thanks to a parameterized system-wide inventory of its flows. It supports the CLCA inventory modelling (i.e. the state of the market before and during the changes) and shows how the changes can be significant or constrained.

Abstract. The transition from a linear to a circular economy is essential to reduce the environmental burden of our society. A key issue is to prevent a shift of the environmental burdens and take the consequences of a decision into account, for example based on a consequential life cycle assessment (LCA). However, limited practical guidance is available on how to implement consequential LCA in the context of the construction sector. Therefore, the aim of this study is twofold. First, to quantify the potential environmental and burdens of introducing circular design alternatives for internal wall assemblies to the Belgian market. Second, to review the methodological implications on the results of a consequential LCA with a particular focus on consistently identifying marginal suppliers and substitution routes, acknowledging the time dependence and closed-loop nature of the design alternatives.
In total seven wall assemblies are assessed over a period of 60 years, with a refurbishment every 15 year.
The results show that a low life cycle impact can be achieved for assemblies that are designed to be used again and have a higher initial impact, such as a plywood boarding connected reversibly to a demountable metal frame substructure, as well as for assemblies with no possibilities for direct reuse that have a low initial impact, such as a drywall system with a wooden substructure. Further, regarding the methodological scenarios on marginal supplier identification, the range of possible outcomes is however much larger for the demountable wall assemblies than for the conventional ones.

1. Introduction

The transition from a linear to a circular economy is essential to reduce the environmental burden of our society by overcoming the divergent interests of economic and environmental prosperity [1]. Despite the efforts in building related research and development, the implementation of circular economy thinking in the construction sector is still in its infancy. It is mainly limited to minimising waste and maximising recycling [2–4]. Nevertheless, more radical experiments appear in the academic and innovation debate. They optimise the valorisation of materials at the end of their first functional service life, e.g. by considering existing buildings as material banks [5], or by designing demountable and reusable building elements such as internal walls [6–8].

However, increasing circularity does not automatically lead to more sustainable products and buildings, which emphasises the need for a quantitative assessment. Established methods such as life cycle assessment (LCA) proved their value for making well-informed environmentally sound design and construction choices [9]. Yet, there is not just one single way of performing an LCA despite the the general framework of ISO 14040/44 [10,11]. Still many methodological choices must be made throughout a study. Against the background of assessing the transition towards the circular economy, the market-based and change-oriented nature of the consequential modelling approach is of great interest, as it allows to make environmentally responsible policy and design choices. To date, there is a lack of consequential LCAs evaluating and illustrating their relevance for the construction sector [12].

In this context, the goal of the present study is to assess the potential environmental benefits and burdens of introducing circular design alternatives for internal wall assemblies to the Belgian market. This assessment is realised by performing a consequential LCA, acknowledging the time dependence and closed-loop nature of the design alternatives. The corresponding objectives of this case study are to (1) collect alternative internal wall assemblies, (2) introduce various consequential modelling approaches to understand the relevance and improve the robustness of the results and to explicitly account for the corresponding modelling uncertainty and (3) include multiple end-of-life scenarios to address the uncertainty regarding future life cycle interventions and technical evolutions.

For this case study, seven internal wall assemblies are assessed. To provide a sound basis for comparison, these assemblies include both conventional and demountable alternatives. The first are designed for a typical linear service life with a waste-generating refurbishment and end-of-life scenario, the latter are designed with a high reclaim and reuse potential at the end of their functional service life.

2. Methods

2.1. Case study

The present case study includes seven wall assemblies that have divergent compositions, but meet the same technical requirements (see Fig. 1). The first four alternatives (i.e. Wall 1 to 4) resemble the most commonly applied wall assemblies in the Belgian construction sector [13], namely masonry walls and drywall systems. They do not follow any design guideline related to the circular economy, but they will serve as a reference. The alternatives (i.e. Wall 5 to 7) feature a wood-based boarding, each time supported by a different demountable substructure. They are proposed by the authors following earlier prototyping by Paduart et al. [7,8]. The fifth alternative consists of prefabricated wooden boxes, while the sixth and seventh alternative rely on a single-profile and an assembled metal frame substructure. These alternative assemblies follow the design guidelines for the circular economy [6]: the substructures are demountable, the boarding is connected in a reversible way and all components resist the wear and tear of repeated disassembly and reuse. More detailed information can be found in Buyle et al. [14].

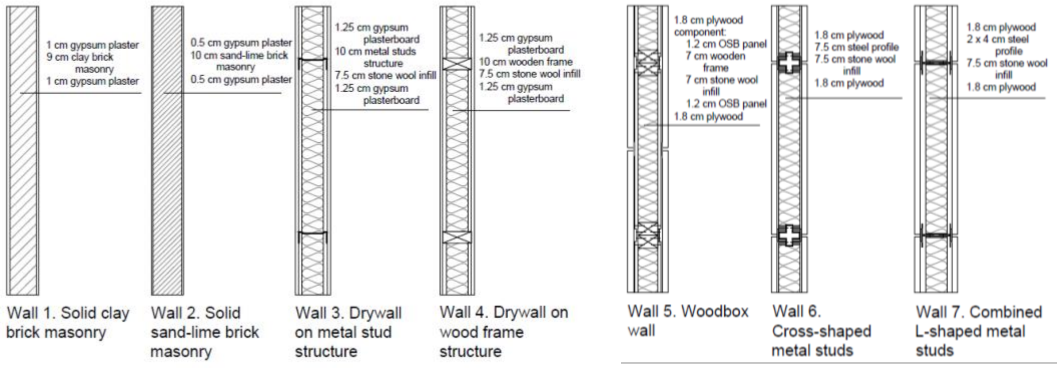

Fig. 1 Conceptual representation of the analysed wall assemblies

2.2. Life cycle assessment

2.2.1. Goal and scope. In the present case study the theoretical framework for consequential LCA of Weidema et al. was followed [15]. This implies that only small and medium scale changes in demand and long-term effects were considered, assuming perfectly elastic markets and no interaction between markets. Within this methodological system delimitation, all wall assemblies and their alternatives are equivalent and compared with respect to the following functional unit: *a 1m² space dividing wall (non-load bearing) that meets Belgian requirements for energetic and acoustic performance of residential, school and office buildings, during a period of 60 years,*

2.2.2. Life cycle inventory. In consequential modelling two of the most important aspects are (1) the identification of marginal suppliers (i.e. the activities affected by a change in demand) and (2) the substitution of non-determining by-products on the market. Additionally, the seven wall assemblies have a different end-of-life potential, varying from direct reuse to demolition with limited recycling potential. However, the actual practice at the end-of-life is highly context and user dependent. Given this uncertainty, multiple scenarios are included: four methodological scenarios regarding the identification of marginal suppliers and five end-of-life scenarios. The substituted activities and the avoided products are always the marginal ones [15]. Consequently, the methodological scenarios affect all life cycle stages including the end-of-life stage.

2.2.2.1 Methodological scenarios: marginal supplier identification The two most important steps in the procedure of Weidema et al. [15] are the delimitation of geographical market boundaries and a systematic identification of market volume trends to identify the suppliers the most sensitive to a change in demand. In this context, a market should be interpreted as all countries in the world from which materials are imported to Belgium, directly or indirectly. Two approaches to identify geographical market boundaries are included, proposed by Buyle et al. [16] and Pizzol and Scotti et al. [17]. The first approach is a bottom-up approach based on an iterative procedure (referred to as scenario [IT]) is starting from the specific location of the change in demand, using trade and production data. The central concept is to define market boundaries by comparing the traded volume of a product to the total production volume of a market. The second approach is a top-down approach based on a network analysis (referred to as scenario [NA]) applied to global trade data where the clusters represent geographical markets.

Next, the suppliers the most sensitive to a change in demand are identified. Within a stable or growing market, suppliers are evaluated based on their potential for expanding production capacity, which is a proxy of their competitiveness. In this case study the trend in production volume was chosen as a criterion, under the assumption that the suppliers yielding the largest increment in production volume are the most competitive ones. The trend in production volume was calculated by applying a linear regression analysis to the time series of yearly production data. Based on this calculation principle, the marginal suppliers were tracked down using two types of data. The retrospective approach (referred to as RETRO) is based on historical data available from statistical agencies, reflecting current trends. The prospective approach (referred to as PRO) relies on forecasted data obtained from other models, reflecting expected trends. The retrospective approach is characterised by a high availability of data with a low level of uncertainty. However, a key assumption in this case is that historical trends are representative for future situations. Indeed, the prospective approach can provide a more nuanced image of expected future developments, yet future predictions are per definition uncertain.

A pairwise combination of the previous approaches results in four methodological scenarios: RETRO[IT], RETRO[NA], PRO[IT] and PRO[NA]. Marginal suppliers are identified at country level, so country specific life cycle inventories (LCIs) were built for all identified marginal suppliers. The ecoinvent database v3.3 was used to model background processes.

2.2.2.2 End-of-life scenarios For the modelling of end-of-life scenarios, the Belgian reference study for LCA in the construction sector, namely Environmental Profile of Building elements (EPBE) [13], was followed as guideline. The five scenarios are briefly described below. Not all scenarios apply to every wall alternative. For the conventional walls, only the three most conservative scenarios can be included ({Bau}, {En}, and {Rec 1}). Direct reuse of the components is technically not possible in those cases as they cannot be disassembled, so both the most advanced recycling scenario {Rec2} and the {Reuse} scenario are excluded.

- Business-as-usual {Bau}: This represents the current practice in Belgium according to EPBE.
- Maximised energy recovery {En}: All combustible waste is sent to waste incineration plants featuring energy recovery. For non-combustible waste the {Bau} scenario is applied.
- Improved recycling {Rec 1}: An improved recycling practice is assumed, based on higher recycling rates compared to the {Bau} scenario, anticipating future technological developments.
- Optimised recycling {Rec 2}: This is a further improved recycling practice, including higher recycling rates and off-site reuse, enabled by Design for Change.
- Maximised reuse {Reuse}: Components are used again directly in the same building without any additional treatment or transport; a 5% material loss assumed for every refurbishment.

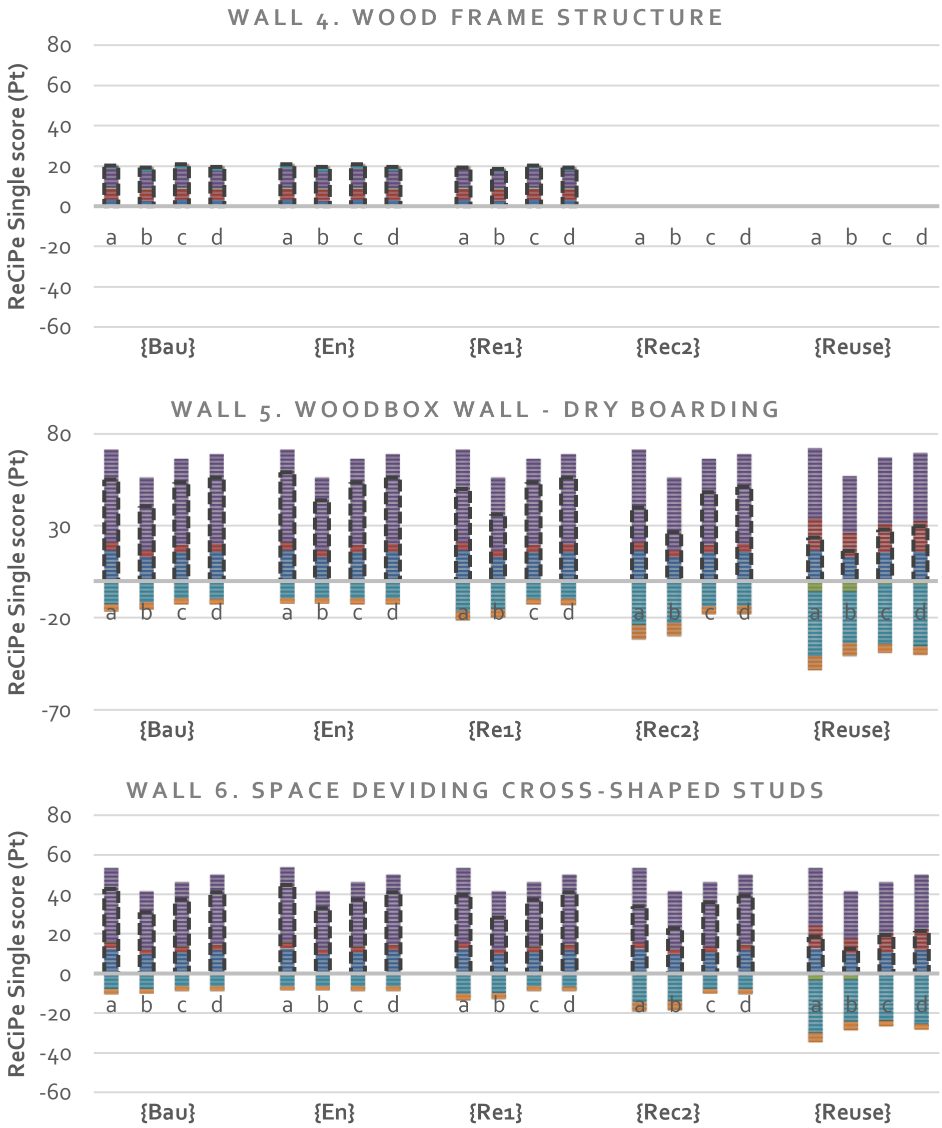
2.2.3. Life cycle impact assessment. The method used for the impact assessment is ReCiPe v1.13, applying a hierarchist perspective. To facilitate the interpretation of the effect of methodological choices in the LCI modelling, a single score indicator is applied. However, in addition to the single scores, results of all midpoint impact categories are included as well and available online (see *Appendices* and [14]).

3. Results

This section presents the results of the consequential LCA, considering the total service life of the wall assemblies. The studied period is 60 years, which corresponds to the estimates in other Belgian research, though individual components can have a shorter service life. An average periodicity of 15 years is assumed for refurbishments as discussed by Galle [18]. The results will be presented based on the classification of different life cycle stages as described in EN 15804 and EN 15978 [19,20]. These guidance documents describe an attributional framework that does not fit the goal and scope of the present case study. Nevertheless, its classification is instructive and will be maintained, even though this is a full consequential LCA.

The life cycle impact of the three demountable and reusable wall assemblies (Walls 5-7) is compared with the conventional assembly with the lowest impact, namely the drywall on wood frame structure (Wall 4), see **Error! Reference source not found.**. For full details, see Appendices and [14]. Three assemblies show the best environmental performance when the entire service life and the different end-of-life scenarios are considered: the conventional drywall with a wooden substructure (Wall 4) and the two assemblies with a demountable metal frame structure but only for the maximised reuse end-of-life scenario (Wall 6 and 7). Apparently, the lowest life cycle impact can be achieved for assemblies designed to be used again but with a higher initial impact, as for assemblies with no possibilities for direct reuse but with a low initial impact. The reason for the high life-cycle impact of the demountable assemblies is that some materials of the demountable walls have a short estimated service life compared to the total studied period. Plywood for example has an estimated service life of 35 years. In other words, even though these walls are designed to be fully reusable, after 35 years they need to be replaced by new ones during the second refurbishment. Wall 5 has a much larger initial impact compared to Wall 6 (27 to 44% higher) and to Wall 7 (24 to 41% higher). So, given a refurbishment rate of 15 years, this wall assembly is not competitive with Wall 6 and 7, nor with the reference Wall 4 from an environmental point of view. Wall 6 and 7 show almost identical results, with a slight preference for Wall 6 with an impact that is 1.5 to 3 % lower than Wall 7.

In Fig. 2**Error! Reference source not found.** the results for the methodological scenarios are presented as well. In the case of the conventional wall assemblies, there is only a small divergence in results of around 10% between the scenarios, while for the demountable ones this deviation can range up to 25%. Many of the typical construction products such as aggregates, clay, bricks, cement and gypsum products are traded on relatively small markets. Therefore, the identified marginal suppliers do not vary that much amongst the scenarios, nor does the impact per supplier.



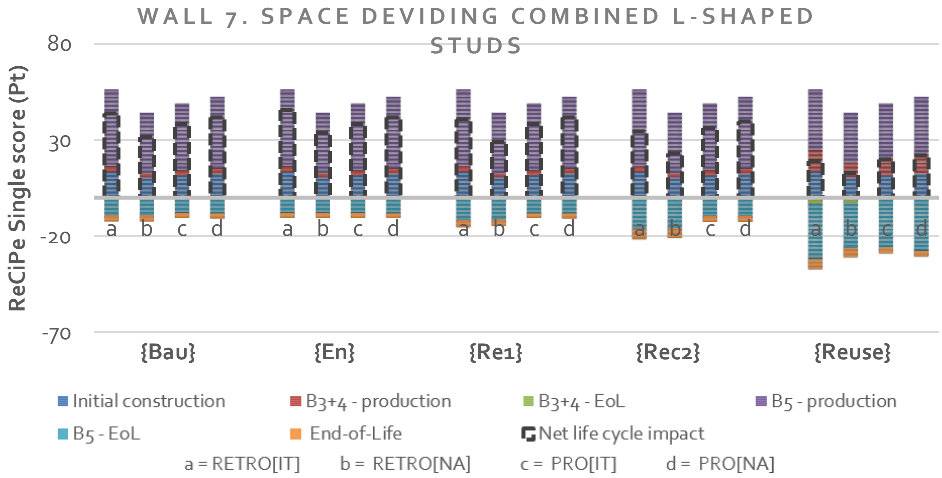


Fig. 2 Life cycle impact for wall assemblies 4-7

The situation for wood-based products is completely different than for all other materials, which apparently leads to larger differences in the outcomes for the demountable walls. First, these products are traded more intensively and over larger distances. This results in bigger deviations between the iterative procedure [IT] and the network analysis [NA] when the geographical market boundaries are defined. Second, climate, forestry practice and dominant tree species can all have a major effect on the final environmental impact, in particular for the midpoint impact category 'land use'. In case of plywood for example, having sawlogs as the most important raw material, the network analysis [NA] results in a market dominated by European countries, as they have intensive trade relationships. The iterative procedure [IT] adds China as an important partner country too, given its direct trade connection with Belgium. Obviously, the inclusion of China leads to increased transport distances, yielding higher impacts for the [IT] scenarios. Additionally, in the retrospective approach, the Chinese market for sawnwood is mainly covered by imports, among others from Russia having less favourable climate conditions, poorer forestry practices and larger transport distances. In the prospective approach the domestic Chinese sawnwood production, which has a lower impact compared to Russia's production, has a much larger share. A similar reasoning applies to the [NA] results, with a shift from Western to Eastern European countries in the retro- and prospective scenarios. However, in this modelling option, the impact increased in the prospective scenario due to higher transport distances and less favourable climate conditions between others.

4. Discussion and conclusion

The present case study contributes to the methodological theory of consequential LCA by making the implications of different modelling choices explicit. Therefore, it takes a multi-model approach, evaluating seven alternative internal wall assemblies and subjecting each of them to four methodological scenarios. Additionally, five possible end-of-life scenarios were considered. The results show that the demountable and reusable wall alternatives have a similar or better environmental profile compared to the conventional ones, if regular refurbishments or transformations are realised by reusing existing components. However, the large range in possible outcomes illustrates the importance of a quantitative environmental in the search for well-informed design choices.

The theoretical framework of Weidema et al. [15] is the most widely used framework which focuses on long term changes in perfectly elastic markets. However, in most studies the suppliers affected by a change in demand and the consequences of a decision are identified based on observations of historical or current trends [16]. In this study clear differences in results were observed when applying both a retrospective and a prospective approach, indicating the limited relevance of retrospective trends when trying to estimate long-term consequences. In reality however development is typically not a linear process, but it follows rather a S-shaped curve [21]. Such non-linear trends can be captured by forecasting models which output forms the basis for the prospective approach. So even though such data are per definition more uncertain, they can provide a more nuanced image of expected future developments. They are particularly relevant when a structural reformation of a segment of the economy can be expected. The latter can be market driven, e.g. a decreasing demand for pulpwood in the paper industry combined with a sharp increasing demand for wood fuel [21], or due to legislation, e.g. the prevalence of renewable electricity production in expected newly installed generation capacity [22].

The methods used in this work consists of two distinct and independent steps. First markets are identified applying an iterative procedure ([IT]) or a network analysis ([NA]), which results in a list of countries. Afterwards the most sensitive suppliers are identified based on their increment in production volumes. In these procedures some criteria were introduced, e.g. to decide when a trade flow is relevant to consider to define geographical market boundaries or the minimum increment in production required for a supplier to be considered as being competitive. Such an approach has some pros and cons. There is no scientific ground for selecting a threshold value, making it an arbitrary choice by default. However, this does not mean that attributing a value to a criterion is a priori a meaningless and random decision. Taking the values attributed to the criteria that affect the size of the identified market as an example. The choice of a low value can be interpreted as a study of all potential suppliers, assuming that the existence of a trade link is a sufficient precondition to react to a change of demand. Choosing a higher value prioritizes the most important trade partners, which indirectly upgrades the magnitude of a trade connection to a criterion for competitiveness as well. So, the inclusion of well-chosen threshold values can obviously be an advantage, as the modelling assumptions can easily be tailored to the goal and scope definitions. In this study the goal was to identify the potential marginal suppliers, so a low value was applied. For statistical support of this interpretation, see Buyle [12]. An alternative approach is proposed by Sacchi [23] and Prosman & Sacchi [24], namely a trade-based criterion for supplier selection focusing on circular supply chains. The effect of a change in demand was followed directly down the supply chain until the end-markets with sufficient unconstrained production capacity are reached. An important advantage here is that indirect trade can be accounted for, which appeared to be relevant in both linear and circular supply chains.

A limitation of this study is that the method was only applied on products without specific function-based requirements supplied to a general market. For such products more data is available and at the same time no additional customer segmentation is needed. Such an additional customer segmentation might result in much smaller market niches or even in a direct link between suppliers. In this case, even if data is available, it might be more efficient to take a shortcut and identify the marginal suppliers qualitatively. More research on this topic in needed.

In this work the main focus was on consequential LCA by following the theoretical framework of Weidema et al. [15]. This framework entails some strong assumptions such as suppliers being fully constrained or perfectly elastic. By relaxing these assumptions, a model could yield a better reflection of reality. There are some other models that can provide relevant results as well. An interesting approach is to integrate equilibrium models in consequential LCA. Such models form a counterpart to the framework of Weidema et al. as typically a short time horizon is considered and the consequences of a change in demand are modelled based on elasticity of supply and demand. Both models are complementary. Weidema's heuristic approach focuses on long term changes in perfectly elastic markets, while equilibrium models assess short term effects. So, a symbiosis of both models could help achieving the long-term goals without inducing short-term negative consequences.

To conclude, this case study points out the potential benefits of introducing demountable and reusable walls. Further research will need to focus on optimising and refining the mentioned wall assemblies and expanding the number of methodological scenarios. In addition, an assessment and multi-objective optimisation at the building level is an opportunity for further research, taking into account the building- and user-specific context.

Abstract. Buildings are one of the largest energy consumers and greenhouse gas emitters in the world. As the largest part of the energy consumed by the existing non-insulated buildings occurs during the operation stage, retrofitting the building stock is crucial to reduce the environmental impact. To guarantee that the retrofit measures provide economic and environmental benefits, the whole life cycle should be assessed. However, the identification of environmental and at the same time cost-effective solutions is difficult due to the complexity and the uncertainty involved. Currently, simplified approaches based on limited assumptions are used that can lead to inaccurate results. This paper proposes a method for identifying robust renovation scenarios for residential buildings in Switzerland. The method and the developed tool use 47 uncertain parameters and Sobol' indices to identify the most influential parameters. As such, robust renovation strategies can be identified in the early design stage.

1. Introduction

Buildings are the largest energy consumers in the world [1]. The largest part of the energy consumption of existing buildings occurs during the operation stage. Therefore, retrofitting buildings is crucial to reduce environmental impacts and meet the United Nations (UN) climate action goals. In order to assess the environmental impacts holistically, it is vital to assess the whole life cycle. *Life Cycle Costing* (LCC) and *Life Cycle Assessment* (LCA) are two well-known approaches for assessing the economic and environmental impacts of buildings. However, the conventional LCA and LCC approaches apply deterministic assumptions for many parameters. These assumptions are taken for the input model parameters (e.g. material properties, selected material costs and environmental impacts) as well as exogenous parameters, which cannot be affected by the designer but directly impact the model response (e.g. room temperature, external climate, discount rates, price growth rates). These assumptions are highly uncertain and the consequent inaccuracy might lead to the big performance gap between the computed model and real result. Therefore, the question of uncertainty and data reliability has to be addressed to apply LCA and LCC as a practical and robust tool to assist policy decisions. Data quality and sensitivity of the results to the input data and the taken assumptions have been discussed in the field of LCA [2], [3]. Recent studies have shown that there is a balance point when the renovation can still be cost-effective and environmentally-friendly [4]. However, studies also highlighted the fact that the resulting uncertainties of LCC and LCA might be higher than the difference between two solutions [5]. Therefore, to achieve the robust renovation scenario in terms of LCC and LCA, the uncertainty sources need to be identified and quantified through rigorous statistical treatment. The current paper proposes a method to define the renovation scenario depending on the level of knowledge of the building. It is based on preliminary investigations in the field of historic building renovation [6]. The aim is to identify a robust renovation scenario by combining advanced statistical methods with the LCA and LCC methodologies. The proposed method is applied to an existing residential building located in Switzerland. The results show how to prioritize renovation strategies and at the same time determining the key parameters influencing the renovation using Sobol' indices [7].

2. Methodology

The methodology of the paper is shown in the Figure 1. First, the model for LCA and LCC calculations is created. After that, all possible renovation measures are selected and uncertain parameters for each measure are identified. Each uncertain parameter is described by a possible variability range and a distribution, which are selected according to literature sources or expert interviews. Then, the sensitivity analysis for all the measures is performed to understand the priorities for the renovation strategy. Finally, the uncertainty quantification on the selected strategy is applied to see the influence on the total LCC and LCA results. These steps are explained in further detail in the following.

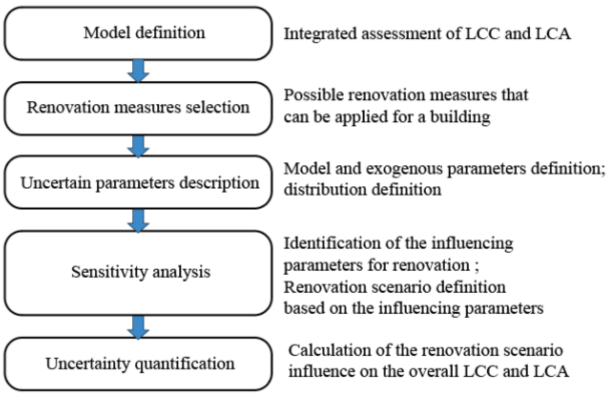

Figure 1. Methodology steps.

2.1. Integrated calculation for LCA and LCC.

The model includes three steps – heating demand calculation, LCC and LCA. The overall objective is to create an integrated workflow for LCC and LCA. The metrics of interest for the integrated assessment are the total costs and environmental impacts. For both, LCA and LCC, the functional unit refers to the use of the building over its lifetime. A period of 60 years is used as a reference study period of the building at the year of renovation according to the Swiss standard SIA 2032 [8]. The whole calculation process is conducted using python programming language.

Heating demand. The first step of the process includes the operational energy demand calculation which is performed according to the Swiss standard SIA 380/1 [9]. The calculation is performed using a quasi-steady state approach based on monthly values in order to achieve low computational costs.
Life cycle cost. The heating demand results are used for the LCC analysis. The stages for LCC include initial costs, operation, replacement and demolition. The net present value approach is selected for this study as a well-recognized and broadly used approach [10]. The cost data is taken from the Swiss Federal Office of Statistics [11].
Life cycle assessment. In parallel with LCC, an LCA is applied. The conventional life cycle stages according to SN EN 15978 with the modules A1-A3 (production), B4 (replacement), B6 (operational energy use) and C1-C4 (end of life) are used as system boundaries for this study. KBOB "Ökobilanzdaten im Baubereich", a Swiss database is used for the life cycle impact assessment of the building materials and technical systems [12]. The greenhouse gas emissions (GHGe) are used as an

indicator for climate change, (unit expressed in kg CO_2-eq) and calculated based on the IPCC Global Warming Potential (GWP) characterizations factors [13].
After the initial model is set, the validation of the heating demand results is performed using the Lesosai software which also complies with SIA 380/1 standard [14]. After the model is set, the possible renovation measures are applied in the model.

2.2. Renovation measures selection
Renovation strategies can be characterized differently depending on the design stage as well as different stakeholders. For instance, the priorities in renovation strategies for the whole Swiss building stock is likely to be different from the renovation priorities for one specific construction period or for an individual building as the level of details and knowledge about the initial model might vary highly. In case of different stakeholders, portfolio managers might have different perspective on renovation strategies and therefore, different goals compared to real estate managers or building owners. Therefore, a strategy that is able to cover all possible renovation scenarios is needed.

The model is able to cover different levels of details. This allows modelling the input parameters and seeing their influence on the total LCA and LCC results. The method allows to assess different renovation strategies and understanding the most influential parameters using Sobol indices.

The range of design parameters is selected to include all possible solutions, i.e. from the current state of the building to renovation solutions that comply or even outperform the requirements according to Swiss standards (e.g., the SIA 380/1 for the heating demand). Initially, the sensitivity analysis is performed to understand the influential parameters for the renovation in terms of LCA and LCC. Afterwards, the uncertainty quantification using polynomial chaos expansion (PCE) is used to see the influence of the input parameters' range on the results.

2.3. Uncertainty quantification
Uncertainty quantification (UQ) aims at identifying all sources of uncertainty in the parameters of a model and assessing how they affect the model response. Sensitivity analysis is an important tool in UQ and allows to identify which input parameters, and combination thereof, influence the model output the most. The analysis is often carried out by propagating the uncertainty throughout the model, *e.g.* using Monte Carlo simulation. However, the resulting computational cost is prohibitive, as it would require thousands to millions of calls to the computational model. In this work, the computational model described above is approximated by a surrogate model, *i.e.* an easy-to-evaluate proxy. More specifically, *polynomial chaos expansions* (PCE) are used as a surrogate model as they allow efficient representation of the model response and can further be used for sensitivity analysis.
Polynomial chaos expansion. A finite variance computational model is considered $Y = \mathcal{M}(\boldsymbol{X})$ that allows to compute some quantity of interest (herein, heating demand, LCA or LCC) and which takes as input an M-dimensional random vector $\boldsymbol{X} \sim f_{\boldsymbol{X}}(\boldsymbol{x})$ whose marginals are assumed to be independent. PCE allows for a spectral decomposition of the random variable Y onto a set of orthonormal polynomials [15]:

$$Y = \sum_{\boldsymbol{\alpha} \in \mathbb{N}^M} y_{\boldsymbol{\alpha}} \psi_{\boldsymbol{\alpha}}(\boldsymbol{X}) \quad (1)$$

where $\psi_{\boldsymbol{\alpha}}(\boldsymbol{X}) = \prod_{i=1}^{M} \psi_{\alpha i}(X_i)$ are a set of multivariate orthonormal polynomials obtained by the tensor product of univariate polynomials. These polynomials are selected according to the marginal distribution of the random variables X, α alpha are a set of indices and y_α are coefficients to be computed.
In practice, this infinite series is truncated into a finite set of polynomials, thus leading to an approximation. The surrogate model is obtained by calibrating the coefficients y_α for a given set of polynomials. This can be achieved using different methods, among which are least-squares techniques. This requires first generating an *experimental design* (ED) $\{ \mathcal{X}, \mathcal{Y} \}$, where $\mathcal{X} = \{\boldsymbol{x}^{(i)}, i = 1, \dots, N\}$ correspond to uniformly sampled input points and $\mathcal{Y}$ are the corresponding model evaluations, i.e. $\mathcal{Y} = \{\mathcal{M}(\boldsymbol{x}^{(1)}), \dots, \mathcal{M}(\boldsymbol{x}^{(N)})\}$. N is the ED size and typically ranges from tens to a few hundreds. Given the

ED, the coefficients are computed using least-squares minimization or other advanced techniques. Details on practical computation of PCE can be found in Gratiet *et.al*[16].

Global sensitivity analysis. Global sensitivity analysis [7] aims at quantifying the importance of each random input in the variability of a model output. Many methods found in the literature are based on the decomposition of the output variance [17]. Sobol' indices are a popular technique that belong to this category of methods [7]. Assuming that the input $\boldsymbol{X}$ are independent, the Sobol' decomposition of the model $\mathcal{M}$ reads [18]:

$$\mathcal{M}(\boldsymbol{x}) = \mathcal{M}_0 + \sum_{i=0}^{M} \mathcal{M}_i\,(x_i) + \sum_{1\le i\le j\le M}^{M} \mathcal{M}_{ij}\,(x_i, x_j) + \cdots + \mathcal{M}_{1,2,\ldots M}(x_1, \ldots x_M), \tag{2}$$

where M_0 is a constant and the other summands satisfy the following orthogonality condition:

$$\int_{Dx} \mathcal{M}_{i1,\ldots,is}(x_{i1,\ldots}x_{is}) f_{X_{i1}}(x_{i1}) \ldots f_{x_{is}}(X_{is}) \quad d_{xi1\ldots}\, d_{xis} \;\; = 0, \quad 1 \le i_1 \;\le \cdots \le\; i_s \le M, \tag{3}$$

It can then be shown that the output variance can be decomposed as follows [7]:

$$D = Var[\mathcal{M}(\boldsymbol{X})] = \sum_{i=1}^{M} D_i + \sum_{1\le i\le j\le M}^{M} D_{ij} + \cdots + D_{12\ldots M} \tag{4}$$

where

$$D_{i1,\ldots,is} = \int_{Dx} \mathcal{M}_{i1,\ldots,is}(x_{i1,\ldots}x_{is}) \quad f_{X_{i1}}(x_{i1}) \ldots f_{x_{is}}(X_{is}) dx_{i1} \ldots dx_{is} \tag{5}$$

The Sobol' indices are eventually obtained by normalizing the partial variances and read:

$$S_{i1,\ldots,is} = \frac{D_{i1,\ldots,is}}{D} \tag{6}$$

The first-order Sobol' indices relate to the univariate term and express the additive effect of each input taken separately. Higher-order Sobol' indices (combination of two or more variables) represent the interaction effects. Finally, the total order index for a given variable represents its own effect together with any interaction. A small value typically means that the parameter has very little effect on the output variability. As a consequence, setting the corresponding variable to a constant value would not affect the distribution of the quantity of interest. On the contrary, a large value means that the analyst should focus on reducing the corresponding parameter uncertainty.

Sobol' indices in the general case are computed using Monte Carlo simulation. However in this paper, we consider PCE-based Sobol' indices as developed by B.Sudret [19]. Sobol' indices can be obtained at no additional cost by simply post-processing the PCE coefficients. Further details on the computational aspects of sensitivity analysis can be found in the corresponding UQLab users manuals[20].

3. Case study

The chosen case study is located near Lausanne, Switzerland. The building was constructed in 1972 and has a total energy reference area of 1440 m^2. The ground floor is partly occupied by the commercial space of 50 m^2. The initial properties of the building can be seen in the Table 1.

Table 1. Initial building properties before renovation

Element	Existing state of the building
Ext.wall (Residential)	4cm mineral wool, U = 0.56 W/(m²K)
Ext.wall (Shop)	4cm mineral wool, U = 0.71 W/(m²K)
Ground floor	2cm cork in the shop, U = 1.4 et 3.2 W/(m²K)
Ceiling against attic	6cm mineral wool, U = 0.5 W/(m²K)

Windows	Double glazing (low-E layer, PVC frame, U=1.91 W/(m²K), gp = 0.55

The current case study was selected from the eRen building models, because they cover different construction periods and were already characterised for their initial states i.e. before any renovation [21]. The construction period for this building was selected to be 1970s as it represents the majority of the Swiss building stock (32.5% of the entire building stock, [22]). Different goal and scope and settings for the model parameters can be chosen for the renovation measures of this building. They are presented in Table 2 for the three scopes of the assessment which are described below in separate sub-sections.

Table 2. Parameters' setting for the renovation of the building envelope in the three assessments

	1st assessment	2nd assessment		3rd assessment	
Goal of the study	*Screening assessment of all possible measures*	*Comparative LCA & LCC of two heating system replacement with a distribution of the U-values for the renovation of the envelope*		*Comparative LCA & LCC of two heating system replacement with specific U-value and materials for the renovation of the envelope*	
Element		**Solution 1**	**Solution 2**	**Solution 1**	**Solution 2**
Heating source and system	Random heating systems (oil, gas, coal, wood pellets boilers) floor and radiators heating	Wood pellets boiler, floor heating	Gas boiler, floor heating	Wood pellets boiler, floor heating	Gas boiler, floor heating
Roof insulation thickness	Random values between the existing state and an improved U-value of 0.15 W/m^2*K			0.2 m	0.1 m
Windows	Random values between the existing state and an improved U-value of 0.6 W/m^2*K			Triple glazed, wooden frame, U-value –1.2 W/m^2*K	Double glazed, PVC, U-value –1.4 W/m^2*K
External walls	Random values between the existing state and an improved U-value of 0.2 W/m^2*K			No insulation	No insulation
Floor insulation thickness	Random values between the existing state and an improved U-value of 0.2 W/m^2*K			0.15 m	0.1 m

3.1 Variability of all possible measures (screening assessment)

In the first screening assessment, we assume the user of the tool does not know which scenarios to apply for the replacement of heating systems and for the renovation of the envelope. The idea is first to describe all possible renovation measures with different U-value requirements for the elements from no renovation up to very low U-values and different heating system types. For example, each building element can be kept either in its current state (uninsulated) or renovated according to different U-values (e.g., 0.25, 0.20, 0.10 [W/m^2*K], etc.). The U-values after renovation were varied using continuous variables for the thicknesses and thermal conductivities values to ease the probabilistic assessment.

Similarly, we also take into account the expected variations of the exogenous parameters, which can be seen in the Table 3. These parameters cannot be influenced by the designer and therefore, this uncertainty cannot be reduced during the design stages. The values were fixed based on variations around the conventional values defined in the SIA 380/1 standard and in the CRB (for costs' parameters).

Table 3. Exogenous parameters in the screening assessment and in the two comparative LCA & LCC

Parameter	Distribution	Range, moments
Room temperature	Uniform	19 - 23 °C
Discount rate	Uniform	1 - 3 %
Price growth for heating	Uniform	3.5 - 5.5%

Thermal bridge	Gaussian	Mean – 10%, Std – 5%
Airflow	Uniform	0.7-0.9 $m^3/(m^2*h)$

After the ranges of model and exogenous parameters are defined, the sensitivity analysis is conducted to identify the most sensitive parameters for this level of knowledge (screening assessment). To understand how the selected levels of performance for the envelope and technical systems influence the total LCA and LCC results, the uncertainty quantification using PCE method is applied in UQlab [23].

3.2 Comparison of two renovation scenarios

Following the screening assessment, in a second step, comparative LCA and LCC are conducted. Two solutions of replacement of the heating system are chosen and compared (cf. Table 2). We assume the replacement of the old oil boiler by a new gas boiler (baseline case) and the replacement of a new wood pellet boiler ("environmental friendly" alternative). Each scenario is coupled with different renovation measures for the envelope (roof, external walls, windows and floor). For each scenario, the renovation measures of the building elements take random values for the insulation thickness, the thermal conductivity, the associated environmental impacts, and the investment costs between the existing state and an improved energy-efficient renovation as already introduced in section 3.1.

In the third assessment (i.e., in the second comparative LCA & LCC analysis), a specific renovation scenario is applied for the building envelope (with a given U-value for each element after renovation. Assumptions for this scenario are presented in Table 2. This scenario represents the one defined in the eRen project. The same range for exogenous parameters as the ones presented in Table 3 were considered in these two comparative assessments.

4. Results

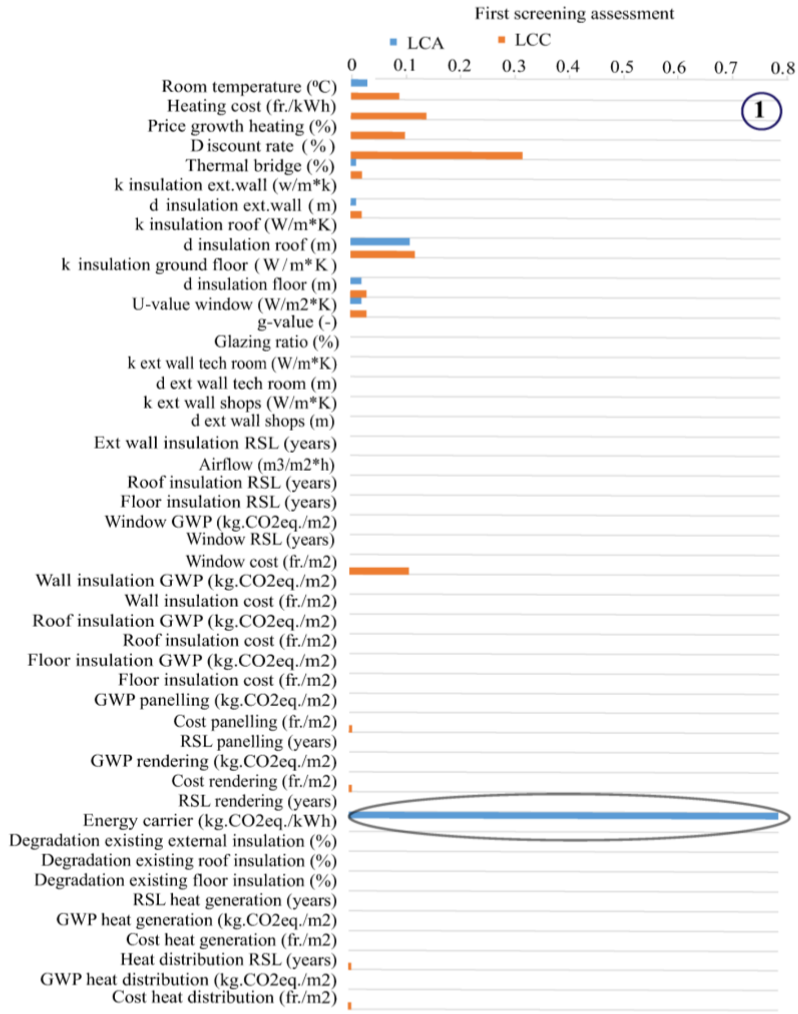

Figure 2 (1). Sensitivity analysis using Sobol indices for the screening assessment when the variability of all the measures was applied.

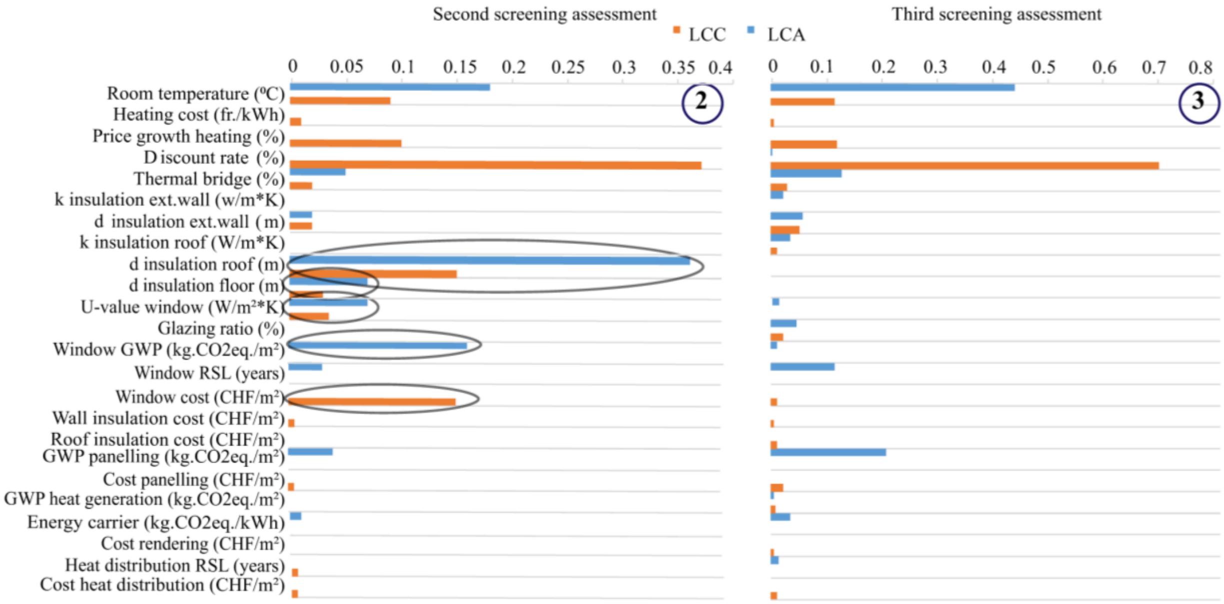
As it was mentioned in section 3, 47 model and exogenous parameters used for the building heating demand, LCA and LCC calculations are considered. The first screening assessment includes a range for all of them. The second and third assessments only include a range for the parameters that have an influence on the total LCA and LCC results.

As it can be seen in Figure 2(1), when the variability of all measures is applied (using assumptions from section 3.1), we notice that from the 47 parameters defined with a range, only about 8 of them present a sensitivity index of more than 0.05. Looking at the LCA, the variance of the output GHG emissions is only driven by the uncertainty on the choice of the energy carrier. In terms of life cycle costs, more parameters are sensitive: model parameters (the heating costs, windows costs, the density of the insulation for the roof) and exogenous ones (room temperature, price growth heating, discount heating). Interestingly, the heating cost is comparatively less sensitive to the output result than the heating environmental costs (energy carrier GHG emissions). This can be explained by the higher variance of the energy carriers GHG emissions directly influencing the output results (GHG emissions of the building, see Figure 3).

In the second and third comparative LCA & LCC, when the energy carrier is selected for each scenario using assumptions from Table 2, there is no more variability on the energy carrier GHG emissions. So the Sobol index becomes zero for this “known” parameter. In this case (Figure 2(2)), other model parameters become sensitive in each scenario of heating system replacement (according to Sobol) e.g., the roof insulation and windows. In terms of exogenous parameters, for LCA, modelling parameters are prevailing in the first and second screening assessment, and once the roof insulation, windows and heating system are renovated, the exogenous parameters become of highest importance. In terms of LCC, it can be seen that the exogenous parameters appear to have high importance already in the first screening assessment (e.g. discount rate and price growth rate for heating).



Figures 2(2) and 2(3). Sensitivity analysis for the second and third assessment (for specific heating systems' choice)

After the sensitivity analysis is conducted, uncertainty quantification for the selected renovation scenario is performed. As is was mentioned earlier, sensitivity analysis is helpful to identify the most sensitive parameters of the renovation measures. It goes along with the uncertainty quantification of different renovation scenarios but it cannot provide the optimal solution for the renovation. Therefore, at the current stage, two options were selected as possible renovation strategies.

Figure 3 presents the probabilistic LCA and LCC results when all renovation measures are considered. The results show an important variability of both GHG emissions and total costs in CHF.

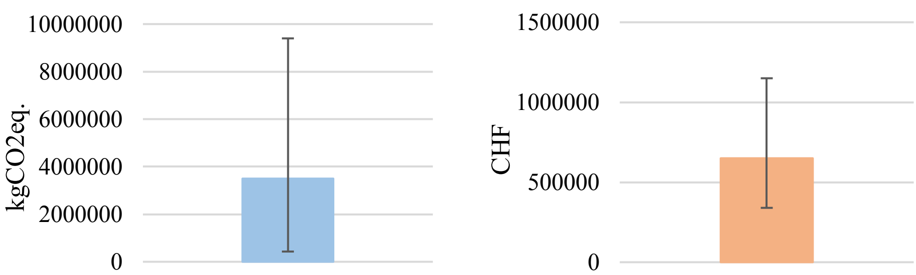


Figure 3. LCA and LCC results for the uncertainty quantification on the screening assessment of the building (variability of all possible measures).

The results for the probabilistic LCA and LCC for the second and third assessment are presented in Figures 4-5.

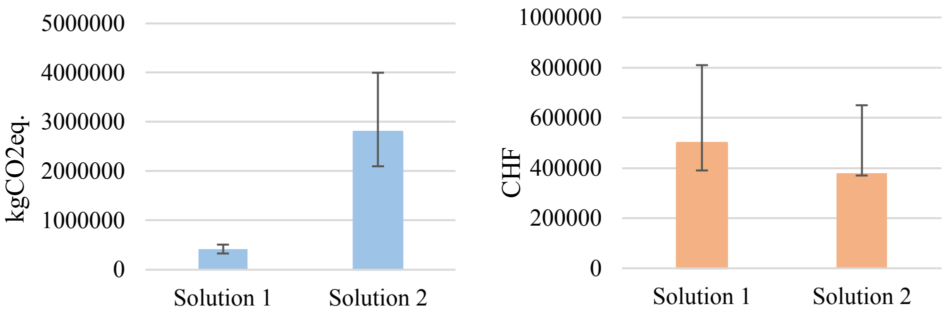

Figure 4. Comparative LCA and LCC results for solutions 1 and 2 using the applied measures of the second assessment.

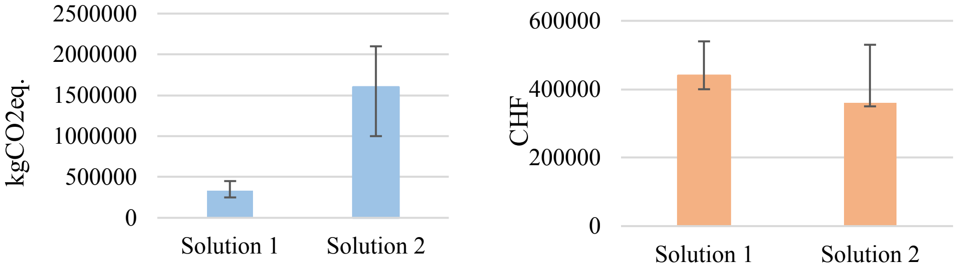

Figure 5. Comparative LCA and LCC results for solutions 1 and 2 using the applied measures of the third assessment

While the first sensitive parameter in the screening assessment is fixed (in the second and third assessment) using low-GHG emissions heating systems' solutions (wood pellets and heat pump), an important decrease in the mean value as well as uncertainty for both LCC and LCA can be observed. It can also be seen from two solutions that the decrease of the mean value for LCC does not occur with the same proportion as for LCA, which means that low GWP renovation measures do not necessarily yield low NPV. Therefore, an optimal solution that is both cost-effective and environmentally friendly still needs to be found. This can be potentially achieved by using multi-objective robust optimization under uncertainties.

Interestingly, Figure 4 shows that solution 1 is a robust solution for lowering the GHG emissions compared to the solution 2 (as the error bars do not merge between the two). In contrast, we cannot distinguish the two solutions in terms of life cycle costs. This shows the usefulness of such combined statistical approach with usual LCA and LCC methodologies.

5. Discussion

The current study shows how to identify the influential parameters for the renovation using a sensitivity analysis. This approach allows understanding the focus of the renovation at the early design stage. At the current stage, the method is able to handle stochastic calculations of LCA and LCC of building renovation scenarios. The renovation scenarios definition can be more or less detailed (see section 4 with a first screening assessment to a very specific third assessment). However, proper optimization process is needed to identify the best renovation strategy.

So further development will include the optimization under uncertainty, which allows understanding the renovation priorities as well as finding the optimal solutions in terms of LCA and LCC.

In this paper, the approach was applied for one residential building in Switzerland. In the future, the aim is to analyse the applicability of this method for the Swiss building stock. In order to find an optimal robust solution for the renovation of the building stock, building archetypes for different construction periods will be analysed.

The current method also shows that there is a non-negligible influence of the exogenous parameters on LCC and LCA, which means that even with identification of a precise renovation scenario with powerful statistical treatment, there are still many uncertainties in the building's life cycle. Therefore, it is crucial to consider parameters like occupants' behaviour, possible degradation rates for the building materials and economical parameters like price growth rates and inflation. The associated exogenous parameters shall also be considered with their uncertainty (including climate change trends) for a more realistic analysis. In the current study, climate data from SIA was used and the modelling of the relevant climate data for this type of analysis is currently in progress.

6. Conclusion

A statistical method combined with existing LCA and LCC methodologies was applied to the renovation scenarios of one residential building in Switzerland. The proposed framework is able to compute probabilistic LCA and LCC to compare different renovation strategies for different levels of knowledge of the existing building. It also identifies the most influential parameters for each type of assessment (screening or detailed). First results show the range of impacts and costs for all possible renovation measures when the energy carrier and heating system are not chosen or known. Once the heating system is fixed, the level of uncertainty on LCA and LCC is much reduced allowing to focus on the renovation of the building envelope. A first comparative LCA and LCC on two renovation scenarios shows that the choice of the best scenario is robust for the LCA while it is not possible to conclude on the LCC part. It can also be observed from the results of uncertainty quantification that the minimum value is always closer to the mean than the maximum value, which means that without uncertainty consideration the values at risk for both LCC and LCA are high. This highlights the necessity of uncertainty propagation when LCA and LCC are used during the decision-making process.

Abstract. Uncertainties evaluation is increasingly gaining traction within life cycle assessment (LCA), due to its key role as environmental decision support tool. When applied at whole-building scale, the large variety of materials, subjective choices and long lifespans introduce parameter, scenario and model uncertainties throughout the life cycle. Since normative choices are unavoidable within whole-building LCA (wbLCA), in this article we carried out a so-called 'scenario' uncertainty assessment for one illustrative case study. First, three uncertainty sources were selected, to include the two drivers most frequently cited in literature (reference service life and end of life management alternatives) and material wastage, a relevant issue to factor in variable construction optimization levels in contexts like Brazil. Cumulative energy demand (CED) and CML 2001 v.2.05 methods were used for calculating deterministic values of non-renewable embodied energy and global warming potential in SimaPro 7.3 The uncertainty assessment combined scenario analysis, stochastic modelling (Monte Carlo simulation of triangular probability distributions for the uncertainty drivers investigated) and global sensitivity analysis (GSA). The GSA confirmed the dominant contribution of the operational phase - strongly influenced by components replacement rate - to of life cycle non-renewable embodied energy and global warming potential result variance, whilst construction and end of life stages showed no correlation with life cycle results. Findings from this research also highlight the strategic importance of gathering service life information adherent to the assessed context. Building components replacement rates induced by the Brazilian standard are overestimated relatively to international figures used in LCAs worldwide.

1. Introduction

The environmental assessment of whole-buildings inevitably includes uncertainties, since they are complex assemblies with a high number of materials, unpredictable lifespans, and hard to predict future uses [1]. Scenario uncertainties can be defined as those resulting from normative choices made throughout the building's life cycle, which create multiple possibilities of conducting the assessment and therefore a range of values for its results [2].

Although the need to assess the influence on normative choices in wbLCA is acknowledged, no consensus was reached on the most appropriate methodology to do it [3]. Scenario analysis practice is recurrent to aggregate uncertainty information to LCA results [3–6]. Despite strategically highlighting materials and life cycle stages that most influence results, it assumes linearity and ignores correlations between parameters [3,7]. A higher number of choices and materials, for example, impose challenges to accurate evaluation through deterministic values, which means that its interpretation is limited.

On their turn, statistical evaluations aims at adding information to how assertive the result value is [8]. Selecting representative distributions is essential to uncertainty analysis, especially when it comes to high influence inputs. Each scenario developed has particular chances of occurring. Uniform distributions can be used when little more is known beyond its minimum and maximum values. Indeed, the scarce studies using MC in the wbLCA literature normally assume uniform probability distributions, which assigns equal probabilities of occurrence to all possible alternatives (scenarios) [2,9]. Though the use of uniform distribution is a step forward relatively to simply performing scenario analysis, it is unlikely to properly describe real life events. Triangular distributions are still imperfect and based on very limited information but can be useful for deriving approximate probability distributions through estimation of three points (minimum, maximum, most frequent) pertaining to that distribution, thus improving assignment of different probabilities to all alternatives considered.

Given the lack of a consensus procedure for assessing how ‘scenario uncertainties’ affect wbLCA results, in this paper we tested three alternative techniques for a selected case study, to identify the most promising approach(es).

2. Method

The LCA was developed in accordance with ISO 14040 [10] and the European Standard BS EN 15978:2011 [11]. The functional unit was the whole-building, and the scope of the study was Cradle-to-grave with options, restricted to modules A1-A3, A4-A5, B1-B6, C1-C2. Using a single inventory database is recommended for consistency sake but was unfeasible at the time of study. We used primary data on cement, mineral admixtures and concrete products. Most secondary data were collected from the Ecoinvent database v3.2, with some inputs from literature. Non-renewable Embodied Energy (EE NREN) and Global Warming Potential (GWP) were selected to illustrate our study, through the use of CML 2001 and Cumulative Energy Demand (CED) impact assessment methods.

The selected case study was a steel frame building designed as a “minimum lifecycle embodied energy and emissions’ (minLCee) Living lab [12], as shown in Figure 1. Its integrated design process optimized resource use, and included storm water management, low-energy space conditioning installations, green roof and wall, PV array, online resource use and internal monitoring, among other recommended practices.

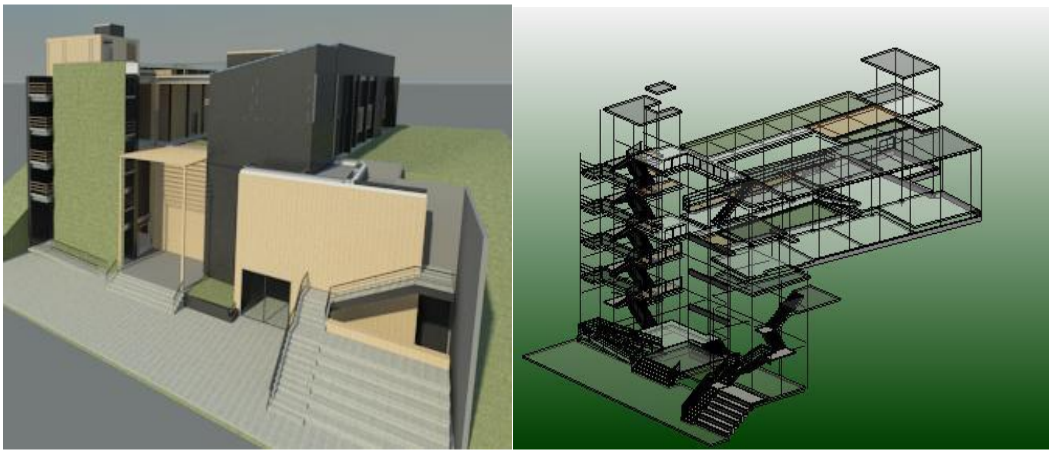

Figure 1 - Renderings from the minLCee living lab's building information model

Insights provided by three different approaches for scenario uncertainty assessment were analysed: multi-scenario analysis, stochastic modelling with uniform distribution, and stochastic modelling with triangular distribution.

2.1. Multi-scenario analysis

We began the uncertainty assessment by using multi-scenario analysis to run the LCAs and consider variations induced by each choice investigated. Scenario analysis is a type of sensitivity analysis frequently applied to evaluate LCA results, which consists of estimating and comparing effects that normative choices introduce in the results, by formulating different corresponding scenarios. Three alternatives plausible in the present or short-term Brazilian context were suggested for each uncertainty source studied [13], and an overall analysis considered the range of possible outcomes. A total of 27 scenarios was developed (Figure 2).

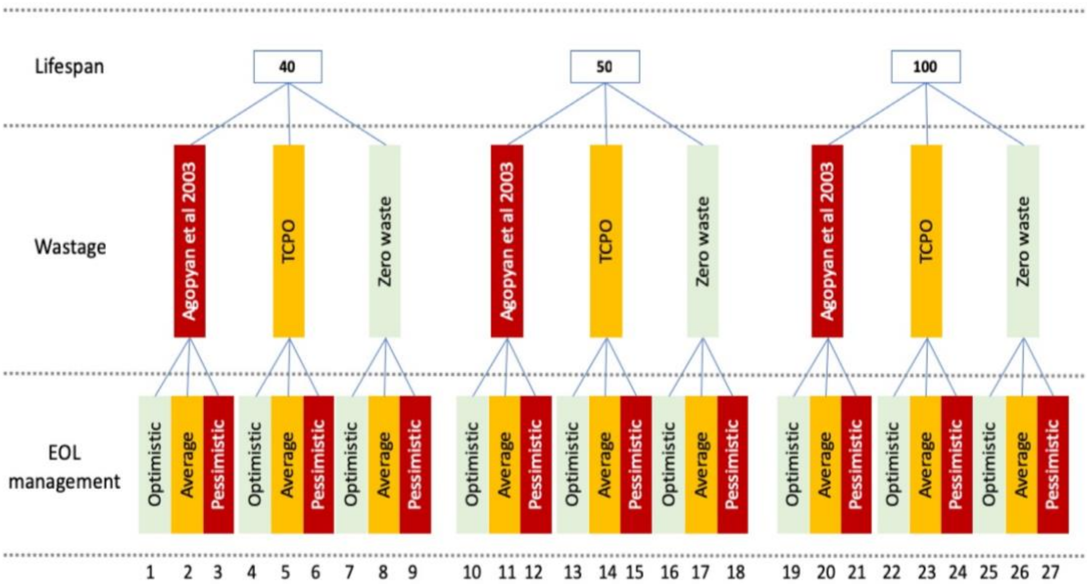

Figure 2 - Range of scenarios analyzed

Our systematic literature review indicated that the most frequently studied wbLCA choices are the building's reference service life information and waste disposal flows. The chosen lifespan scenarios were based on the Brazilian performance standard [14] minimum compliance level (50 years), and inspired by the lowest (40 years) and highest (100 years) values found in the literature review, to respectively take into account the international trend of producing buildings with elongated service life to make better environmental use of resources, as well as developing countries reality characterized by waste and maintenance intensive technologies [15].

To meet the stipulated reference service lives scenarios, the steel frame was protected against corrosion. Since the case study is situated in a C3 corrosivity category environment [16], the protection system was a 200mm-thick alkyd resin surface coating that creates a barrier between the environment and the structure, with a durability of 15 years.

Regarding waste disposal flows, different scenarios were developed to represent realistic alternatives for demolition/deconstruction and material transport to suitable management sites. Scenario A outlines an extremely inadequate disposal, in which 100% of the produced CDW is sent to the city landfill. Scenario B acknowledges the Brazilian construction reality, in which a 21% of CDW is recycled [17]. Finally, scenario C follows the European waste policy new directive for 2020, in which waste is seen as a valuable resource and 70% of CDW is recycled [18].

Finally, a third uncertainty source was included to consider material wastage during construction and maintenance activities. Since wbLCA are typically carried out before actual construction takes place, wastage is estimated and the choice for value source might influence the overall environmental performance. Although wastage is not explicitly addressed in the wbLCA literature reviewed, and the latter scenario seems to be assumed as default, such procedure would significantly underestimate impacts in the Brazilian reality. For this article, we considered a zero waste scenario and two additional variants, using the wastage values extracted from the Brazilian Table of Price Composition (TCPO) [19] and from Agopyan et al [20], whose collection of bottom-up representative field data from all over the country exposed the significant deviations that some construction services and activities could show relatively to the national average, although data were representative for construction practiced 15 years ago and such deviations can be outdated. TCPO presents typical average values and is an information source largely used by the national construction community and offers an updated - though less inclusive - outlook to ground contextualized assessments.

2.2. Stochastic modelling and global sensitivity analysis

Stochastic modelling was performed by running Monte Carlo sampling simulations (MC) with the @ Risk Excel add-in to quantitatively estimate the uncertainties arising from modeling choices made over the wbLCA. The analysis used 10,000 iterations for each impact category, as recommended in the literature.

Production stage modules A1-A3 and construction module A4 (transport) were calculated as deterministic points since they are not influenced by the normative choices considered (material wastage, service life, EOL management strategy). The output computed in the MC simulations were the sum of values in each life cycle stage.

The input data for MC depends on the probabilistic distribution chosen to best represent the model. Triangular probabilistic distributions assumed for each of the uncertainty sources analyzed in the construction, use and end of life stages. Three point's estimates were derived from occurrence frequency of each normative choice extracted from the reviewed literature for each scenario.

From the MC-simulated results, we ran global sensitivity analysis to identify the most influential inputs in the output's uncertainty measurement (contribution to variance) and in obtaining additional parameters iteration information [7].

3. Results and Discussion

3.1. Multi scenario analysis

Figure 3 and Figure 4 show life cycle results for the multiple scenarios developed. For both impact categories selected (non-renewable embodied energy and global warming potential), the influence of reference service life on wbLCA results is very clear: the columns are basically proportional to the reference service life, with slight contributions from the other (construction wastage and EOL) aspects factored in.

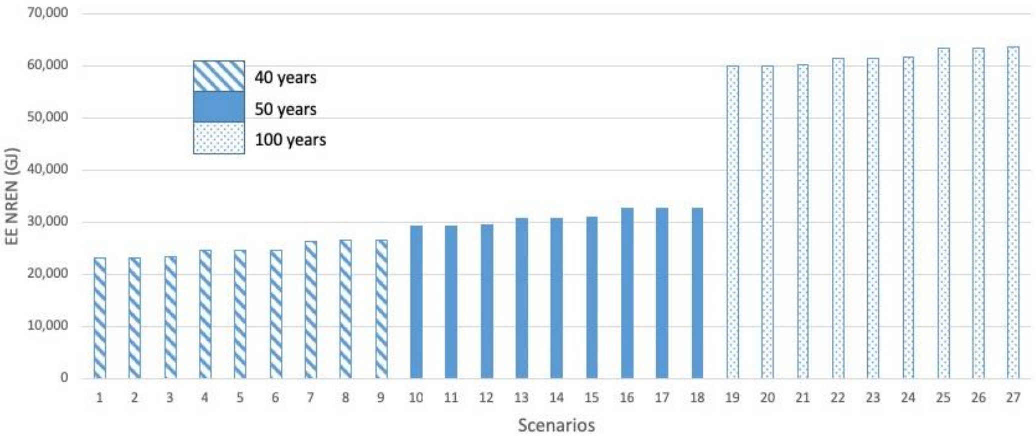

Figure 3 - Multi-scenario results for embodied energy, non-renewable

The variation resulting from waste disposal alternatives after the building's service life was negligible, and alterations between scenarios do not exceed 2%. As to material wastage during construction activities, discrepancies between wastage values extracted from [19] and [20] were not expressive, but figures in both sources are considerably higher than zero waste assumption.

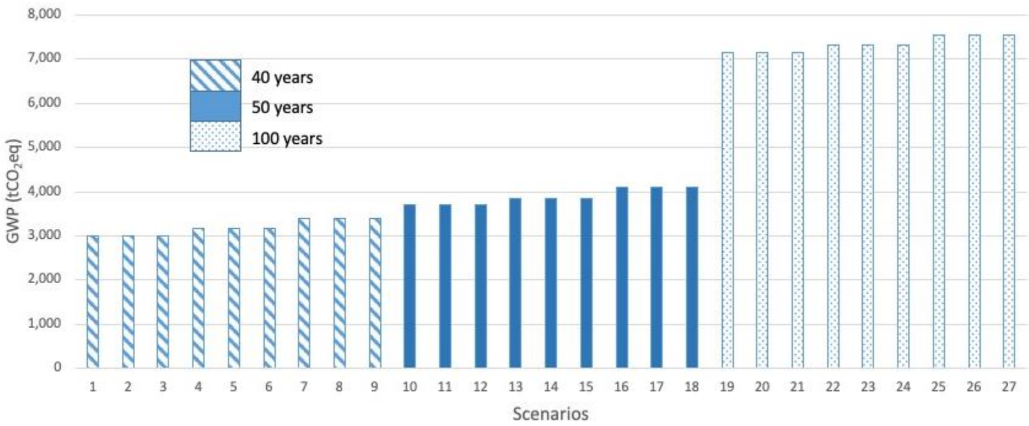

Figure 4 - Multi-scenario results for embodied GWP

3.2. Stochastic modelling

Table 1 details the inputs used in the uncertainty analysis. Even though the calculation model is simplistic in terms of its inputs and chosen distribution, it represents current whole-building LCA practice, in which accurate probability distributions are typically unknown and input parameters to generate even simple distributions unavailable.

In order to show how triangular distributions improve a given input's description relatively to less-informed uniform distributions, Figure 5 superposes uncertainty histograms displaying the range of possible final results for non-renewable embodied energy and respective occurrence probability . The uniform distribution flattens the curve and dislocate the (lower value, most probable) upper portion mostly towards higher (but least probable) values instead.

Table 1 - Input parameters for the Monte Carlo simulation

Input parameter detailing					
Variable	**wbLCA stage**	**Impact category**	**Values**		
			Min	**Average**	**Max**
Wastage	Construction (A5)	EE NREN (GJ)	382	1,768	3,708
Lifespan	Use (B1-B5)		8,902	15,066	45,886
EOL management	End-of-life (C1-C2)		164	225	349
Wastage	Construction (A5)	GWP (tCO_{2eq})	537	697	931
Lifespan	Use (B1-B5)		878	1,570	5,031
EOL management	End-of-life (C1-C2)		7	7	8

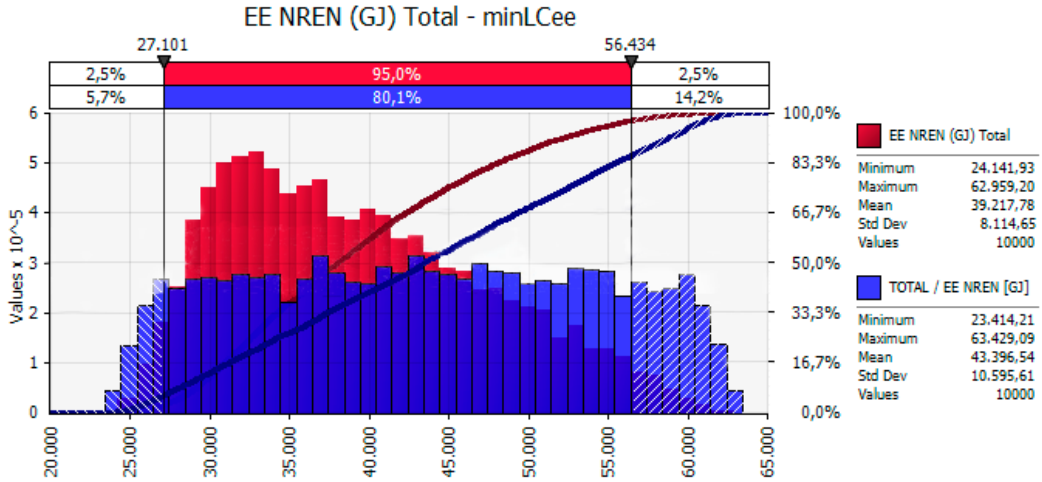

Figure 5 - Uncertainty statistical evaluation histograms, with the range of probable occurrence frequencies (axis Y) for the possible case study results for non-renewable embodied energy when uniform (blue) and triangular (red) probability distributions are assumed

Figure 6 features scatter plots showing the lack of correlation (homogeneous clouds, with Pearson coefficients near zero) between values of non-renewable embodied energy at construction (red dots) and end of life (green dots) stages and the life cycle total.

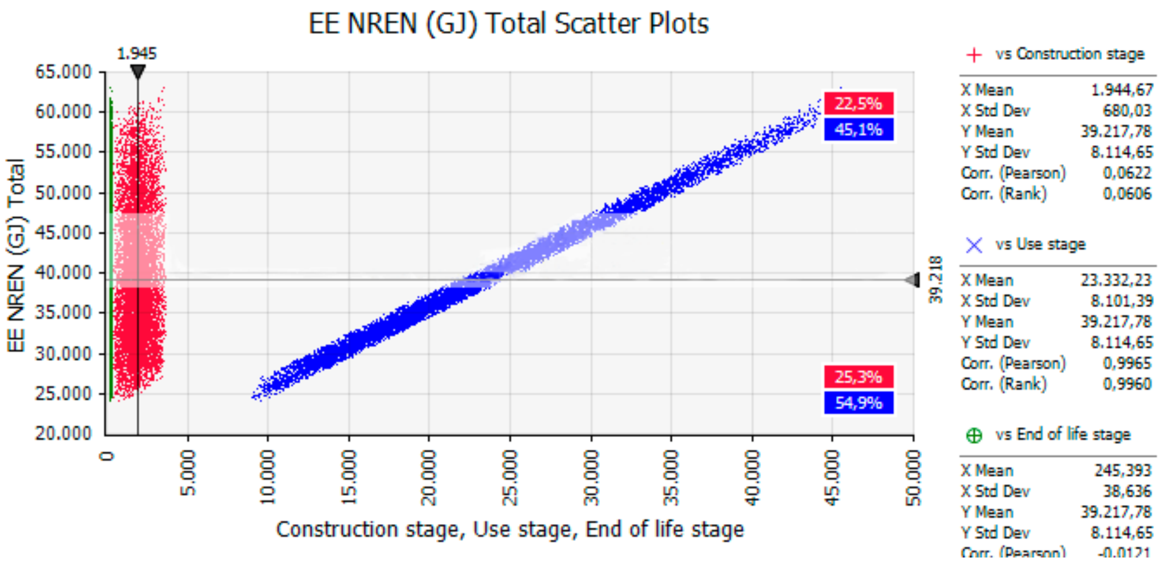

Figure 6 - Scatter plots for embodied energy non-renewable at construction, use and end of life stages

The data points resulting from the operational stage iterations (blue dots), which is strongly influenced by components replacement rates to achieve the established service life, assume a linear layout that indicates a solid correlation with the wbLCA results (Pearson coefficient near 1). Global warming potential results follow exactly the same pattern.

The global sensitivity analysis also confirmed the dominance (99,2%) of the operational phase's contribution to final wbLCA result variance. The uncertainty modelled in the construction stage contributed with the remaining 0,79%, whilst EOL effect was negligible, as shown in the radar graph (Figure 7). Such analysis is particularly useful in LCAs with a high number of choices to consider, for enabling evaluation of each input contribution separately.

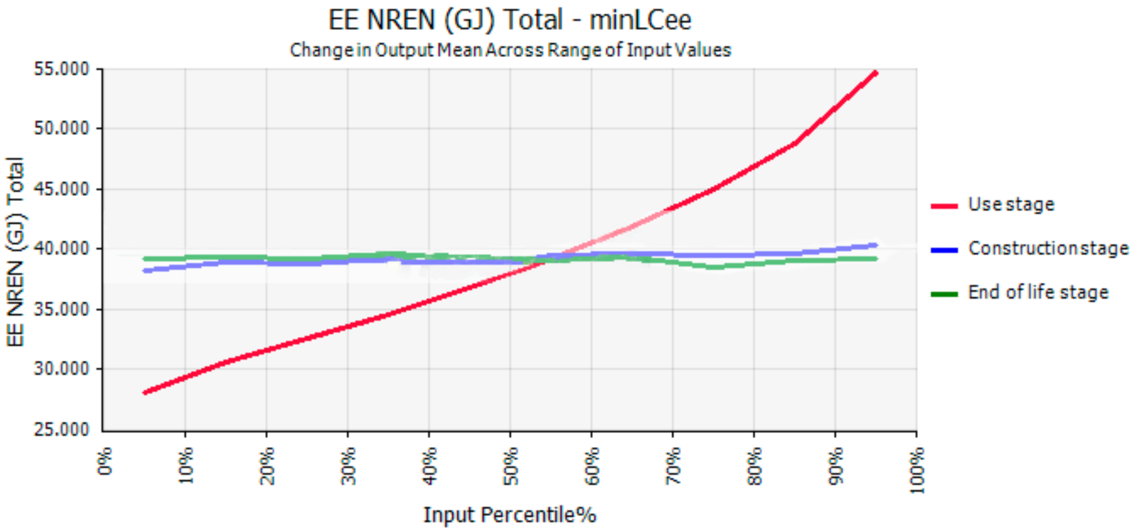

Figure 7 - Radar graph for EE NREN showing how the average output (life cycle EE NREN) changed through every input (values for use, construction and EOL stages) value interval. The sharper the slope of the line, the greater the influence.

4. Conclusions

To assess how scenario uncertainties affects wbLCA results, and to identify proper approaches to carry out such assessment, we performed uncertainty analysis through different, but incremental techniques: scenario analysis followed by stochastic modelling with probability distribution.

The sensitivity analysis presented a range of possible outcomes, with the use of deterministic values. It is a simplistic way of finding outcome variations attached to a diverse set of alternatives, and usually takes an expert eye to extract detailed and relevant insights. Nevertheless, it is important to point out macro trends and hotspots, like the use phase, in the case study analyzed.

After that, stochastic analyses were conducted to provide refined descriptions by adding occurrence probability in distribution curves. It became clear that uniform distributions typically represent the ignorance or data limitation regarding the input to be modelled rather than provide a good description of real-life phenomena. In this sense, triangular distributions offer a better approach to refine data entry and support further propagation of uncertainties regarding the realistic preferences of analysts in relation to the normative choices involved. Ideally, more accurate probability distributions should be pursued to describe the normative decisions involved in LCAs, but this seems still distant from quotidian decision-making processes in the construction sector. Also, this is a simple calculation model with few (only three) input parameters, devised for preliminarily testing a potentially improved methodological procedure. As such, the influence of triangular distributions and rectangular distributions on the result are still very clear. Increasing the number of iterations to 100,000 does not change the histograms shape. However, if several calculation steps are performed with multiple inputs, the results would possibly have to take a different form due to the central limit theorem. This should be further investigated.

Regardless of the classification, scenario analysis does not detract from the use of uncertainty assessment methods, since they have different purposes. At the current status of wbLCA inventory in countries like Brazil, despite failing to account for realistic variability, uniform distributions might be still useful to support MC simulations in cases of extreme lack of information.

The global sensitivity analysis showed the contribution of variation for each input data to the total uncertainty, and the correlation between the simulated data points for the inputs relatively to both impact categories outputs considered. For this study, the use stage contribution to the result variance was roughly 100%. Such findings highlight the strategic importance of gathering service life information adherent to the assessed context. Our model used building components replacement rates induced by the Brazilian standard, which are clearly overestimated relatively to international figures used in LCAs worldwide. It does not mean that international figures are better grounded, since recommended figures for carrying out LCA in some countries were basically transferred from elsewhere and some tools and e.g. certification approaches admit usage of the same values worldwide.

Diagnosis of uncertainty treatment in neighbourhood life cycle assessments

Zara O O C, Guimarães G D, Gomes V

School of Civil Engineering, Architecture and Urban Design, Department of Architecture and Construction, University of Campinas, Brazil

oliviaorquiza2@gmail.com

Abstract. Urban areas are complex, multifunctional, long-lasting dynamic systems responsible for impressive resource consumption and environmental impacts. Assessments at the neighbourhood scale offers an important complexity compromise. This paper scrutinizes approaches for handling uncertainty analysis (UA) and sensitivity analysis (SA) in LCAs at the neighbourhood scale, aiming at identifying inconsistencies, limitations and challenges, and supporting the development of assessment guidelines. A systematic literature review was performed. Results from the final 35-paper sample show that only one-third of the papers actually performed some calculation. Two of the most recent ones used Monte Carlo (MC) simulations, whilst SA was mainly carried out through scenarios. Despite no clear trend is shown, this may indicate attempts to also apply MC at the neighbourhood scale. The basic quest in UA and SA, particularly global sensitivity analysis, is to balance quality and completeness of output information and computational force needed. Automating calculations, using lighter sampling methods and fast calculators should be further investigated. Finally, future studies could also focus on defining a minimum group of parameters to investigate and on which strategy to follow in specific data availability circumstances. Fuzzy sets seem better for environmental assessments with high degree of uncertainties and probabilistic distributions give results that are more precise. Dynamic models, future scenario uncertainty and spatial uncertainties propagation should also be further explored once the basic challenges for uncertainty assessment are overcome.

1. Introduction

A true sustainable future can only be achieved if urban settlements are diagnosed and treated at the core of the problem as they converge most economic, social and environmentally damaging activities. On the environmental front, traditional urban planning and city management seems to be struggling to deal with the multifunctionality, longevity and dynamism of urban systems, longing for powerful conceptual methodologies that can comprehensively handle its complexity, such as Urban Metabolism and Life Cycle Assessment (LCA).

Neighbourhoods, on the other hand, represent a city's primary cell and characterize the minimal scale for addressing urban spaces socio-economic aspects and the typical scale for urban development projects. Assessments at this scale, consequently, offer an important complexity compromise. Nevertheless, the intricacy inherent to the scale still culminates in an enormous amount of data management and, seeing as LCAs involve numerous calculations, its use to support decision-making can be hampered by the various uncertainties embedded in them [1]. Therefore, addressing uncertainty issues [2–7] is fundamental for improving data quality and the reliability and credibility of LCA studies.

This paper scrutinizes approaches for handling uncertainty analysis (UA) and sensitivity analysis (SA) in LCAs at the neighbourhood scale, aiming at identifying inconsistencies, limitations and challenges, and supporting the development of assessment guidelines. To do so, a systematic literature review was carried out aspiring to answer the following research question: '*How are neighbourhood LCA researcher/practitioner dealing with uncertainty issues?*'.

2. Method

A previous systematic mapping analysis (SMA) [8] was updated. From its 101-paper final sample, 41 articles specifically dealt with neighbourhood LCA, and were scrutinized to understand how uncertainty issues are being dealt with in LCA at that scale. Through an adaptation of systematic literature review (SLR) guidelines [9] and systematic mapping process [10,11], the research was developed following eight main steps:

i. Definition of main research questions driving the research;
ii. Search process;
iii. Relevance screening using exclusion criteria;
iv. Paper classification through a keywording process;
v. Data extraction and mapping;
vi. Comprehensiveness ranking regarding uncertainty issues;
vii. Synthesis of findings in descriptive or statistical manner;
viii. Discussion and analysis of the information extracted from the most relevant papers.

3. Results and Discussion

3.1. Definition of main research questions

Besides the main research question propelling this study, for each paper reviewed, additional sub-questions were also outlined to drive the research process: (a) *Was an uncertainty and/or a sensitivity analysis conducted?* (b) *Which types of uncertainties were analysed?* (c) *Were the uncertainty sources explained?* (d) *Were different types of uncertainties analysed simultaneously?* (e) *Were quantitative or qualitative uncertainty importance analysis performed on parameters?* (f) *Was the correlation between parameters acknowledged, discussed or explicitly accounted for?* (g) *Was the uncertainty methodological framework explained?* (h) *Were temporal and spatial variabilities considered?* (i) *How was the uncertainty distribution expressed and why?* (j) *Which mathematical calculation method was used?* (k) *Was mass and energy conservation discussed?*

The first research sub-question (a) aimed at determining if UA and SA are being tackled in the studied scale and with which frequency. The second, third and fourth sub-questions (b, c and d) intended to find if researchers at this scale investigate different types and sources of uncertainties in their studies and if/how they handle simultaneity effects. The fifth and sixth sub-question (e and f) envisioned to explore if researchers consider correlations and interactions between parameters and their individual contribution to total result uncertainty. The seventh sub-question (g) targeted at verifying if the UA presented by each work followed a determined framework and if that was transparently described. The eighth sub-question (h) aimed at finding if/how geographical and temporal variability were considered. Lastly, the final three sub-questions (i, j, and k) sought to understand the mathematically approach regarding UA and SA.

3.2. Search conduction

The search for primary papers to be analysed in this SLR begun by selecting only the researches classified as 'neighbourhood LCA' or 'neighbourhood hybrid LCA' at the second level keywording process of the previous SMA [8]. Subsequently, the following search terms and string formulation were applied to the 41 resulting papers: 'uncertaint*' OR 'sensitivit*' OR 'variabilit*' OR 'distribution' OR 'scenario'.

3.3. *Screening of relevant papers*

Seeing as these 41 articles had already been screened in regards to database provenance, peer reviewing, English language and being field or scale related, the main criterion that guided the inclusion of a paper on the final sample was that it should acknowledge at least once one of the search terms mentioned above: uncertainty, sensitivity, variability, scenario or distribution. After this process, 35 (85%) papers formed the final SLR sample.

3.4. *Keywording*

Each paper was then assigned to a keyword that best described its approach regarding uncertainty, sensitivity or scenario assessment (Figure 1). Nine papers (26%) regarded only scenario evaluation; 10 papers (29%) dealt superficially with uncertainty and sensitivity issues, usually by simply acknowledging its importance but not performing calculations; 4 articles (11%) regarded the three aspects simultaneously but only for reviewing purposes, not performing calculations. Twelve papers (34%) actually developed some calculation regarding either uncertainty (7 paper / 20%) and/or sensitivity analysis (5 papers / 14%), but in different detail levels.

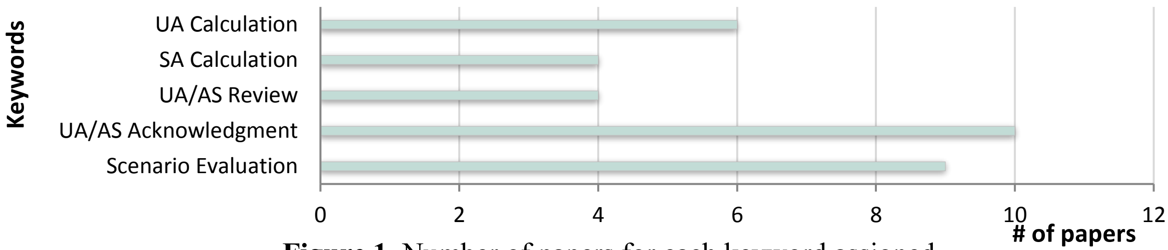

Figure 1. Number of papers for each keyword assigned

3.5. *Data extraction and mapping*

Besides the 14 categories presented in the previous SMA [8], the information collected from the 35-paper SLR sample was further categorized concerning: (i) uncertainty analysis performance; (ii) sensitivity analysis performance; (iii) scenario evaluation performance; (iv) uncertainty location; (v) uncertainty nature; (vi) uncertainty level; (vii) simultaneity; (viii) uncertainty importance analysis; (ix) correlation between parameters; (x) uncertainty framework; (xi) temporal variability; (xii) spatial variability; (xiii) uncertainty distribution form; (xiv) calculation method; (xv) conservation of mass and energy; (xvi) keyword; (xvii) ranking; (xviii) main findings.

3.6. *Ranking assessment*

The sample was categorized from A to E to describe how uncertainty, sensitivity or scenario issues were dealt with. Papers that actually performed some sort of UA calculation were rated as ‘A’; those that performed SA calculation, as ‘B’; review papers, as ‘C’; articles that only acknowledged UA or SA, as ‘D’; and papers that only performed scenario evaluation were rated as ‘E’. Finally, the papers were also assigned marks - (+++), (++) and (+) - according with the number of aspects (UA, SA or scenario) undertook simultaneously, until configuring a 10-class relevance ranking shown in Figure 2.

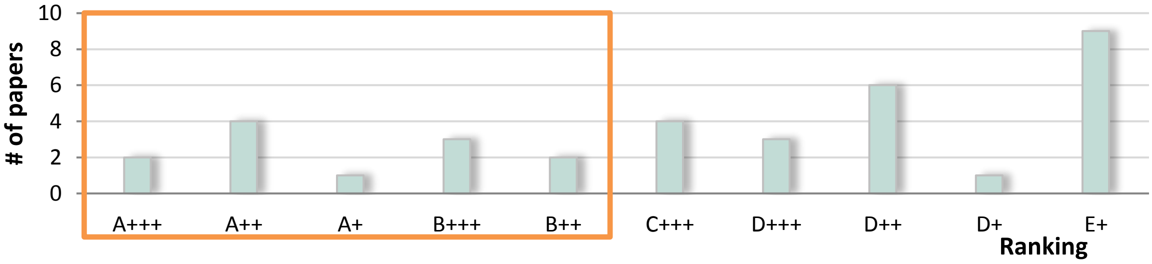

Figure 2. Paper relevance ranking categories

3.7. Synthesis of findings and Discussion

3.7.1. Uncertainty and sensitivity analysis performance. From the overall SLR sampled papers, 22 papers (63%) referenced uncertainty or sensitivity issues in some way. As mentioned above, 10 of the papers (29%) simply acknowledged the existence [12,13] and importance [14,15] of UA and/or SA, but did not calculate them. For instance, Fan et al. [16] highlighted the existence of uncertainty and subjective information as one of their study's limitations. Peuportier and Roux [17] recognized that their neighbourhood LCA results would be more robust if a sensitivity analysis was performed in buildings life span and occupants' behaviour. Huang et al. [18] stated that further research should be done to validate their new integrated life-cycle model for carbon footprint evaluation of districts results, and that a sensitivity analysis should be applied when using different data method and sources.

The empirical nature of the LCA performed by Norman et al. [19] removed some of the inherent uncertainty about the real world environmental effects of urban form and confirmed the validity to adopt widely acknowledged strategies such as automobile transportation reduction, public transit use increase, land use focused on higher density development near employment area, use of renewable energy and alternative fuels. Authors also recognized that their relative results' sensitivity to the choice of functional unit demanded a meticulous consideration given the repercussion that functional unit assumptions may have on urban land use policy.

While still not showing any uncertainty or sensitivity calculation, Heinonen et al. [20] acknowledged them in different aspects of their study. First, those authors opted to use a 25-year lifespan in their residential development LCA indicating that a longer perspective would only considerably increase the use phase assessment uncertainties and would not help to explain the major findings. Subsequently, they approached future uncertainties, stating that, although they accounted for emissions temporal allocation, they did not consider fluctuation on their intensities and consumption volumes over time, which would be very difficult to predict. Finally, while those authors recognized that a number of uncertainties present in their assessments could decrease results accuracy, they affirmed that those uncertainties were detailed in previous studies and should not compromise the general findings, as long as the average residents' aggregate level is maintained in the analyses. Lastly, while exploring perspectives to build a contextualized urban typo-morphologies library to facilitate LCA scaling up from building to territory scale, Sibiude et al. [21], proposed the characterization of representative city cells (qualitatively and quantitatively) that could be aggregated to create higher scale data. Authors, however, acknowledged the need for sensitivity studies to determine cell dimension and system's components data granularity issues, and the need for the evaluation of results uncertainty due to interactions between cells.

In another front and with more analytical depth, the four review papers (11%) also tackled UA and SA on neighbourhood LCA. Through a systematic mapping, Skaar et al. [22] investigated how algorithms and parametric LCA have been used to contribute to decision making for material, buildings and neighbourhoods. Among the 16,209 papers mapped, authors found that, the methods most used were simulation (14.7%), sensitivity analysis (9.4%), multicriteria (7.6%) and propagation (7.1%). Uncertainty analysis was performed in only 3.7% of the papers and statistical procedures such as Monte Carlo (2.1%) and Fuzzy sets (4.5%) had similar lower frequency.

Lotteau et al. [23], on the other hand, reviewed the UA performed by Stephan et al. [24] and the SA performed by Nichols and Kockelman [25], and highlighted the fact that the evaluation of scenarios performed by the other seven case studies on their sample could also be considered as sensitivity analysis. Additionally, authors emphasized that, considering that neighbourhoods are long-lasting complex objects, systematically including UA related to long-term temporal evolution of key parameters is an important challenge to be conquered.

Castaldo and Pisello [26], while reviewing different building dynamic approaches and tools for simulation of realistic dense urban environments, identified grey models as a good 'bottom up' method to be used when a system is lacking information or when a huge input data uncertainty is detected. Those authors also recognized UA and SA as important procedural extensions analytical tools to calibrate dynamic simulation methods, and that key parameters selection, model uncertainty ranges determination, improper model assumptions, simulation code errors and the lack of robust numerical algorithms must all be accounted for.

Mastrucci et al. [27] tackled UA and SA in different fronts in a review of bottom-up building stocks LCA studies analysed according to aggregation model (archetypes or building-by-building), energy analysis (statistical or engineering-based) and LCA performance. Authors highlighted the high uncertainty level of background inventory data adaptation for defining future energy mix scenarios; the higher uncertainty of end-point LCIA methods (relatively to mid-point) due to less consensual physical and social aspects, which introduce subjective value choices; and that while normalization and weighting steps should be addressed more often to enable comparability across studies, they represent an additional uncertainty source. Similarly to Lotteau et al. [23], Mastrucci et al. [27] concluded that few studies quantitatively evaluated input data uncertainty and variability and their propagation throughout the LCA, and that SA was mainly carried out through scenarios describing the evaluation of the stock, policy effects and refurbishment strategies.

The 12 studies (34%) that actually performed some sort of UA and/or SA calculations (highlighted in Figure 2) will be discussed in section 3.7.6.

3.7.2. Uncertainty types, sources and simultaneity. The type and source (location, nature and level [1,5]) of uncertainty was almost never specified in detail by authors. In the few cases it was, authors referred to parameter uncertainty [2], such as lack of representative inventory data or lack of knowledge of uncertainty distribution and, to a lesser extent, model uncertainty, such as temporal and spatial characteristics lost by aggregation, and the need for performing dynamic modelling.

For that matter, Mastrucci et al. [27] emphasized that uncertainty of model inputs, model parameters and modes structure is currently a major issue in LCAs of large building stocks due to the amount of missing information and assumptions to be made, suggesting that input parameter uncertainty characterization and modelling should be carefully addressed in this scale. Moreover, simultaneous analysis of different uncertainty types was seldom performed and, as Skaar et al. [22] have highlighted in their review, despite some advances regarding global sensitivity analysis application, simultaneous accounting for varying parameters and involved uncertainties is yet another under-researched method.

3.7.3. Uncertainty importance analysis and correlations. The lack of emphasis of the sampled papers on the contribution that individual parameter uncertainties might have on the total result uncertainty shows that uncertainty importance analysis [3] is under-researched in neighbourhood LCA studies. Correlation between parameters, although more expressive, are also rarely characterized and quantified. Resch and Andresen [28], while developing a relational database tool focused on systematizing and storing result data and study design for building LCAs, were among the few authors who acknowledged the importance of investigating the relationship between variables.

3.7.4. Uncertainty methodological framework. Due to the variety of types and sources of LCA uncertainty, UA should be guided by a framework [3], however, reviewed papers in general did not reference or present a precise uncertainty framework to be followed, making comparability between studies even harder. Uncertainty characterization phase [1] was almost never discussed in depth by authors and each followed their own process and calculation method. These facts are corroborated by Mastrucci et al. [27], who recommended the development of an uncertainty propagation framework supported by global sensitivity analysis and fast calculators, such as surrogate models, to overcome the limitations of lack of uncertainty propagation and stochastic sensitivity analysis in engineering-based models commonly applied to assess energy demand of buildings stock LCAs.

Although it did not constitute an uncertainty framework per se, Skaar et al. [22] suggested that, to account for LCA uncertainty, first a sensitivity analysis should be carried out to recognize the dominant parameters of the overall considered system, enabling a simplified LCA model while permitting a sharper overview of the multiperformance criteria and multiobjective optimisation decisions variance. Those researchers also recommended expanding the system of interest in terms of scales (from component to neighbourhood) and LCA stages (from A1 to C4 [29]) whenever possible and to use algorithms to manage the complexity and nonlinearity enhanced in the scale transition process. Such algorithms would help to reduce the risk of designing buildings that are suboptimal in the neighbourhood context; to address the key challenges of time and resource use; and to explore consequences, among others.

3.7.5. Temporal and spatial variability. Accounting for spatial characteristics and temporal evolution is very important to ensure that urban assessments effectively support decision-making. For more robust results, temporal evolution, dynamic models, future scenario uncertainty, spatial uncertainties propagation and scaling errors should be properly tackled [27]. Although static approaches are still majority, these aspects were fairly acknowledged by the studies reviewed. Stephan et al. [24], for instance, recognized the great uncertainty embedded in potential technological breakthroughs and the increased renewable energy's market share, and investigated the changes in key parameters over time, testing the effect of the parameter evolution on all scenarios studied. The first step of the methodology proposed by Walker et al. [30] is the recognition of area-specific measures, who also acknowledged the importance of having hourly energy consumption to identify accurate energy performance. Finally, the study presented by Sibiude et al. [21], as mentioned in section 3.7.1, focused on enhancement perspectives to simplify scaling up from building to territory.

3.7.6. Uncertainty distribution and statistical calculation method. Most of the twelve papers (34%) that actually performed some sort of UA and/or SA calculations did not detail the calculation process and methods used, but rather highlighted main assumptions made. From those, five papers (14%) focused on SA and, while some were more superficial [31,32], others went deeper into the subject. For instance, Lausselet et al. [33] proposed a LCA model for neighbourhood and performed a sensitivity analysis based on Sensitivity Ratio to investigate critical parameters, finding that the travel distance per inhabitant and the building' energy load were the two most influential parameters on the total emissions.

Nichols and Kockelman [25] developed a system of statistical models, energy equations, and estimates to account for a life cycle energy assessment (LCEA) of four different neighbourhoods in Austin, Texas. Those authors used Elasticities to estimate the relative sensitivity of neighbourhood energy consumption in response to changes in the built environment or user behaviour, concluding that, from the several urban design variables used in calculations, changes in population density and residential unit size could trigger the greatest per capita energy savings. Nichols and Kockelman [25] also suggested caution with their initial estimates due to the amount of uncertainty involved, and recommended the expansion of the built environment variables and household behaviours for future research.

Last but not least, while comparing LCEA and life cycle cost (LCC) of two social housing neighbourhoods in Mexico city – one compact design near the centre area and one sprawled layout located in the city outskirts – Ochoa-Sosa et al. [34] performed three sensitivity analysis to understand how commuting data influenced overall results. The first two SA consisted in modifying, respectively, the total commuting time and transportation spending ranges, and the data source for average speed for all trips and for public transportation. These aspects affected the overall results but did not change the relative results between neighbourhood cells (NC). Finally, 100,000-iteration Monte Carlo simulations (assuming normality in all data sources and unknown standard deviations as 5% of mean values) were carried out using R language and environment to iteratively change all data inputs and register the differences in CED and LCC. Those authors then concluded that the compact NC would have an overall better performance for CED (64%) and LCC (69%).

Analogously, some of the seven studies (20%) that performed UA calculations were more superficial regarding calculation processes and methods used [28,35–37] and others were more thorough. Stephan et al. [24] acknowledged the considerable amount of uncertainty that infringed their low-density neighbourhood LCA study in Melbourne, Australia, and used an interval analysis to account for data uncertainty and variability by determining suitable literature based ranges around the nominal values of embodied energy and operational and transport requirements. Those authors assumed symmetrical uncertainty boundaries to simplify the assessment, and stated that parameter uncertainty was very likely overestimated (due to the many parameters having a normal rather than a flat distribution), but that it should not affect findings, since the parameter deviation would occur similarly in both scenarios compared. Stephan et al. [24] also alleged that a probabilistic uncertainty model was not produced due to insufficient information for all the parameters assumed in the study.

Using an Urban Building Energy Model (UBEM) tool called the “Urban Modelling Interface”, De Wolf et al. [38] performed energy and carbon simulations on a residential neighbourhood block in Al-Qadisiyyah, Kuwait, to determine the embodied and operational carbon life cycle impact of current and 3 future scenarios situations (Upgraded envelope performance; Low carbon materials; and PV + Low Carbon). Simulation input parameter uncertainty was tackled by defining archetype descriptions as probability distribution and subsequently updating these to posterior joint multivariate distribution by Bayesian calibration using measured energy data points. De Wolf et al. [38] also acknowledged that a sensitivity analysis of the different building geometries could be performed due to the diversity of results.

Finally, Walker et al. [30] proposed a new decision support assessment methodology based on life cycle performance design (LCPD) and key performance indicators (KPIs) focused on the transition towards energy neutral neighbourhoods. The method followed four main steps and included a probabilistic sensitivity analysis at the end. First, the neighbourhood boundaries defined by stakeholder’s inputs are combined with local knowledge and area-specific resources and measures, to identify the realizable scenarios intrinsic to the geographical area. Subsequently, the annual energy performance of each scenario is estimated through simulation models based on the current energy consumption and the building’s demand profile. The authors emphasized the importance of having smaller resolution data at this point, such as hourly energy consumption, to identify the accurate energy performance. Then, a performance assessment of the energy consumption, CO_2 emissions and associated costs of energy infrastructural components is done considering all life cycle stages and using LCPD-based KPIs. In this step, a knowledge-based deterministic approach is used to predict the operational stage energy demand variation of the buildings until 2050 and results are represented in a performance matrix. Lastly, the performance matrix is converted into an opportunity-loss matrix using the minimax regret method, and decision makers decide on the best development scenario. Afterwards, this chosen scenario is further inspected through a 10,000-iteration Monte Carlo simulation of the KPIs parameters uncertainties to find the deviation of the results and the most influential uncertainty parameter. Finally, a multi-criteria decision-making matrix is used to assess the threats, risks and barriers to realize the chosen scenario via a weighting process.

4. Conclusions and final remarks

The SLR made very clear that uncertainty and sensitivity analysis are not being sufficiently performed nor detailed. None of the neighbourhood LCA studies reviewed presented a UA and/or SA comprehensive enough to satisfy all of the uncertainty facets proposed in the data extraction and mapping phase of this SLR. Few studies quantitatively evaluated input data uncertainty and variability and their propagation throughout the LCA, and SA was mainly carried out through scenarios describing the evaluation of the stock, policy effects and refurbishment strategies. These scarce quantitative results say little about the magnitude of uncertainties involved, beyond the general acknowledgement that they are certainly high. Indeed, neighbourhood LCAs are embedded with high uncertainty level due to urban settlements multifunctional characteristics. The large scale and complexity facilitates measurement imprecisions, lack of representative inventory data due to the high number of parameters, potential correlations and lack of knowledge about probability distribution. The dynamism and intricacy of its systems enhance temporal variability and non-linearity issues (Table 1).

Table 1. Neighbourhood LCA Uncertainty Examples

	Type/Source	Goal and Scope	LCI	LCIA
Location	**Parameter Uncertainty**		Data aggregation / extrapolation Building stock embodied energy Lack of knowledge of uncertainty distribution	Foreground unit process data representativeness and variability
	Model Uncertainty		Extrapolation from similar processes Variability in process relationships Static/linear modelling	Modelling structure representativeness
	Scenario Uncertainty	Functional unit Neighbourhood boundaries Modelling framework	Building stock lifespan Allocation methods Waste handling	Impact categories selection Time horizon of impacts Spatial horizon of impacts
Nature	**Epistemic Uncertainty**	Geographical representativeness Temporal representativeness Technological representativeness	Energy consumption (annual/hourly) Commuting distance/time Foreground and background data representativeness	Indicators representativeness Indoor vs outdoor emissions Regional environmental sensitivity
	Ontic Uncertainty	Variability of performance characteristics	Occupants' behaviour variability Societal and institutional variability Technological breakthroughs	Indicators' relationships variability CF variability

The type and source of uncertainties was almost never specified in detail by authors. Also, simultaneous analysis of different uncertainty types was seldom performed, despite some advances regarding global sensitivity analysis application. That is possibly related to the computational requirements, which are added to the high amount of missing information and assumptions to be made when assessing large building stocks. In this regard, uncertainty propagation frameworks, supported by e.g. global sensitivity analysis and fast calculators, such as surrogate models, may help to overcome the limitations of lack of uncertainty propagation and stochastic sensitivity analysis.

Authors generally do not detail their uncertainty assessment framework, do not state or detail the uncertainty characterization phase (location, nature and level of uncertainty) and follow their own process and calculation methods. Furthermore, important aspects regarding UA and SA are not being significantly considered, such as uncertainty importance analysis, correlations between parameter, temporal and spatial variability and conservation of mass and energy. A protocol for declaring the methodological framework and uncertainty assessment steps would be very helpful for comparing studies and advancing the body of knowledge in the field.

Two – but among the most recent - papers used Monte Carlo simulations, but with great disparity in the number of iterations used. The basic quest in UA and SA, particularly global sensitivity analysis, is to balance quality and completeness (i.e. number of parameters simultaneously analyzed) of output information and computational force needed. In terms of computational capacity, shifting from 10,000 to 100,000 makes a big difference. In other scales it seems to have some consensus on using 10,000 iterations and it is not clear if 100,000 would be really needed to reach convergence.

In UA carried out in other scales, MC support seems dominant. Although the reviewed literature does not indicate a similar clear trend, this may be an indication of attempts to apply sampling techniques also at the neighborhood scale. For buildings, for example, a robust assessment procedure can be to define, for each uncertainty source investigated, data points to describe at least a triangular probability distribution as input for MC simulations, which in turn supports global sensitivity analysis. An undisputable limitation is the high number or scenarios needed (at least three per uncertainty source). This number grows progressively as the number of parameters considered increases, meaning that several LCAs must be carried out to feed the simulations, which will also increase computational demand. If this part can be somehow automated, its application might become more frequent in the near future. Also, sampling methods with less computational requirements, like the Latin hypercube sampling, or the already mentioned use of fast calculators and surrogate models.

Finally, future studies could also focus on defining a minimum group of parameters to investigate in LCAs at this scale, and on which strategy to follow in specific data availability circumstances. Fuzzy sets seem better for environmental assessments with high degree of uncertainties and probabilistic distributions give results that are more precise. Static approaches are still majority in the specific literature, but dynamic models, future scenario uncertainty and spatial uncertainties propagation should be further explored once the basic challenges for uncertainty assessment are overcome.

Abstract. The concept of building's sustainability is progressively evolving, from the mere issues of limiting the energy needs of the building, extends to include new areas. The long-term sustainability visions (in Switzerland the "2000 W Society" by year 2100) imply not only technological changes but above all radical changes in the human behaviour. A multidisciplinary study, carried out by SUPSI and specialists, proposes a method for determining the parameters for the design of a building by year 2100. It also shows that in order to achieve long-term sustainability goals (primary energy reduction and CO_2 emissions per capita, 2000 W and max 1 ton CO_2), alimentation can be considered as a building need. The high potential in reducing primary energy needs in this area makes possible to compensate others energy consumptions and CO_2 emissions of the building inhabitants and of the building itself. The sustainable building of the future shall therefore: - present a zero or compensated operating energy need; - present minimal energy need for construction; - allow food production (Urban Farming, Building Integrated Agriculture) through natural and regenerative agriculture (self-production); - promote and act as a shelter for local flora and fauna (regenerative); - respect the soil stratigraphy (reversible).

1. Introduction

The concept of building's sustainability is progressively evolving, from the mere issues of limiting the energy needs of the building, it extends to include new areas. The long-term sustainability visions (in Switzerland the "2000 W Society" by year 2100 [1]) imply not only technological changes but above all radical changes in human behaviour. This vision is in line with the objectives of the Swiss Federal Council's Energy Strategy 2050 [2] and is a recognized instrument of the Swiss energy policy. In addition, land consumption and biodiversity loss are increasingly becoming important issues in Switzerland.

The present study proposes measurable values and target design parameters concerning energy and CO_2 emissions for the construction, operating energy and mobility of buildings by the year 2100. Moreover, it integrates themes such as biodiversity, reversibility and the innovative concept to consider alimentation as a building need in order to achieve long-term sustainability goals (primary energy reduction and CO_2 emissions per capita, 2000 W and max 1 ton CO_2). A concept of total sustainability is proposed.

2. Methodology

2.1. Society 2000W (Swiss long-term sustainability vision)

The 2000 W Society vision refers to a maximum per capita energy need equivalent to the consumption of 2000 W for 8’760 hours/year. Per capita consumption includes the areas of living, mobility, food, general consumption and infrastructure.

In the field of buildings’ construction, the 2000 W Society vision is translated in the technical norm SIA 2040 [3], which imposes limits on energy and CO_2 emissions for construction (grey energy), operating energy and mobility related to buildings. These limits have to be respected and operated by the end of the year 2050 (intermediate target of 3500 W per capita). Buildings, sustainable neighbourhoods and the 2000 W Areas built in Switzerland today are in line with the SIA 2040, i.e. the vision of the Society at 2000 W at 2050. The objective of the study is to provide measurable values and design parameters that are concretely applicable in the daily practice but extending the limits (kWh / m^2) and ($kgCO_2$ / m^2) from 2050 to 2100.

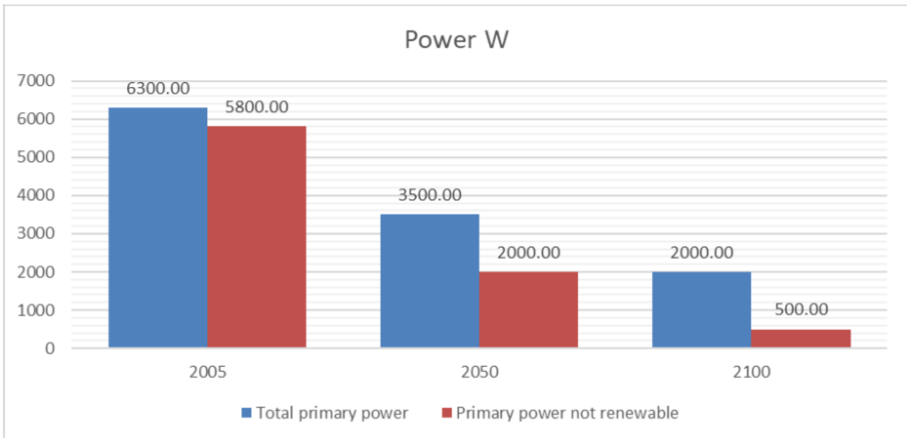

Figure 1: Per capita energy power (total and not renewable) today (2005), targets for 2050 and 2100

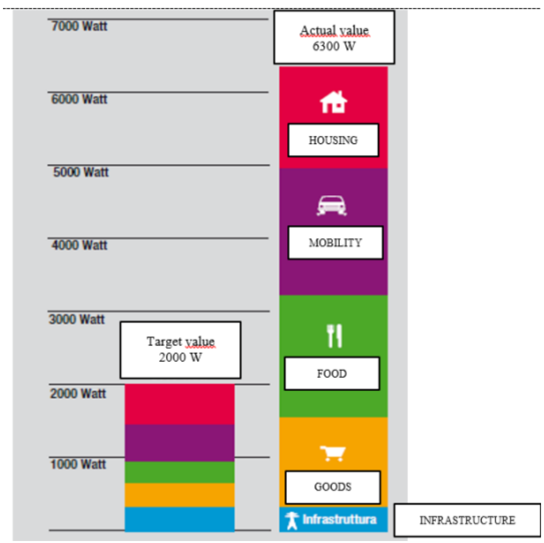

Figure 2: Sectors considered in the 2000 W Society concept. The objective for the year 2100 is to reduce by two thirds the maximum per capita total energy need to the consumption of 2000 W for 8,760 hours per year, which is currently around 6000 W.

The technical norm SIA 2040 imposes limits on energy and CO_2 emissions for construction (grey energy), operating energy and mobility related to buildings so that the energy performance of the construction sector can achieve the objectives by the year 2050 (3500W per capita). The study extends the design limits at year 2100, using the same methodology as the actual norm and the 2000W Society (for housing). The value of non-renewable primary energy extended at 2100 for buildings results actually too low to be achieved in relation to what is feasible today (refer to Figure 3) [4].

An innovative approach is proposed to solve this problem. Is introduced the concept that another need is to be considered related to the building and its occupants: food. This topic is important in the way to get the goals of the achievement of the Society 2000 W. The total energy primary power today in the field of food is deduced from the global average per capita Switzerland balance according to the 2005 statistics and amounts to 1’300 W and 2.08 tons of greenhouse gases [5]. Relating these quantities to buildings and applying the reduction factors on total primary energy at 2100, the target design values were obtained at the year 2050 and 2100 (refer to colums “2100 Theoretical target” and “2100 Reachable” of Figure 3).

Housing	SIA 2040		SUPSI Study			
	2050		2100 Theoretical target		2100 Reachable	
	Primary energy not renewable [Mj/m^2]	greenhouse gas [kg/m^2]	Primary energy not renewable [Mj/m^2]	greenhouse gas [kg/m^2]	Primary energy not renewable [Mj/m^2]	greenhouse gas [kg/m^2]
	new buildings		new buildings		new buildings	
Construction	110	8.50	*27.5*	4.25	110	8.5
Operating energy	200	2.50	*50*	1.25	13	0.7
Mobility	130	5.5	*32.5*	2.75	104	4.9
	440.00	16.50	**110.00**	8.25	**227.00**	14.10
Alimentation (food)	*683.00*	*17.33*	217.00	4	98	5.67
Total			**327.00**	12.25	**325.00**	19.77

Figure 3: Targeted values at 2100 in the different areas and reachable values (housing).

As can be deduced from Figure 3, the theoretical limit value of non-renewable primary energy calculated at 2100 (110 MJ / m^2), is difficult to reach (evaluation according to the the SIA D0236 norm[4]) despite by providing efficient, well-insulated, low grey energy constructions, which exploit renewable energy sources (e.g. wood) in areas well served by public transport in the peri-urban area. However, considering a personal completely vegetable diet, it is possible to obtain a value of non-renewable primary energy that is half of the limit value (98 MJ/m^2 vs 217 MJ/m^2). Therefore, this energy and emissions savings can compensate the other needs for construction, operating energy and mobility. With this innovative approach it is possible to reach the total target value at 2100 of 327 MJ / m^2 (limit 327 MJ / m^2, obtainable 325 MJ / m^2) (Figure 3 and Figure 4).

The theory introduces the innovative concept that it is possible to establish and respect the values targeted at 2100 in the areas of construction, operating energy and mobility, acting also in the context of the alimentation related to the building. Food can be considered as an energy need (with consequent emissions of greenhouse gases) related to living and the building itself similarly to the sector of mobility. In this way, considering the sector of food, it is possible to raise the target value on the building in a feasibility field but respecting the global limits at 2100. The target values for non-renewable primary energy for the Society 2000 W at 2100 are shown in the column “reachable” in Figure 3 and Table 1.

It should be noted that the values established at 2100 regarding operating energy, construction and mobility, although they are possible to be achieved, remain very low. The design of the building must therefore use materials and systems characterized by very low grey energy content (e.g. low or no tech solutions), characterized by a complete use of renewable energy sources. The respect for these target values remains a design challenge today that needs to be investigated.

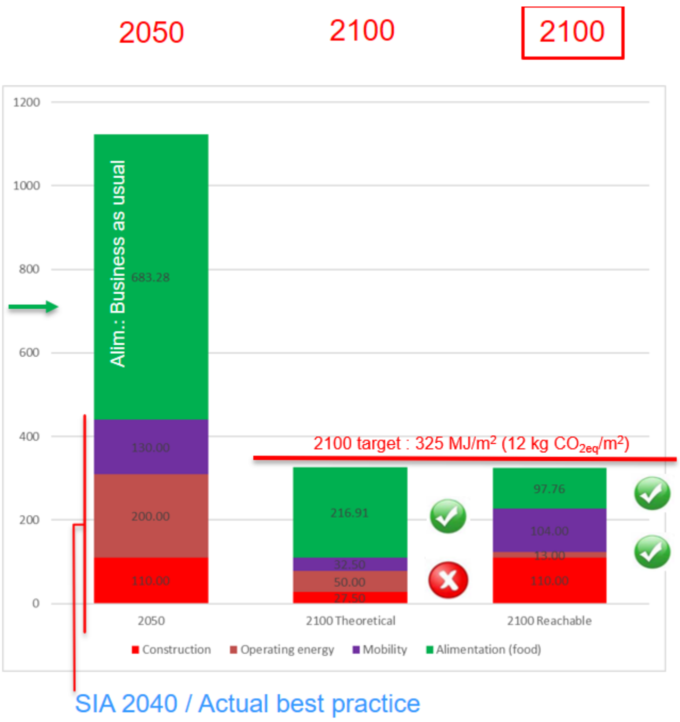

Figure 4: Achievement of the new values targeted at 2100 (2100 feasible column) considering the compensation of the energy needs of the building thanks to the energy saving due to diet. Without compensation, the objectives on the building are not reachable (2100 theoretical column)

Table 1: Proposal of project target values in terms of not renewable primary energy for the building by the year 2100 within the framework of the Swiss Sustainability Vision (2000W Society).

	2100 Design values	
Areas of analysis	Primary energy[a] (MJ/m²)	CO2 emissions (kg/m²)
Construction (gray energy)	110	8.5
Energy needs	13	0.7
Mobility[b]	104	4.9
Nutrition	98	5.67
Total energy	325	19.77
Total power [W]	*618* [c,a]	

[a] Not renewable primary energy
[b] Daily mobility
[c] Considering a swiss average of 60 m² / inhabitant (Society 2000W)

2.2. Alimentation

The alimentary theme can be no longer ignored and is to be tackled on a global [6][7][8][9], territorial [10][11][12], and local level, also by constructions [13], and by living [14] more generally. In 2011, study "Environmental Impacts of Swiss Consumption and Production" [11] edited by the Federal Office for the Environment showed that among the consumption categories, nutrition is the most important and causes 30-40% of the total environmental impacts. Moreover was confirmed in 2018 by the "Swiss Environment Report" [15] that the sector of consumption and production with the greatest environmental impact is food (28%), followed by housing (24%) and mobility (12%). Furthermore, a study [12] regarding the Society 2000 W, identified 107 people who would already respect today the concept of a 2000 W Society in terms of energy but do not respect the vision in terms of greenhouse gases because their meat consumption is responsible of approx. 0.9 ton / year alone, thus making impossible to respect the total limit for all areas (1 ton). Finally, it has already been determined in studies carried out analysing the energy impacts of in-place 2000 W Society buildings in Zurich (technical requirements for the year 2050), that the food sector (meat consumption) is very critical for the achievement of the per capita energy balance and emissions target [14].

From the point of view of buildings' construction and architecture, this topic is translated through the integration of food productions in the cities or directly in buildings (Urban Farming and BIA - Building integrated agriculture [13]). The winning pavilion designed by the Swiss Solar Decathlon team could represent a valuable example [16]. The diet is strongly characterized by the behavioural aspect. In the present study, in order to allow energy or CO_2 compensation through food, a regime without animal derivatives is considered as it is characterized by the lower impact in terms of energy and CO_2 [5].

2.3. Biodiversity

Considering that in Switzerland about half of the natural habitats is threatened [17], nearly half of the native species are threatened [17], that 60% of urbanized areas are watertight [17] and urbanized areas may be richer in species than agricultural areas [17], the urban space can be considered a refuge for species that have lost their natural habitat.

In a view of total sustainability, biodiversity must be integrated into all aspects related to the building and the external area. It is possible to design the building in order to act as a refuge for flora and fauna (on facades, roofs and nearby area), so that the building can help regenerate an impoverished soil with its presence.

2.4. Reversibility

The expansion of urbanized areas and infrastructure causes fragmentation of habitats for animals and plants [17]. In Switzerland between 1985 and 2009, the urbanized area increased by 23% [17]. The soil is therefore to be considered as a non-renewable resource.

The sustainable building should avoid soil sealing and compaction. Typically, the building is suspended, i.e. with punctual pile structures. By the end of the computed building life-time the soil should be returned to the environment without damage and enriched in biodiversity (regeneration). Loss of soil and fertility must be avoided.

3. Case Study

After the execution of the study, the intention is to build an experimental building in Ticino in collaboration with a private partner. The experimental pilot building will have to enable the inhabitants to respect the per capita parameters of the Society 2000W at year 2100 as well as to be regenerative and reversible (construction technology should increase local biodiversity). In this phase, preliminary evaluations were carried out on the construction characteristics that a single-family building (2 people) should have in order to respect the construction limits described in Table 1.

Three different housing plans (Figure 5) and 3 different system configurations have been evaluated (heat pump and photovoltaic, wood heating, wood heating with certified electricity purchase) for each scenario (total of 9 scenarios). The limits concerning non-renewable primary energy have been verified. With regard to mobility, the average standard conditions in Ticino were considered, while for food it was considered a completely plant-based regime without animal derivatives [5]. The preliminary characteristics of the building (construction / plant) were determined in order to respect the limits, in terms of W per capita.

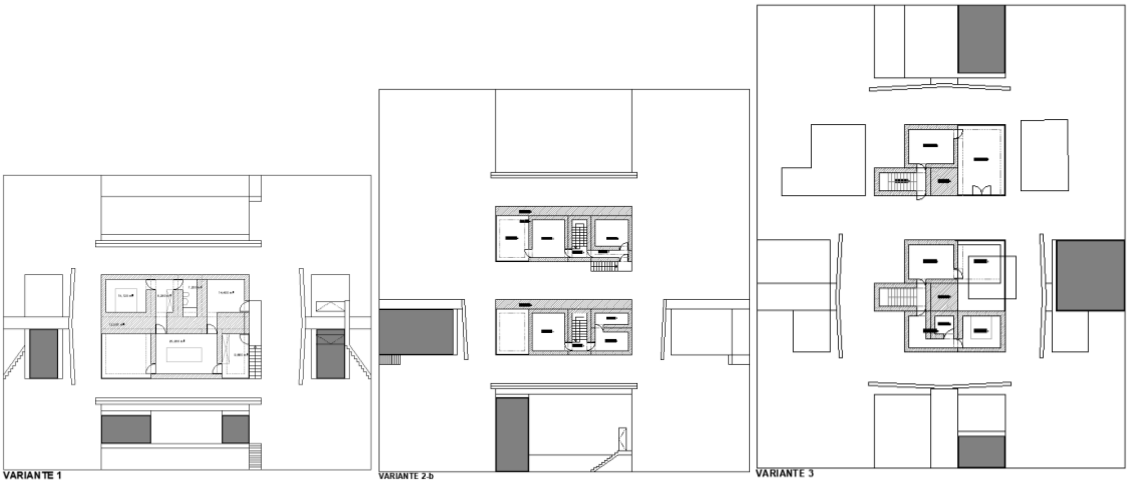

Figure 5: 3 different housing plan were evaluated. (1) Single floor suspended with concrete blade (94 m^2). (2) Two suspended floors with pillars (94 m^2). (3) Two floors compact (125 m^2).

Table 2: Case Study - Target values and project values

	Case Study	
	2100 Target values	Project
Areas of analysis	Primary energy[a] (MJ/m^2)	Primary energy[a] (MJ/m^2)
Construction (gray energy)	110	111.78
Energy needs	13	13
Mobility[b]	104	167[e]
Nutrition	98	98[f]
Total energy	325[c]	389
Total power[W]	***618*** [c]	***580*** [d]

[a] Not renewable primary energy
[b] Daily mobility
[c] Considering a swiss average of 60 m2 / inhabitant
[d] Considering the project value of 47 m2 / inhabitant
[e] Considering 2 parkings and the average public transport service in Ticino Canton
[f]Standard Swiss complete vegetarian nutrition

The study variant that presents the energy characteristics shown in table 2 (respecting the 2100 Targets values in term of Total power per capita and nearly reaching the energy requirements in terms of MJ/m^2) is the housing plan number 2 with the following general characteristics:

• The building structure must be compact, the internal surfaces limited
• Building envelope and structure should be prefabricated in wood
• Transmittance of the construction elements according to the Swiss state of the art (0.15 - 0.20 W / m^2K)
• Wood heating in central position of the house without heat distribution
• Domestic hot water heating by a heat pump
• Without photovoltaic or thermal solar panels
• Purchase of certified electricity from renewable sources (hydroelectric)

Notes:

- Photovoltaics: the annual amount of grey energy of a photovoltaic system (in the considered cases) is broadly equivalent to the annual compensation in terms of operating energy computed according to the technical norm [18]. Basically, the presence of a photovoltaic system involves roughly ca. +120 MJ / m^2 in terms of grey energy and subtracts approx. 120 MJ / m^2 in terms of operating energy (systems from 10 to 14 kWp);
- Due to the fact that in the vision Society 2000W there is the possibility of considering the certified energy purchased as full renewable, the presence of a photovoltaic system is always unfavourable (buying certified energy compensates the operating energy without having the grey energy load of the PV system).
- At this stage, for the agricultural self-production of food a surface of at least 2’000 m^2 was estimated. The area has to be cultivated through natural and regenerative agriculture which should provide self-sufficiency after 7 years with a commitment of 1 person for 4.8 hours per day.
- The targets established have not been reached in terms of energy MJ / m^2 but in terms of power per capita (W). Mobility has a certain weight in respect of the limits, however, it is a sector hardly influenced by designers because it depends on where the building is build.

4. Conclusion

Swiss energy policy has ambitious long-term goals. The way to reach them is not yet determined. This study provides a multidisciplinary approach to determine the characteristics of buildings and living-style in order to achieve sustainability goals both from an energy and a long-term environmental point of view. An innovative holistic approach, which partly concerns technical and design aspects, partly regarding behavioural aspects such as nutrition is proposed. The innovative concept of alimentation considered as building need in the energy balance, has been introduced.

The energy values (present and achievable target) for the alimentation related to the building were quantified (today 683 MJ/m^2, target 98 MJ/m^2). A proposal for a practical design limit value for the Society 2000W at 2100 is quantified (considering operating energy, grey energy, mobility, nutrition) at 325 MJ/m^2 (618 W per capita) primary non-renewable energy. A preliminary case study has shown that the values are achievable today by focusing on a low-tech approach, with low grey and operating energy, and with a fully plant based diet.

A vision of total sustainability of the buildings that will be the home of a mankind of the near future for which integration in the ecosystem with positive impacts is a moral imperative is proposed. The shift of the paradigm of the role or non-role of mankind in the ecosystem allow to reinterpret inhabitation and construction technology.

4.1. Next Steps

The next steps are:
- Calculation of the energy and emission target by year 2100 considering the global energy need (renewable and non-renewable)
- Verification of the feasibility of the target for a CO_2 neutral construction (0 kg / m^2)
- Determination of technical solutions, materials and approaches to achieve the objectives concerning the target of grey energy needs of the construction through pilot projects (construction of an experimental single-family house)

- Development of systems for integrating the production of eatable plants onto the building envelope through models in full scale
- Quantification of the objectives in the sector of biodiversity regeneration
- Development of building foundation systems and site management in order to preserve the stratigraphy of the soils.

HYBRIDisation – a resilient strategy in times of change and transformation

Schwehr P, Schuchert C L, Winterberger F

Lucerne University of Applied Sciences and Arts, Competence Center Typology & Planning in Architecture (CCTP), CH-6048 Horw

peter.schwehr@hslu.ch

Abstract. Our built environment consists of spaces, buildings, and cities that are subject to ever-changing social, economic, ecological and cultural demands. The demand for high quality living space is becoming ever more significant for densifying urban areas. When lifestyles, modes of working and recreational activities intertwine, new concepts on all scales must follow. Consideration of resilience of all kinds is becoming an important part of planning. It requires typologies with resilient characteristics, which can also take on new tasks perhaps not yet known of today. This paper recognises such a typology in the hybrid. Hybrids possess a variety of characteristics and benchmark parameters. A code inherent in them renders them capable of reacting to various situations and differing requirements. Depending on its constitution and purpose, the hybrid code affects a variety of architecturally relevant, environmental levels, namely district, neighbourhood, building, unit, components, infrastructure and processes. "Hybridisation" describes the process of the deliberate application of this code on all levels ("design and injection"), albeit also its decoding, i.e. activation of processes of change. In this way "new genetic alliances" are created, in which differing hybrids interact. By offering advanced adaptability through HYBRIDisation, buildings become resilient to change and allow for diverse modification and development throughout their lifespan, resulting in improved learning ability. This paper explores strategies of HYBRIDisation and the consequences for the interlinked levels to enable hybrid and resilient levels of environment.

1. Initial Situation

Today, long-lasting construction is a top priority in the building industry. In day-to-day planning and on various levels, this leads to challenges for planners, buildings and processes and begs questions as to which strategies are suitable to meet them.

1.1. Demand for planning security in times of upheaval and uncertainty

Buildings and districts are subject to permanent pressure to adapt. Stressors make them fragile and force the testing of their justification for existence. If these programmes, e.g. for living or work, change, they are very often no longer compatible with the built hardware. It is precisely in times of fundamental change, like digitalization and migration for example, that programmes are written in rapid cycles, something that does not correspond with the usual 50-100 year durability of our buildings. Moreover, solving the problem with incomplete and only partially predictable knowledge in times of upheaval is business as usual in planning. One approach, which takes account of these circumstances, takes the "unknown as the basis" [1] and seeks "approaches for dealing with uncertainty". [2] We have to admit to ourselves that we can only predict future developments to a limited extent, cannot control them and most certainly cannot plan them. [3]

1.2. Demand for resilience in the construction industry

We need buildings that can stand up to "stress" [4] arising from change for the longest possible period, yet do not rule out their own development. So instead of the maxim of resistance and consequent defensiveness against development, a resilient strategy that sees in those new requirements an opportunity for continued development. Here resilience is the yardstick of a system's robustness. If it can overcome stressors, renew itself, continue to develop and emerge from transformation even stronger, then it qualifies as a resilient system. Endurance is the overlying objective, with resilient characteristics and strategies as the route to follow. An important basic prerequisite for resilience is the scope for potential action. Places and buildings in which things can be tried out and which find justification in the event of success whilst, in the event of failure, allowing other possibilities to be tried out without great outlay. [3]

1.3. Demand for intermixed "urban areas"

Studies have shown that, by 2050, about 66%, and by 2100 about 85% of the world's population will live in cities. [5] The associated necessary densification, in combination with changed lifestyles and ways of living and working, puts typologies used to date additionally under pressure and underlines the need for new typologies. By way of reacting to the anticipated population increase in cities, the "urban quarter" construction area category was introduced in Germany in 2017. This category corresponds with the "model of a city with short routes, places to work on site and good social mixture". [6] The goal is to support areas that accommodate residential space and "service and business enterprises in small-scale, mixed use. […] This mobilises additional living space where the city is at its most attractive, ensures well-functioning intermixing and makes conservative use of land." [7] These new zoning codes make it possible to build higher and more densely in "urban areas", and use an apartment as both working and living space. Consequently a new hybrid, multifunctional typology of buildings is necessary. The challenge now is to formulate structural, creative and location-specific typology approaches in such a way that they correspond with current demands and can hold their own in changing times.

1.4. Demand for multifunctional and adaptable building

New ways of working and living, alongside increasing intermixing and combining of different functions, is leading not only to new zones but also increased blurring of what were to date clear distinctions between specific typologies (home, office, school etc.). New demands for multifunctionality and 24/7/365 usage of buildings are taking over. Future usage scenarios orient themselves towards the now. No statements can be made for the long term regarding their validity or certitude. Typologies established and used to date cannot do justice to this requirement for capacity to change and react because of their specificity and monofunctionality, and are under scrutiny as to their usefulness.

1.5. Summary

The future challenge to our built environment is marked by great uncertainty in relation to future developments. We find ourselves in times of upheaval: "globalisation, digitalization, climate change, urbanisation, demographic change and migration, declining status of nation states, increasing economic power of large private companies, […]. New technologies like blockchain and Artificial Intelligence are scarcely tangible as keywords for individuals but, in actual instances of change like gentrification, segregation, Fitbits, one-click shopping, rising sea levels and self-driving cars, they are already influencing day-to-day life today...". [3] John N. Habraken put it in a nutshell with "You can't control!". We therefore need spaces, buildings and neighbourhoods that can react as an open system to changing requirements and which, despite change, are guarantors of high-quality living space. Our spaces, buildings and neighbourhoods must urge us to act and thereby to fulfil our responsibility.

Whilst the focus used to be on endurance, today it is the built environment's transformability and the ability to react rapidly that indicate a resilient city. Resilient architecture will always be open architecture that seeks to interact with its environment, enters into collaboration and uses synergies. For this there is a need for new ways of thinking and architectural systems that can enter relationships with one another at a variety of levels and overcome the isolated way conventional monofunctional typologies operate. Hybrids can make an important contribution to this, exhibiting as they do the very resilient characteristics needed in times of unpredictable development.

2. Hybrid code, hybrids und hybridisation

2.1. Definition and demarcation

In connection with multifunctional characteristics, the term hybrid was selected for the profile of requirements for future construction and processes. Supplementing Per et al, which limit a hybrid to an "opportunist building, which makes the most of multiple skills, a key player which revitalises the urban scene and save spaces" [8], the term "hybrid" gains additional scope, to the effect that hybrids indeed do not just cover the building, instead reaching over various characteristics and benchmark parameters. Among their assets, hybrids have at their command a code that enables them to react to diverse situations and different requirements. Depending on its composition and purpose, the hybrid code works on different, architecturally relevant, environmental levels. Levels are district, neighbourhood, building, unit, room, infrastructure and processes for example. These levels are summarised as "hybrids". They are comparable with layers one above the next, which are connected at some points for a certain period. Through the "transmission of stimuli", impetus is delivered, interactions are strengthened and synergies between levels are made possible. On the one hand, "hybridisation" describes the deliberate installation of the code in these levels ("design and injection") and, on the other, its decoding, i.e. the activation of processes of change. Thus, through the interaction of the more widely differing hybrids, "new genetic alliances" are created.

The interaction between hybrids and hybridisation constitutes information processing involving two information levels of the built environment. One information level relates to the genotype. Stored there are all of the information about and characteristics of the hybrid. It is activated by a second information level – decoding. Decoding leads to different characteristics of the hybrid then visibly appearing as phenomenological characteristics, the phenotype, according to arrangement and dominance. Thus, for example, the potential for an ability to adjust is lodged in the genotype, but only becomes apparent phenomenologically in the event of change. In biology, this process of activation and inhibition of characteristics is called "epigenetic imprinting" and explains "when and which contents from the genetic handbook of an organism are to be used". [9] Following this epigenetic principle, the activation of structural and procedural characteristics of the hybrid in the course of hybridisation has to be seen as decoding of the hybrid code.

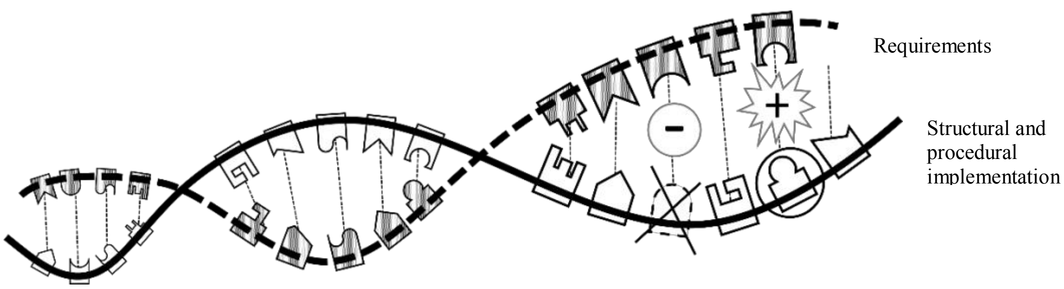

Figure 1. The characteristics of the built environment stored in the hybrid code are decoded and activated by the requirements. The structurally lodged assets of the genotype now appear as the phenotype.

Table 1. Definitions

Term	Analogy / definition
Hybrid code	**“Vaccine”** Structural and procedural characteristics that allow an architectural element to mutate into a hybrid
Hybrids (hybrid levels)	**“Recipient”:** An architecturally relevant environmental level infected by the hybrid code and inherently possessing the capability to change
Hybridisation	**“Vaccine, activation”:** From deliberate designing of the hybrid code, on through laying down its hybrid characteristics in the corresponding architectural element, to activating the hybrid. In addition, the process of interaction and cooperation between the differing hybrids is described by hybridisation.

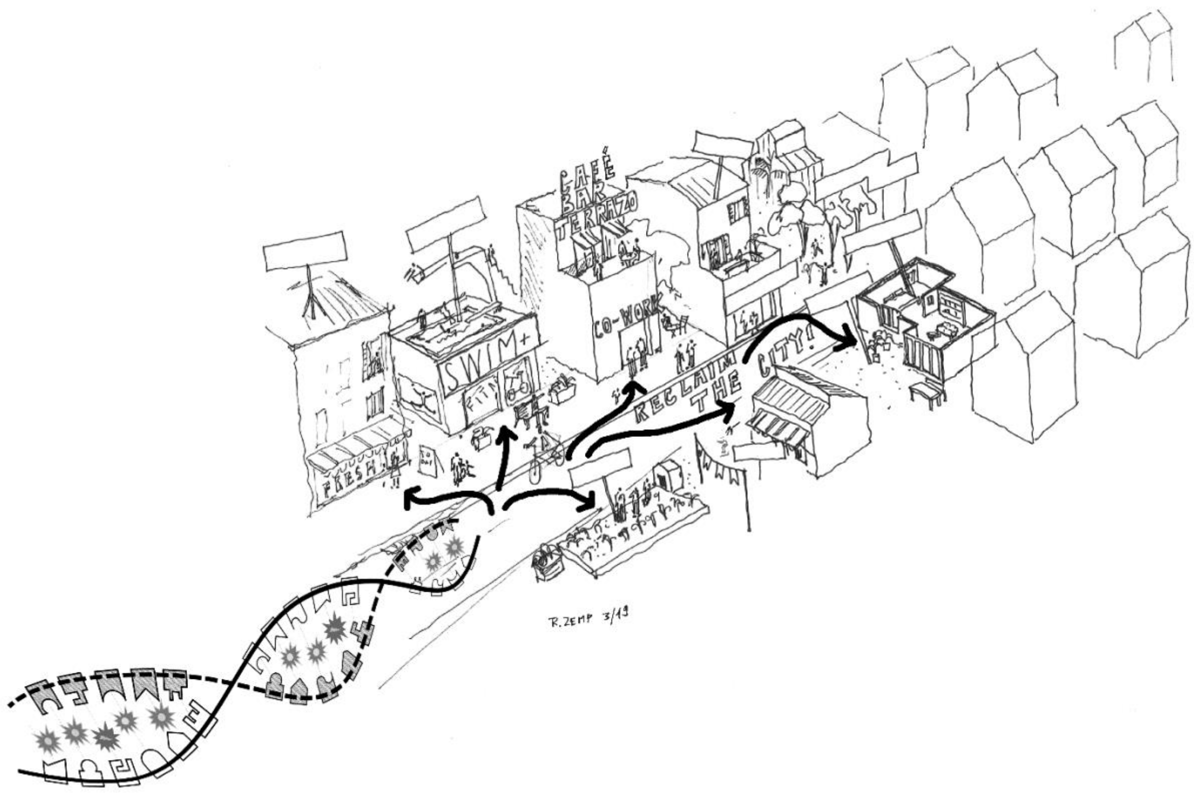

Figure 2. Effect of hybridisation

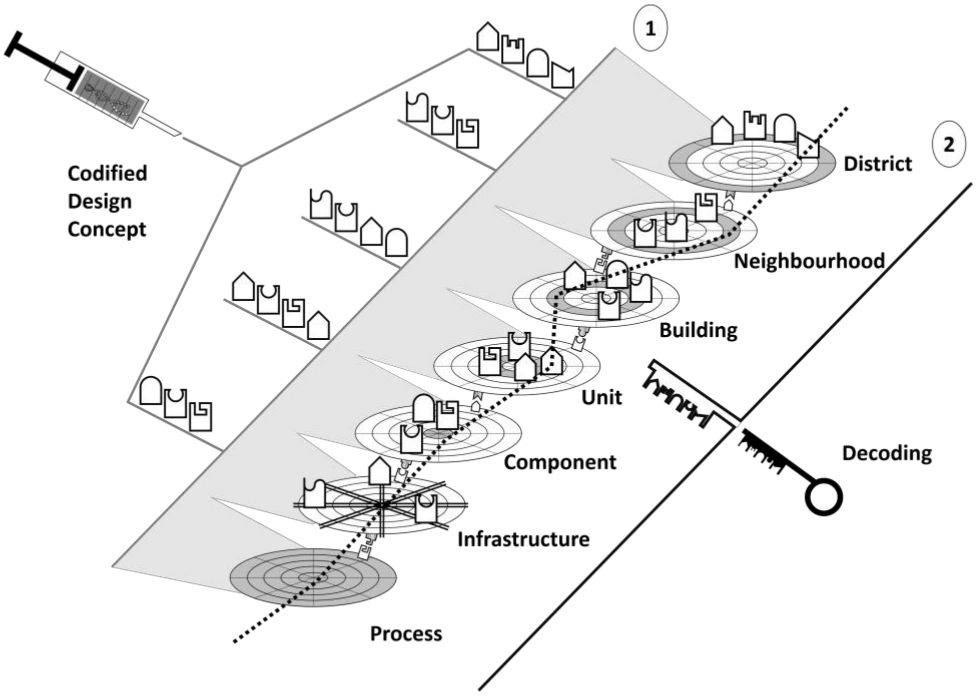

Figure 3. All levels are coded with the codified design concept, i.e. potential is laid down (1). In the event of external pressure to adapt, the code is decoded, i.e. the potential is activated (2).

2.2. Demarcation of hybrid buildings and typology

Hybrids differ substantially from conventional, specific and generally monofunctional typologies (e.g. schools, residential buildings etc.). Hybrid buildings can result from the sensible combination of requirements on various originally monofunctional typologies for example (e.g. living and work) and thereby enable multifunctional use. Thus, for example, simultaneous or staggered living and working can take place in one unit of usage, substantially raising the building's occupancy in the course of a day. This is possible if the higher requirements of one use (e.g. acoustics/living) are determining factors for the hybrid building. However, a higher ceiling for example only makes sense if the unit of usage is also used as an office. Seen from this point of view, monofunctional typologies seem more efficient than hybrid ones. But if the demands on the building change, monofunctional typologies are subject to substantial pressure to adapt, due to their specificity and efficiency alongside a dearth of buffer zones. With this in mind, resilient strategies are aimed primarily not at raising efficiency but rather their effectiveness, their efficacy, with their measures then being implemented efficiently for the sake of sustainability. This demands the sensible treatment of reserves and buffers. The combination of adequately sized and proportioned rooms with usage-neutral floor plans and unbundled building services are lodged in their genotype. They constitute the specific code for hybrid building and enable more appropriate, simpler changes of use and support the transformation of the built environment.

Table 2. Comparison between hybrid building and familiar typology characteristics

Character Hybrids	Character Typology
Application-specific	**Task-specific**
Has "unexpected mixing of functions"	Conceived for a specific use
Appropriation as a principle, scope for action	Prescribed use
Multi-used	**Mono-functional**
Oriented towards usage and changes thereof (e.g. learning)	Oriented towards function (e.g. school)
Based on unknown future	Based on tradition
Use creates form	Form follows function
Full-time activity	Part-time activity
Environment as system boundary	**Building as system boundary**
Focus impact on city	Focus on building

Sensible interaction with environment required Uses synergies	Focus on plots Self-optimisation
Open system Interconnected and open to development Anti-fragile (disruption = opportunity), fault-tolerant Great diversity From visible to undercover	**Closed system** Singular and complete Fragile (disruption = danger), fault-prone Limited diversity Visible
Changes within and outside the system through spontaneous or planned **initiation** Change can only be planned and controlled to a certain extent (e.g. appropriation by new users)	**Changes** within the system as **reaction** Change can be planned and controlled (e.g. classroom reconstruction)

An example of a hybrid which influences the whole district is the multifunctional building named Frizz23 in Berlin (D). Primary goal of the realised concept was to create "commercial with dwelling" which would be enriching for the existing neighbourhood. The city property which had recently become vacant wasn't sold for the usual market price but developed in a participatory dialog process with local stakeholders. A number of different means of funding facilitated the desired social mix. The plot was sold at a reduced price. The difference in relation to the market price was added to the price of the freehold flats and credited to the co-operative flats. This cross-financing makes affordable housing possible at a price per square metre of € 9.50 a month.

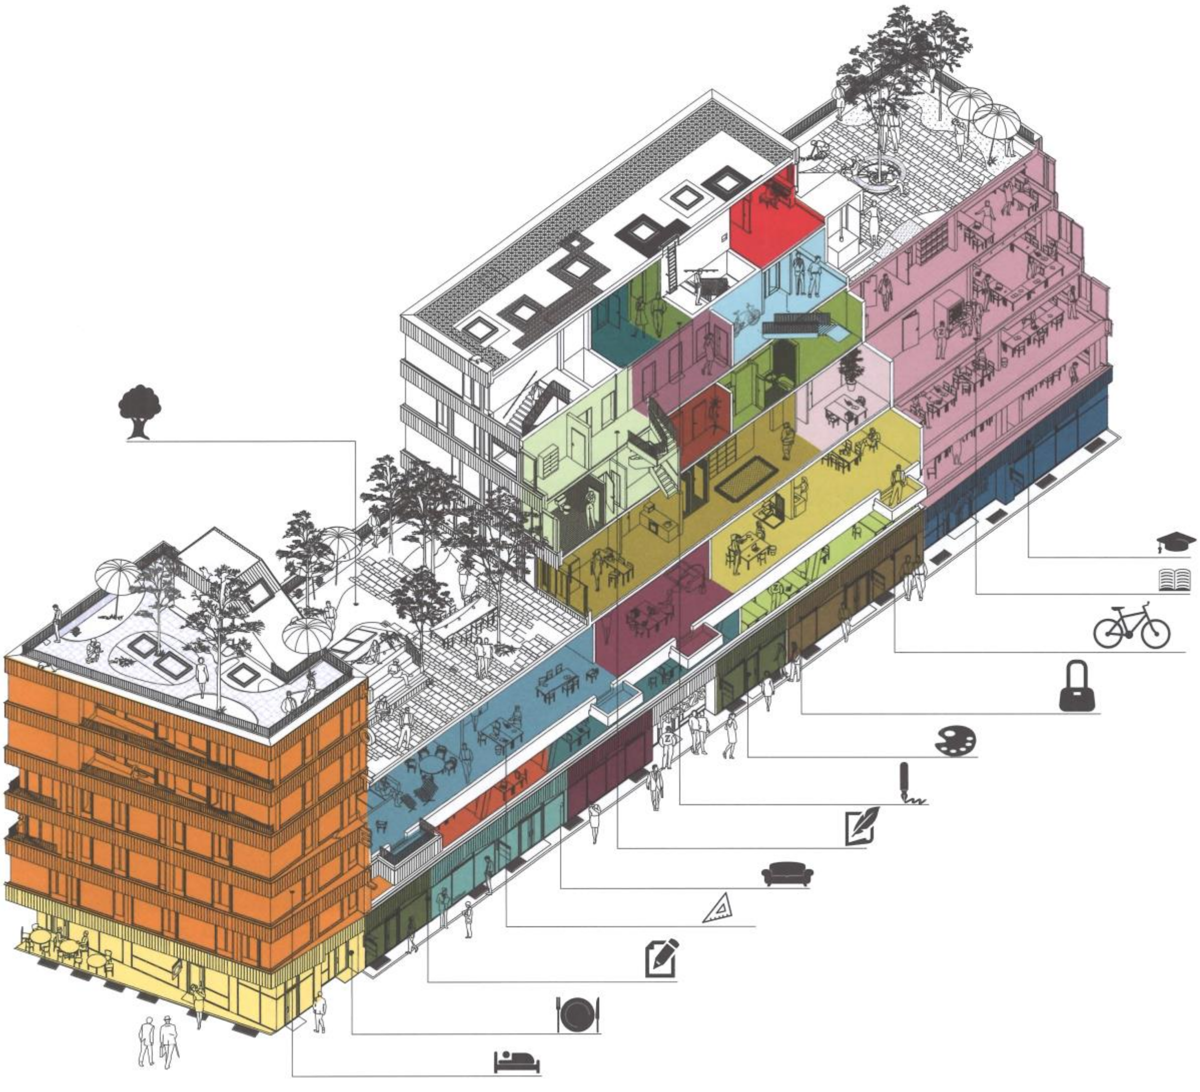

Figure 4. Frizz23, Hybrid Building in Berlin (D)
(Architects: deadline Architekten, Matthew Griffin, Britta Jürgens) [10]

A variety of floor plans and a differenciated mix of uses from trade to dwelling allows for the "self made and mixed city" [11] and makes it possible for the building to be "lively even at night". [12]

Figure 5. Social mixing through a variety of floor plans and mixed uses (by Deadline Architekten) [11]

That way, FRIZZ23 takes on the role of an incubator in the neighbourhood. It triggers developments, enables interactions, and adapts to new demands. This process of hybridisation usually takes place in several phases and at different times as will be shown below.

Phase 1: Define, Design and Inject Codified Design Concept
At the beginning, the program for the projected hybrids is defined. At the end of this phase, the requirement profile of the projected building is determined and the target agreement (e.g. space allocation plan, use, cost ceiling, deadlines etc.) is formulated. [13] The degree of hybrid character desired is defined and the corresponding structural and procedural characteristics of the hybrid are determined.

With the help of scenarios-methodology and transdisciplinary think-tanks [14], one must identify the relevant developments that will be influencing buildings in the future and formulate scenarios of possible developments. The scenarios serve as the foundation for further decisions. At the end, the design concepts are determined by mathematical spatial concepts and represented in an objective, unprejudiced manner. As a rule, plans, sketches and models serve to illustrate the outlined building concept. This serves as the guideline for the realisation of the building. [15] The building or processes are injected with the hybrid code and can now mutate into open systems, which means constructed or applied as hybrids based on the codified design concept.

The hybrid code orients itself towards the fundamental principles for resilient urban development. [3] The interaction of these principles forms the basis for a strategy to be developed specifically for each of the levels and processes involved and which is then lodged structurally and procedurally in the code. Three important fundamental principles that enable the hybrid to develop itself further according to the requirements of resilience are: it is adaptable, multifunctional and works synergistically.

Table 3. Hybrid Code – Codified Design Concept

Fundamental principles	Process-related characteristics	Structural characteristics
- adaptable - multifunctional - synergistic	- scenario-based - user-oriented - transdisciplinary - sense of responsibility - reflective - cooperative - incomplete/open/unexpected	- equivalent - usage-neutral - well-proportioned - replaceable/exchangeable - unbundled - fault-tolerant - independent (services) - offers buffer - effective - specific - appropriate / sufficient - sharing - life-cycle-oriented - recyclable - ephemeral

The fundamental principles cannot be clearly demarcated. They have a collective effect in the overall framework, differently weighted according to the specific objectives of the design, and give rise to the planned procedural and structural characteristics. Here the hybrid code is not to be seen as some panacea that is equally applicable to all environmental levels. It must be conceived specifically for each case, in order that it can act as an incubator, enabling the various environmental levels to react specifically to the pressure to adapt and amplifying their potential for further development. The hybrid code lays down the attributes for the desired resilient characteristics. The code concept is primarily about building up capabilities for the active configuration of ongoing adjustments and strategic transformations. Here the focus is not on conserving but rather it is directed proactively with the future in the sights of its strategies. As a result, the ability to react quickly and an appropriate level of effort in the process of change are important factors for successful activation and on to understanding the city as an open system.

Phase 2: Decoding

In this phase the hybrid code is decoded and hybrid activation follows. Through the scenarios considered beforehand and the resulting, specifically constituted hybrid code, the structural and procedural characteristics lodged in the corresponding level now take effect. This decoding leads to the hybrid being able to meet the new requirements as well as possible and creates new scope for action in urban development. Motivated by new societal, technological, ecological and economic changes, which act as stressors placing the city under pressure to adapt and triggering disruptions, the process of transformation is activated. The term disruptions here does not mean singular events, instead it is far more an overarching theme tending towards persistence and with a societal and global dimension. In terms of stress, they mobilise exceptional powers over a more extended period and necessitate reactive high performance. [16] As soon as the structurally lodged elements (e.g. dismantling lightweight partition wall) or processes (e.g. district management) are activated, the code is decoded and the hybrid principles can emerge specific to level. Hybrids have the ability to react with different strategies in their code.

Hybridisation is a planned process and leads to elements mutating into a “specimen of opportunity which has the mix-used gene in its code”. [8] The hybrid code was deliberately conceived for this situation. Through the process of hybridisation, impetus is unleashed towards resilient urban development. This contrasts with conventional, multifunctional building like a shopping mall located, as a rule, isolated at the city limits and making no contribution to long-term urban development. In this sense, hybrids are not separable from the process and purpose of hybridisation and take on a central role as incubators and catalysts of resilient transformation of the built environment in a city capable of development.

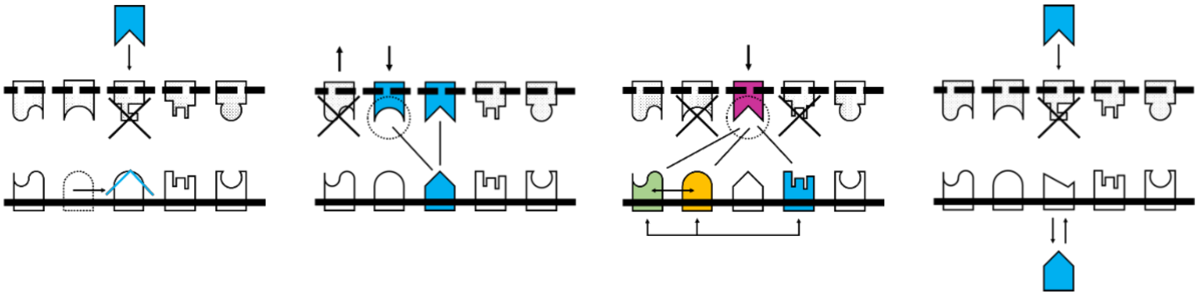

Figure 6. Principles of hybridisation in the interplay of requirements (upper strand) and structural and procedural implementation of the built environment (lower strand): adaptable, multifunctional, synergistic

Table 4. Structural and procedural implementation of hybrid principles

	adaptable – multifunctional – synergistic			
District	Special zones and areas for experimentation and ephemeral structures	Intermixed districts with corresponding compensatory spaces	Densified construction as an expression of culture of space	Scale and grading of different degrees of public space
	Interim use as activator of development	Diverse forms of construction	Renunciation of speculation and sale of urban land	Public space as a place to meet
Neighbourhood	Mix of semi-public intermediate space through placement of volume and façade design	Strengthening of neighbourly activities through provision of space and scope for action	Variety of services on offer for local shopping and sharing economy	
	High quality of intermediate space	District meeting places as incubators of experimentation and development		
Building	Diversity of residential provision through mix of typologies	House rules that do enable and don't hinder	Provision of rooms that can be additionally rented and subdivided	System of access enables different uses
	Unbundling of systems (primary, secondary and tertiary structure)	Sectional configurations and floor plans include buffers (e.g. height, riser zones etc.)	Construction and operation geared to conserving resources (including recyclability of materials used)	High degree of standardisation; modularisation and prefabrication
Unit	Rooms with equivalent proportion and orientation	Appropriation by users (e.g. completion of interior by tenants)	Neutral floor plans allowing easy adaptability	Planning based on users daily needs
Components	Application and installation oriented towards lifecycle	Design enables multiple occupancy and use (e.g. raised floor)	Robust, fault-tolerant and reparable building services	
	Simple accessibility and replaceability	User-friendly usability		
Infrastructure	Harness synergies through resource networks	Maintain independence and state control (e.g. water, public transport, power)	Polyvalent structure for use with various media	Human scale and more non-motorised mobility
Process	Reinforce the activities of those affected (e.g. volunteer agency)	No hindering of new approaches by standards and regulations	Principle of incomplete planning and permanent reflection	

	Cooperative planning culture and urban development (e.g. through citizen involvement)	Forward-looking perspectives through transdisciplinary think-tanks

2.3. Summary
What all hybrids have in common is their fault-tolerant character. As a result, they lend themselves to development and, in a figurative sense, are "adaptive". The systems involved do not have to be demolished or reconstructed with great effort. Instead, they overcome disruptions, can reorganise themselves and adapt to the new requirements. The strategies of hybridisation react to any prevailing dearth of offers or create new offers within the district on the basis of altered requirements. Consequently they are suitable for the strategic transformation of the city and create scope for action.

The great challenge here is to take account of unknowns already at the planning stage and to confer on hybrids structural or procedural capabilities that enable them to react. "This is where planners and clients reach their limits: which scenario is likely to occur? How will my client live and work in 10 or 20 years? What effect does this have on planning today's buildings? What are appropriate measures?" [17] Here we cannot avert the need to make assumptions and take a position. If the world changes, our built environment must be able to change too. This should be accompanied by winning and maintaining scope for action: The city is a "stimulating place […]. Not limited, instead complex, opening up possibilities for its occupants to make something of their lives. […] An orderly city is imposed on its occupants and limits their possibilities; a complex, disorderly city challenges its occupants to create something of their own". [18] In this process, hybrids are indispensable.

This paper arose as a result of a research focus on evolutionary algorithms in architecture. Central to the academic work is an analysis of strategic transformation of the built environment and its processes.

Abstract. The paper presents a study on the thermal and hydrological response of lightweight extensive green roofs with lightweight mineral wool growing media in different European climate conditions. The green roof heat and mass transfer model was developed and experimentally validated. It was then integrated into a developed software tool for the whole year analysis of the green roof thermal and hydrological performance. The results of performed numerical analysis showed that heat losses in heating season and heat gains in summer months of the green roof is smaller compared to the reference non-vegetated roof in all considered climate conditions and depends on thickness of lightweight mineral wool growing media and especially on the green roof's irrigation scenario. The results of numerical analyses also demonstrated that the water retention of green roofs can be considerably improved if irrigation scenario considers the weather forecast. The weather forecast based green roofs´ irrigation also improves retention at stormwater events.

1. Introduction

Green roofs gain great attention of urban planners and architects recently because of advantages comparing to other build elements of the urban environment. Besides improving urban microclimate conditions, the improved building energy performance and water retention are among most important advantages [1–4]. Because of that green roofs are gaining a predominant role in building retrofitting especially in the form of extensive green roofs because of low additional structural load, low maintenance and low cost comparing to intensive solutions [3–5]. Most common the advantages of green roofs are studied during summer time conditions [4, 6]. Beside reduced building's heat gains due to increased roof thermal resistance and high percentage of dissipated solar radiation by the foliage layer, considerable decreasing in outer surface temperature compared to traditional roof are observed [2]. Green roofs have significant impact on the thermal response of the building's envelope in the winter time conditions as well. Water in growing media enhance green roof thermal capacity [7] and can effectively store heat from solar radiation which reduces roof heat losses [8]. At freezing ambient air conditions, the process of water freezing further improves the energy efficiency of green roofs [9].

Especially in urban environment water retention is one of the key advantages of green roofs as it improves stormwater management [1, 10–12]. Green roofs, if properly designed, can retain significant stormwater and help mitigate flooding events thus addressing serious environmental impacts of excessive and uncontrolled urban runoff [10]. Selection of the growing media and plants influence green roof's retention capacity as well as evapotranspiration and thus irrigation needs. Wong and Jim [11] reported that in case when mineral wool is used as substrate considerable water retention and sufficient peak mitigation can be achieved even with a thin substrate layer. Zhang et al. [12] established that plant composition could have an influence on reduced substrate retention capacity due to created preferential flow pathways (due to plant roots) within the green roof growing media. As demonstrated in several studies appropriate irrigation water use strategy, based on weather prediction, can save considerably amount of drinking water [13–14] and it also increases retention capacity of green roofs at stormwater events [12].

As it could be concluded from the literature review thermal and hydrological response of the green roof largely depends on substrate (growing media) thickness and composition. The objective of this research is to evaluate the thermal and hydrological response of lightweight extensive green roofs with mineral wool growing media in different European climate conditions. Thermal and hydrological response of green roofs with different substrate thicknesses and irrigation scenarios is compared with reference lightweight roof to show multilateral benefits of the green roof. The potential of weather predicted irrigation on stormwater management and reduction of irrigation water use is also evaluated.

2. Green roof thermal and hydrological model

Green roofs are roof constructions that enable vegetation growth on top of a flat or low sloped load-bearing roofs. Green roofs consist of several layers such as (waterproof) root membrane, drainage layer with filter membrane, substrate (growing media) and vegetation (foliage) as it is shown in figure 1. In recent years lightweight extensive green roofs emerge in the market with some competitive advantages such as simple installation, low investment and maintenance cost as well as lower thickness and weight compared to extensive (and intensive) green roofs. The growing media thickness is between 2 cm and 10 cm and overall weight 17–40 kg/m² when dry and 42–75 kg/m² when completely saturated. Lightweight extensive green roof of system Urbanscape® with lightweight mineral wool growing media and Sedum-mix plants which thermal and hydrological performance is studied in this paper is also shown in figure 1.

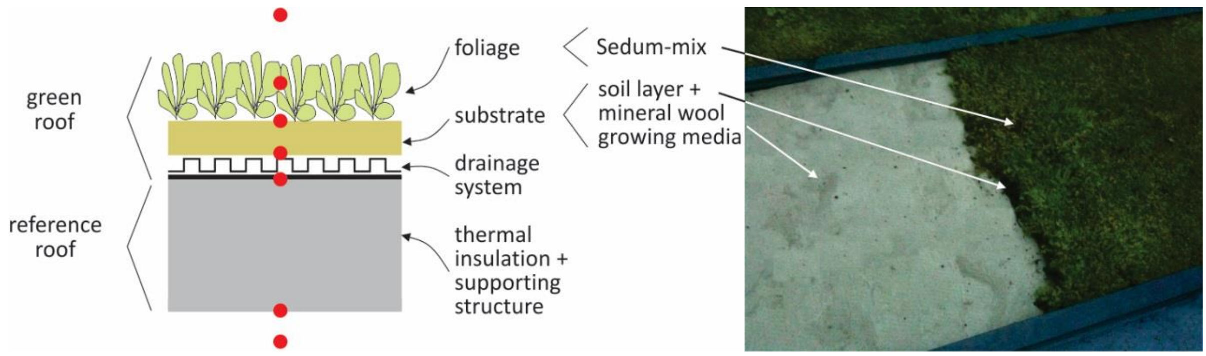

Figure 1. Schematics of reference and green roof composition (left), temperature nodes (red dots) and photo of green roof with Sedum-mix plants and lightweight mineral wool growing media (right).

To predict the green roof thermal response in summer and winter conditions and to study retention of the rainwater the quasi dynamic thermal and hydrological model of the green roof with a lightweight mineral wool growing media was developed. Because evapotranspiration process influences the heat and mass transfer, as well as green roof's growing media thermo-physical properties, the hydrological model was combined with the thermal response model of the green roof building construction. Heat transfer in the green roof is transient because of time dependent short- and long-wave radiation, outdoor and indoor temperatures and heat accumulation. Heat transfer can be determined considering one-dimensional transient heat transfer process between temperature nodes. At each temperature node energy balance equation is developed. For the greening layer (foliage and substrate) heat and mass transfer model is coupled considering two outdoor boundary planes – at the foliage temperature node and at the substrate surface temperature node, and taking into account global solar radiation absorbed by the foliage $G_{glob,0,f}$ (W/m^2) and the substrate $G_{glob,0,s}$, long-wave radiation exchange between the sky and the foliage $\dot{q}_{IR,f}$ (W/m^2) or substrate $\dot{q}_{IR,s}$ as well as between the foliage and the substrate $\dot{q}_{IR,f,s}$, convective heat flux $\dot{q}_{conv}$ and latent heat flux by evapotranspiration $\dot{q}_l$ as it is presented in figure 2. Foliage convective heat flux $\dot{q}_{conv}$ is determined according to Newton's cooling law where the convective heat transfer coefficient is calculated based on the leaf area index (LAI), aerodynamic resistance to heat transfer and leaf-air temperature difference [15, 16].

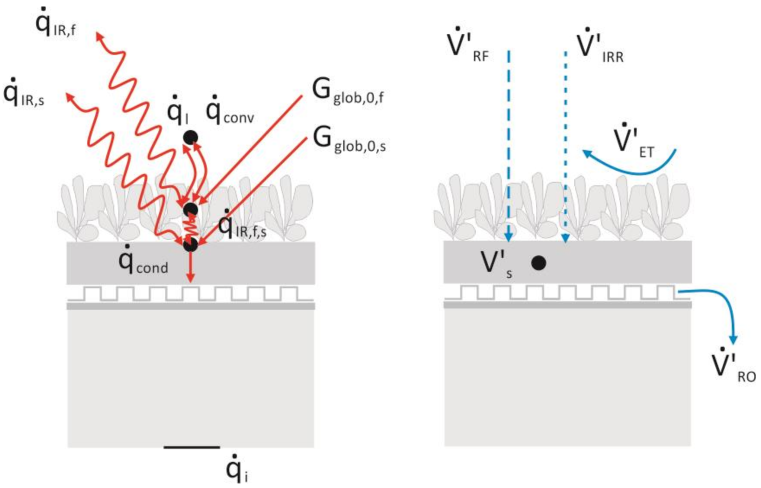

Figure 2. Heat fluxes considered in the energy balance at main temperature nodes (left) and mass fluxes considered in the water balance (right) of the green roof.

Latent heat flux $\dot{q}_l$ is determined from the evapotranspiration $\dot{V'}_{ET}$, which is calculated using Penman-Monteth equation for hourly or shorter time steps [17]. The water content within green roof substrate, in our case lightweight mineral wool growing media, has a significant impact on heat conduction and heat accumulation in greening layers as it influences material properties such as thermal conductivity and specific heat capacity; therefore, water balance must be considered. Water content in greening layer also influence evapotranspiration. For this reason, Penman-Monteth equation was upgraded for water stress conditions using results from our laboratory experiments. The substrate water content for each time step τ is determined from the green roof water balance:

$$V'^{i}_{s} = V'^{i-1}_{s} + (\dot{V}'_{RF} + \dot{V}'_{IRR} - \dot{V}'_{ET} - \dot{V}'_{RO})^{i} \cdot \tau \quad (1)$$

The substrate water content V'_s (mm/m²) is determined from the amount of rainfall $\dot{V}'_{RF}$ (mm/h m²) and irrigation water $\dot{V}'_{IRR}$ delivered to green roof in each time step (1 h) as well as amount of water lost due to the evapotranspiration $\dot{V}'_{ET}$ and runoff $\dot{V}'_{RO}$ of excess water in each time step. Runoff appears when calculated water content exceed the saturated water content $V'_{s,sat}$ of lightweight mineral wool growing media:

$$\dot{V}'_{RO} = (V'_s - V'_{s,sat})/\tau \quad (2)$$

Heat conduction and heat accumulation within the green roof growing media is calculated considering thermo-physical properties which varies with water content in the moistened substrate [18, 19]. Model also considers possible phase change (latent heat) at freezing temperature conditions [19]. Only for the loadbearing structure and thermal insulation layer (layers that are equal as for the reference non-vegetated roof) constant material properties are considered. Energy balance equations and thermo-physical properties calculation is presented in detail in [19].

For numerical model development the temperature in radiation flux equations and saturated water pressure terms are linearized. The implicit finite-difference equations are formed and they are solved using the matrix inversion method within MS Excel environment. Developed numerical model was validated with experiments as it is presented in chapter 3.

For year round thermal and hydrological response analysis, a software package "PET tool" was developed in the way that enables comparative all year thermal and hydrological performance analysis of the green roof and the reference (non-vegetated) roof. In the analysis, meteorological data from the Meteonorm 5 database are normally used. Thermal and hydrological response of the green and the reference roof is determined on the hourly time step interval whereby the indoor air temperature can be defined on monthly time scale.

3. Experimental validation

Thermal and hydrological response of green roofs have been extensively experimentally investigated since 2013 for three different compositions of lightweight extensive green roofs installed on the flat lightweight loadbearing thermally insulated ceiling of the laboratory test building [9] (Ljubljana, Continental climate). Green roofs consist of root membrane, drainage layer with filter membrane, lightweight mineral wool growing media and Sedum-mix blanket. Green roofs differ on thickness of lightweight mineral wool growing media (2, 4, 8 cm). Thermal and hydrological response of green roofs was simultaneously compared with reference roof (flat lightweight loadbearing thermally insulated construction without green roof layers). Each of the ceiling construction, called module, has dimensions of 1 × 3 m. The U-value of green roofs and reference roof is 0.157 W/m²K. A weather station Vantage Pro 2 was installed to monitor meteorological parameters. Heat flux sensors were installed on the inner and outer surface of the thermal insulation layer. Temperatures inside lightweight mineral wool growing media, thermal insulation and loadbearing layers were measured using T-type thermocouples. Rainwater runoff from each module was measured using water tank with diameter of 250 mm with pressure sensor which monitors water column high. Developed green roof numerical model was validated with all year round experimental data for green roofs with different thickness of lightweight mineral wool growing media including also short dry periods with reduced evapotranspiration due to water stress conditions. Figure 3 shows measured and with numerical model determined inner surface heat fluxes $\dot{q}_i$ for the green roof with a 2 cm thick lightweight mineral wool growing media for selected weeks during winter and summer weather conditions. Measured $\dot{q}_{i,exp}$ and modelled $\dot{q}_{i,num}$ inner surface heat fluxes differ in average less than 0.5 W/m², slightly larger differences are noticed only for daily extreme values. Higher differences are observed for summer period because a constant inner surface heat transfer coefficient was assumed.

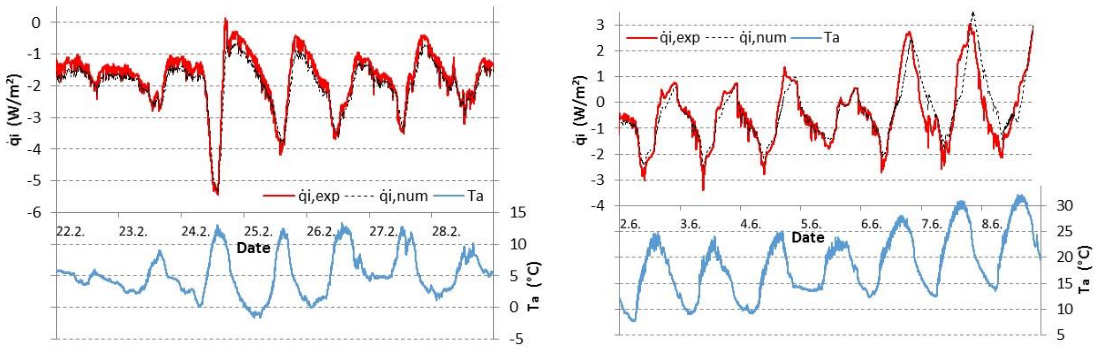

Figure 3. Measured $\dot{q}_{i,exp}$ and modelled $\dot{q}_{i,num}$ heat fluxes on the inner side of the green roof and ambient air temperatures T_a in winter and summer week.

Hydrological balance and modelling of the evapotranspiration $\dot{V}'_{ET}$ was validated with comparison of measured and with numerical model determined water runoff from green roofs. Figure 4 shows comparison of measured and with numerical model determined daily runoff water normalized on m² of the green roof area for the green roof with a 2 cm thick lightweight mineral wool growing media layer. Daily rainfall is shown as well. Figure 4 also shows with numerical model determined substrate water content $V'_{s,num}$ which indicate that water stress conditions occur (4.-5.8. and 10.-12.8.) and that developed model of evapotranspiration is adequate for such conditions as well. From the comparison of experimental and numerical results it can be concluded that developed green roof numerical model is adequate. Experimentally validated green roof numerical model was used to perform hour-by-hour whole year green roof thermal and hydrological response studies for different climate conditions.

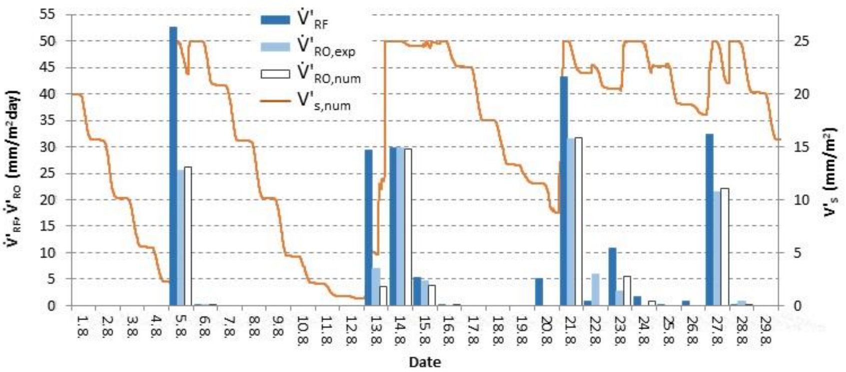

Figure 4. Measured daily rainfall $\dot{V}'_{RF}$ and runoff $\dot{V}'_{RO,exp}$, modelled daily runoff $\dot{V}'_{RO,num}$ and hourly substrate water content $V'_{s,num}$ in the 2 cm thick green roof's lightweight substrate during selected summer time period.

4. Green roof performance analysis

Heat losses of lightweight extensive green roofs in heating season as well as heat gains in summer were compared to reference roof construction for selected European cities with different climate conditions. Analysis are performed for the case of lightweight reference roof construction with 10 cm of thermal insulation and U-value of 0.34 W/m²K. Thermal response of reference roof is determined for the case of dark roof with solar absorptivity of 0.7. Green roofs with different thicknesses of lightweight mineral wool growing media (thickness of 2, 4, 6 and 8 cm) and different irrigation scenarios were considered in analysis and retention of rainwater as well as irrigation water needs are also evaluated. Maximum or saturated green roof water content depends on lightweight mineral wool growing media thickness. For the considered thicknesses (2, 4, 6 and 8 cm) the maximum water content $V'_{s,sat}$ is 25, 37, 54 and 66 l per m² of the green roof area are taken into account in the water balance (Eqs. 1 and 2). Three irrigation scenarios are considered in the analysis:

- no irrigation; maximum possible water retention, probably water stress conditions and risk of plant withering and reduced heat dissipation;
- irrigation; when substrate water content drops below 20 %; irrigation water amount corresponds to increase of the water content up to 50 % of saturated water content; in this way enabling good green roof performance and still some storage to handle stormwater events;
- irrigation considering 5 days weather forecast; no irrigation if precipitations are forecasted, otherwise regular irrigation (explained in previous paragraph).

Three cities – Ljubljana, Wien and Athens with different climate conditions (Continental high and medium rainfall and Mediterranean) were selected for analysis. Figure 5 shows average monthly ambient air temperature T_a, average daily solar irradiation on the horizontal plane $H_{glob,0}$ and monthly rainfall $\dot{V}'_{RF}$ for selected cities. It can be seen that average yearly ambient air temperatures in Ljubljana and Wien are similar (approx. 10 °C) while in Athens is over 18 °C. Yearly solar irradiation in Athens is 40% higher than in Ljubljana and Wien. The highest yearly rainfall is in Ljubljana – 1395 mm/m²a. Wien receives 44% and Athens 26% of that amount.

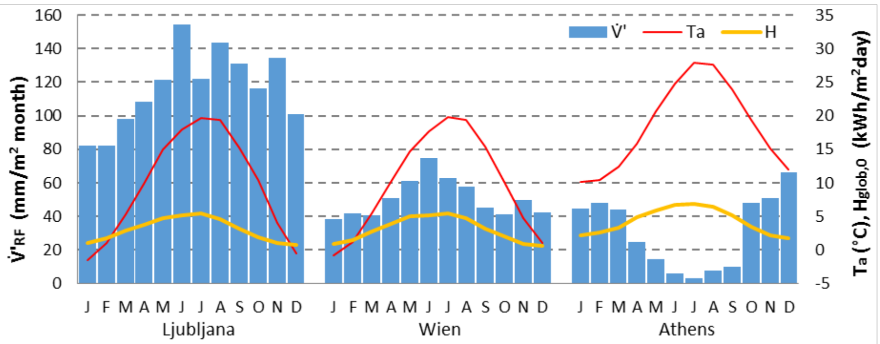

Figure 5. Average monthly ambient temperature T_a, monthly solar irradiation on horizontal surface $H_{glob,0}$ and monthly rainfall $\dot{V}'_{RF}$ for selected cities.

Indoor temperature and period of the heating and the cooling season were selected according to the city climate conditions: 20/24 °C and Nov.-Apr./June-Aug. for Ljubljana and Wien and 22/26 °C and Nov.-Mar./June-Sept. for Athens. For the reference non-vegetated roof heat losses and heat gains in defined heating and cooling period are shown in figure 6. For the green roofs reduction of heat losses Δq_h and heat gains Δq_c compared to the reference roof (absolute values) in kWh/m² in defined period are shown (figure 6) for different thicknesses of the lightweight mineral wool growing media and considering presented different irrigation scenarios: no irrigation (noIRR), regular irrigation (IRR) and irrigation considering weather forecast (IRR-wf).

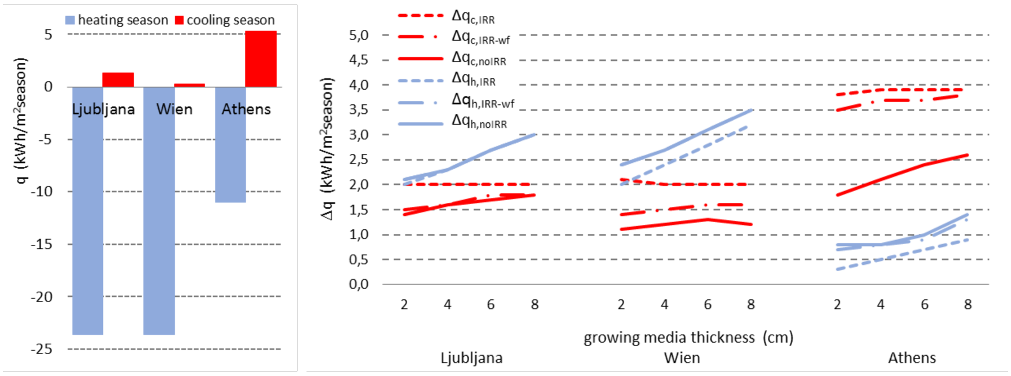

Figure 6. Heat losses and heat gains of reference roof in defined heating/cooling season (left) and reduction of heat losses and heat gains of green roofs compared to the reference roof at different green roof irrigation scenarios (right): no irrigation (noIRR), regular irrigation (IRR), irrigation considering weather forecast (IRR-wf).

It can be seen that heat losses in heating season in cities with Continental climate are almost the same, while in Athens they are more than 50% lower in spite of higher considered indoor air temperature. As expected the highest heat gains in the cooling season are observed in Athens with Mediterranean climate. Reduction of heat losses of green roof in comparison to reference non-vegetated roof is in case of no irrigation in the range from 7% to 15% for all three cities and is higher at higher thicknesses of lightweight mineral wool growing media. Green roof irrigation can influence the heat losses reduction for up to 5% in Athens and 2% in Wien, while it does have almost no influence in Ljubljana. Results indicate that although mineral wool growing media is moistened it provides some additional thermal insulation effect. In the cooling season the reduction of heat gains is the highest in case of regular irrigation thus avoiding reduced evapotranspiration due to water stress conditions. Results indicate that in Ljubljana and Wien heat gains observed for reference roof turns into heat losses for all green roofs – also those without irrigation.

Lightweight mineral wool growing media thickness (2, 4, 6, or 8 cm in the study) and irrigation scenario can be selected regarding to energy savings or regarding to retained rainwater and water needs for green roof irrigation. As it can be seen from Figure 7 green roofs with 4 or 6 cm of growing media performs much better than one with 2 cm because retained water is higher and water need for irrigation is lower. Increasing thickness to 8 cm has an effect mostly only on reduced heat losses in heating season. Nevertheless, results clearly indicate that most favourable results are obtained if irrigation based on weather forecast is applied for green roofs: retained water is practically the same as in case of no irrigation but there is no risk of plants withering; use of irrigation water can be considerably reduced, especially in case of thin substrate; and it does not influence much the reduction of heat losses in winter season and reduction of heat gains in the cooling period – with only exception of Athens with very low rainfall amount in summer months. Analysis of outflow for Wien also showed that in case of weather forecast irrigation there is no outflow from green roof with at least 6 cm of growing media (only two events in case of 4 cm) in the most rainy months from April to September.

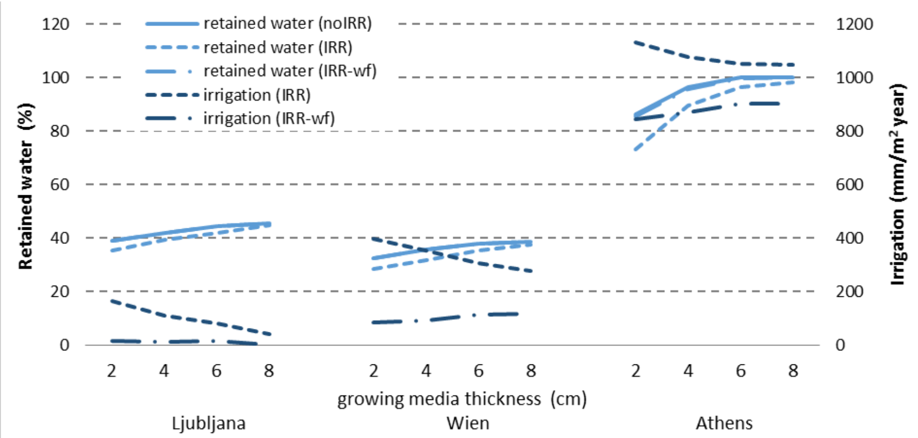

Figure 7. Retained water and water consumption for irrigation of lightweight extensive green roofs with different thicknesses of lightweight mineral wool growing media; irrigation scenarios: no irrigation (noIRR), regular irrigation (IRR), irrigation considering weather forecast (IRR-wf).

5. Conclusions

The thermal and hydrological response of lightweight extensive green roofs with lightweight mineral wool growing media was studied in different European climate conditions. In the analysis, the range of possible thicknesses of rock mineral wool substrate was considered, as well as three different anticipated irrigation scenarios. The thermal response was compared with the reference non-vegetated roof, which has, according to the calculation methodology, the same U-value of 0.34 W/m^2K. The results showed an up to 15% reduction of heat losses in the heating season. The highest energy savings were observed for the thickest lightweight mineral wool growing media, which indicates on additional thermal resistance of moistened green roof substrate. The growing media thickness does not have an effect on the heat gain reduction in summer period, as most of the heat is dissipated trough evapotranspiration. The weather predicted irrigation can reduce summertime cooling effect – on the other hand, it almost enables the theoretically highest water retention capacity – equal to that of no irrigated green roof. Analysis also showed that weather predicted irrigation can provide substantial savings of irrigation water, especially in case of lightweight mineral wool growing media thickness of up to 4 cm. The analysis also showed that the optimal green roof composition, i.e. the thickness of the substrate layer, can only be determined by taking local climate conditions into account.

Integrating climate change in life cycle assessment of buildings: literature review

Ramon D, Allacker K

Department of Architecture, Faculty of Engineering Science, KU Leuven, Belgium

delphine.ramon@kuleuven.be

Abstract. The operational energy use and related greenhouse gas emissions of buildings are typically influenced by changes during the building service life such as climate change, technological evolution and energy mix evolution. Only few LCA studies consider these temporal variations. This paper investigates how climate change is currently considered in LCA studies. Three aspects related to the influence of climate change on the life cycle impact of buildings are focused on: (1) changes in operational energy use (heating and cooling) due to changes in the climatic context of the building, (2) changes in operational energy use due to technological evolution or climate regulations and (3) changes in energy mix due to climate regulations. All three influence the energy use and related environmental impact but the extent of the effect depends on the considered region, time step and environmental indicators. It is hence recommended to choose an appropriate time period when considering climate change in LCA and consider variations within a time period via dynamic building simulations or to include a static correction. A holistic set of impact categories should be focussed on to avoid burden shifting and the most influencing parameters should be checked via a sensitivity analysis.

1. Introduction

In 2017, buildings accounted for 36% of the final energy use worldwide and for nearly 40% of the CO_2-emissions [1]. Various studies identified that the operational energy use contributes most to the life cycle CO_2 emissions of a building [2–4]. This includes the energy needed for heating, hot water supply, air conditioning, ventilation, lighting and auxiliary energy used for pumps, control and automation [5]. Several parameters influence the operational energy use and related CO_2 emissions of buildings, such as energy equipment technology and characteristics, occupant behavior, climate conditions, energy mix and policy rules [6–10]. In addition, these parameters typically change over the life cycle of the building. Current environmental impact studies however typically do not consider these changes [11]. Operational energy use is for example often estimated based on a one-year dynamic calculation for a representative year [2,11] or a static calculation based on degree days [4,9,12,13] and standard Life Cycle Assessments (LCAs) assume a static (current) energy mix for the whole building service life.

This is confirmed by Collinge et al. [8], stating that current LCA approaches are mostly static assuming point values for flows (inputs and outputs), emissions and characterization factors. Time-related changes however do affect these variables considerably [7,8]. Dynamic LCA (DLCA) does take into account these temporal changes and is defined by Collinge et al. [8] as "*an approach to LCA which explicitly incorporates dynamic process modelling in the context of temporal and spatial variations in the surrounding industrial and environmental systems*". Only few LCA studies were found that indeed consider these temporal variations when assessing the life cycle impact of buildings.

In his paper Collinge distinguishes dynamic methods applied to the Life Cycle Inventory (LCI) and Life Cycle Impact Assessment (LCIA). Su et al. [7] follows this distinction and further divides them in four dynamics: technological progress, variation in occupancy behaviour, dynamic characterisation factors and dynamic weighting factors. The first two aspects are related to the building processes (inventory), while the last two are related to the impact assessment. Negishi et al. [6] defines three levels of which the first two (i.e. building technology level and end-user level) overlap with the first two dynamics defined by Su et al. His additional third level considers changes in the external system of the building, i.e. changes in energy production mix, climate conditions and climate regulations.

This paper focuses on one of these changes in the external system of the building, more specifically climate change. The aim is to investigate how climate change is currently taken into account in LCA studies and if any recommendations for improvement can be formulated. Three aspects related to the influence of climate change on the life cycle impact of buildings are focused on: (1) changes in operational energy use (heating and cooling) due to changes in the climatic context of the building during its service life, (2) changes in operational energy use due to technological evolution or climate regulations and (3) changes in energy mix (increase of renewable energy) due to climate regulations [14]. For example, the increased efficiency regulations lead to a shift towards electrical heat pumps being partly responsible for an increase in electricity use [14].

The next section presents the state of the art regarding the consideration of climate change in dynamic LCA considering the three aspects mentioned before based on a literature study. The influence on both the energy demand and related emissions are reviewed. The state of the art is discussed and recommendations for improvement are formulated in a final section.

2. State of the art

A state of the art is provided for each of the three aspects related to climate change and LCA as mentioned before (section 2.2 – 2.4). This is preceded by an overview of the state of the art of methods used in LCA to calculate the operational energy use (section 2.1).

2.1. Estimation of life cycle energy use and related environmental impacts

In current LCA practice, the operational energy use of buildings is calculated in different ways. A first method is based on heating and cooling degree days, applied amongst others in the research of Passer et al. [4], Isaac and Van Vuuren [9] and Roux et al. [15]. Heating or cooling is assumed to be needed from a certain external temperature onwards till a certain indoor temperature. The research of Trigaux et al. [16] defines dynamic equivalent heating degree days which consider internal heat gains and detailed solar gains. The yearly heating energy calculation includes in addition to these gains also the thermal losses through the building envelope (transmission and ventilation losses).

A second method is to use dynamic energy simulations. Komerska et al. [17] integrates thermal dynamic building simulations (i.e. DesignBuilder model) in their LCA study of office buildings in Poland to evaluate different façade solutions. A one-year simulation is used to estimate the energy consumption for the different solutions and kept constant during the building service life. Azari et al. [11] established an integrated framework by combining the Athena Impact Estimator for Buildings (LCA tool) and the eQuest energy analysis tool. The dynamic building energy simulation performed with eQuest is manually entered in the Athena framework. Similar as to Komerska et al. this is a point value in the sense that the input for Athena exists of the annual energy consumption for the different energy uses (i.e. lighting, space cooling, space heating and other).

The research of Allacker et al. [2] combines dynamic energy simulations with LCA on the building level to calculate the effect of micro-scale measures on the macro-scale and to compare different scenarios. In this study, climate datasets of three cities (Athens, Strasbourg and Helsinki) are used to represent three climatic zones across Europe. Different studies [9,18] have included multiple locations to get insights in the effect of regional climate. Again, these studies assume the climate unchanged over the building service life.

The research of Collinge et al. [8] used measured operational energy uses based on monitoring. Monthly data for energy uses and historical fuel mixes for the electricity grid and heating plant were available. The use of monitored data is of course only possible for constructed buildings and is not an option in the design phase. In his research, a dynamic mathematical model was developed considering at each moment in time the different energy uses and fuel mixes. The service life of the building is divided in two periods before and after renovation. Before renovation the detailed data is used, while for the period after renovation an estimation is made based on a model and kept constant for the remaining years. The model allows to keep constant values over the different time steps.

2.2. Changes in operational energy use due to climate change

Buildings are typically designed for certain environmental conditions but will have to deal with other conditions during their service life. The energy performance of a building will inherently be influenced by global warming. Worldwide, a reduction of the heating demand of 34% is expected by 2100 under a median climate change scenario, while an increase of the air-conditioning energy demand by 72% is expected [9]. It should be noted that part of these global changes is also caused by non-climatic drivers such as increasing income, population growth, and energy efficiency [9,19]. Globally the net effect on energy demand is expected to be relatively small compared with the total energy demand, however this highly depends on the climate change scenario (and related weather data) and assumptions made [9,18,20,21] as well as the region considered. For Europe, the IPCC report [22] states an increase of the cooling energy under a 3.7°C scenario to increase by 74% to 118% by 2100. A decrease of 0.7% per year is projected from 2010 onwards for heating energy.

In Europe, the share of cooling in the total building final energy use tripled since 1990 to 12% [19]. Most literature sources agree on the fact that raising temperatures are expected to decrease the heating demand of buildings and to increase the cooling demand [9,15,20,22–24]. However, there is more discussion about how big this effect will be depending on the region studied as well as the climate change scenario considered [19]. More specific, till 2050 a reduction is expected, followed by an increase in the second half of the century. For Europe, the reduction in heating demand is expected to outweigh the increase in cooling demand for the northern and central part at least till 2035 [9,25–27]. For the southern part, this is not the case and an increasing cooling demand will lead to a net increase. In addition to changes between heating and cooling loads, also seasonal patterns will be influenced by climate change having impacts on energy needs and mixes [9]. Winter peaks are expected to be less pronounced in future.

Looking to the related greenhouse gas (GHG) emissions, Isaac and van Vuuren [9] state a clear increase in the second half of the century on global level where India will be the most affected country. An increase of CO_2-emissions from 0.8 Gt C in 2000 to 2.2 Gt C in 2100 is projected which is about 12% of the total CO_2-emissions from energy use. Looking to heating and cooling separately, heating related emissions are stated to decrease with 36% by 2100 while the cooling related emissions are expected to increase with 72% by 2100 [9]. Heating is commonly foreseen with secondary energy sources while air conditioning in buildings is often anticipated by electricity likely leading to increased emissions and to overweigh the reduction of the heating related emissions [24,28]. Though this conclusion is very sensitive to the scenario used and the region studied [9,24]. In addition, several studies stressed the importance of the energy efficiency of the cooling system in buildings to reduce emissions [24,25,29].

The research of Williams et al. [24] presents a methodology for the early design stage which links the GHG emissions of heating and cooling energy with climate change, more specifically with changing external temperatures through a unique building fingerprint. The fingerprint is calibrated based on selection of weather years representing average, cold and warm years for a low, median and high emission scenario out of the 3000 years generated with the UKCP09 Weather Generator for different climate change scenarios. The fingerprint allows to calculate the GHG emissions for any weather year for that specific building and to consider the effect of climate change related uncertainties. Different climate change scenarios were found to influence the total GHG emissions during the life cycle to an important extent.

The research of Colling et al. [8] used energy consumptions based on utility meters between 1979 and 2009. Changes in emission factors were found to have the biggest influence. Although, the electrical energy consumption increased over this period (due to an increased building footprint), it was outweighed by the decrease in GHG emissions from the energy supply. The latter was mainly caused by a decarbonisation of the district steam production (switch to 100% gas).

The research of Roux et al. [15] considers a variable energy use (and energy mix) for different time perspectives. The building service life is divided in three periods around 2020, 2030 and 2050 for which a certain energy use (and mix) are assumed to be constant. The energy use is estimated by projecting current degree-days with a high and low climate change scenario to the respective points in time.

The research of Negishi et al. [6] proposes a five-step framework which integrates the time dimension at different steps of the LCA. In the first step a dynamic energy simulation is performed with the COMETH software as it allows to consider long-term temporal changes such as a decrease in heating demand due to global warming. Similar as to the research of Roux et al. [15], the service life is gridded in different periods characterized by constant parameters for the processes involved. By contrast, depending on the building subsystem, these periods could be limited to one year and should not necessarily encounter multiple years.

2.3. Changes in operational energy use due to technological evolution due to climate regulations

The EU has set the goal to decrease GHG emissions by 80 to 98% by 2050 [30] which requires changes in the current energy systems and hence energy mix. To achieve this, amongst others, goals are set for further efficiency measures of equipment [14]. The strengthening of energy efficiency policies is expected to result in a trend towards electrification of the heating need (i.e. heat pumps) [14,30]. Though, electrification does not necessarily lead to lower environmental impacts. The research of Blom et al. [10] shows that even though a heat pump does not use fossil fuels, it could have higher environmental impacts than a gas-fired boiler depending on the coefficient of performance (CoP) caused by the higher environmental impact of electricity than natural gas in the Netherlands. Including the materials and refrigerants of the pump even increase the difference with a boiler. In contrast, further improvement of the efficiency rate will partly compensate this difference in future.

In the past decades, policy increased insulation values for building. By consequence, the thickness of insulation improved, glazing systems develop from single glazing to triple glazing systems with coatings. However, once a building is insulated, the effect of additional insulation is rather small on the total heating energy as shown in the research of Waddicor et al. [25]. It was even found to slightly increase the cooling load due to an improved air tightness and reduced thermal bridging. Improving window insulation has an important influence on the energy demands, however a good balance should be found between reducing solar gains in summer and increasing in winter. While a good insulating value is recommended for different regions, low g-values are only recommended in hotter arid locations and could lead to higher heating loads in cold locations. His study further highlights the increase of efficiency for the chiller as the most effective measure to reduce cooling energy as mentioned by other studies before [24,29].

2.4. Changes in energy mix due to climate regulations

In addition to increased efficiency measurements, also goals are set to reduce the use of fossil fuels and increase the use of renewables influencing the energy mix. By consequence, trends such as a shift from oil to gas and electrification of heating are expected [14]. Electricity is the fastest growing form of final energy use and multiple studies stress the importance of electricity in future. In Europe fossil sources are however still used for more than 50% of its production [27]. The energy mix evolution will have an influence on energy consumption related emissions of a building [10,12,15,24,31]. However, in most of the LCA studies an average energy mix is used and kept constant for the full building service life even though this mix is subjected to temporal variations from daily to decadal scale [15]. Multiple studies were found to investigate a specific aspect of a changing energy mix (i.e. specific equipment component or mix evolution) but only few were found to study this in a building LCA.

In Europe, the increased share of renewables in the electricity mix is mainly driven by an increase of wind power [14]. The solar and biomass fraction both increase as well, but not as significantly as for wind. Multiple studies investigated the influence of climate change on the solar and wind power generation. For PV generation, it is unlikely that climate change will be a threat in Europe. Studies confirm possible decreases in the range of 15% and possible increase of some percent [32,33].

The research of Blom et al. [10] compares the use of gas and electricity consumption in Dutch apartment buildings. For the Dutch situation, the research shows a higher impact of the electricity consumption per MJ of energy than for gas caused by the low heating demand of the building. Gas is found to have a higher impact when considering the average consumption of all households in all dwelling types. Changing the sources for electricity generation influences the environmental impact, however, they should be chosen carefully as impacts could be shifted to other indicators. This shifting applies in general when reducing heat demand by increasing electric share or replacing gas by electricity consumption. A holistic approach is hence recommended to take well-founded decisions between multiple options.

The effect of the country specific electricity mix is highlighted in amongst others the research of Vuarnoz et al. [31]. For the year studied, the 17% of the electricity on the Swiss grid supplied by Germany was responsible for 70% of the GHG emission of this Swiss mix caused by the high share of fossil fuels used in the German electricity production.

Roux et al. [12,15] describe the importance of considering temporal variations in the electricity mix. In Roux et al. [15] a business as usual evolution and a scenario with the introduction of a carbon tax in France were used to predict future energy mix evolution. Further research of Roux [12] considers the hourly variation in the electricity mix. In this case, the environmental impact of the mix for that hour is multiplied by the consumed energy instead of using a yearly average environmental impact. It was found that the annual average mix leads to an important underestimation for Global Warming Potential (GWP) and Abiotic Depletion Potential mainly caused by higher shares of coal and gas power plants during winter. By using an hourly time step, differences in electricity production between on- and off-peak hours can be accounted for as well as on-site electricity production. Consistency between the energy simulation and electricity mix evaluation is hence recommended. The need for a representative hourly mix is stressed as real years could be subject to climatic or economic conditions and in consequence might not be representative for the years after. In further research [34], Roux stressed the importance of up-to-date data if electricity has an important share in the system as linked technologies and installed capacity change rapidly (e.g. increase in renewable power plant capacity).

3. Discussion

A literature review showed the relevant impact of climate change and climate regulations induced changes on the energy use and related GHG emissions. Based on the reviewed researches, LCA studies should be performed for an appropriate spatial context (e.g. full country or specific region or even city) as climate change impacts on buildings and climate policies could differ to a large extent from region to region. Further, three aspects are highlighted to be considered when performing a building LCA which are discussed in the following subsections: (1) considered time step; (2) holistic approach; and (3) uncertainties.

3.1. Time steps within service life of a building

As stated by Su et al. [7] ignoring time-varying influences decreases the accuracy of the assessment results. Time-varying influences can be defined on the short-, mid- and long-term perspective. When considering effects of climate change and long-term energy mix evolution, time steps of 20-25 years come forward as changes are mostly projected to future points in time (i.e. 2030, 2050 and 2100). Dividing the service life in two or three periods as proposed by Roux et al. with a certain energy use and energy mix for that period seems a good option to encounter these changes. Alternatively, linear interpolation could be used between different scenarios in time. However, as both climate change and mix evolution do not change linearly, it would not necessary give an improved accuracy. For the energy mix defined, it was found that considering daily, weekly and seasonal variations are important. Instead of using an annual average mix, it is recommended to use per time period a yearly profile encountering these variations.

Technological changes rather evolve year by year. Replacement of elements will moreover intervene with these longer periods defined for climate change effects and energy mix. A shorter time step, as suggested by Negishi is more suited for the replacement of technical equipment.

Ideally changes in energy use due to climate change and technological evolutions are encountered by multi-year dynamic building simulations. If impossible or unworkable, the authors suggest to consider the change by technological improvement by applying a correction on the estimated energy use due to climate change (e.g. 5% reduction due to increased system efficiency of the heating system).

3.2. Holistic approach

A holistic approach is recommended to avoid burden shifting when considering changes between different end-energy uses, energy mixes and technologies. Other indicators than GWP should be focussed on such as acidification and terrestrial ecotoxicity. The shift towards more electricity use instead of fossil fuels has a significant negative impact on those indicators. Not considering those could lead to burden shifting.

3.3. Uncertainties

As all the studied changes will happen in future, it is important to consider the related uncertainties to come up with robust choices. Firstly, the influence of the climate change scenario chosen was highlighted multiple times in the reviewed literature. Considering multiple climate change scenarios as done by Williams et al. is recommended by the authors to get insights in the spread of energy use and related emissions. The multiple climate models available can be used to investigate the spread across different climate change scenarios. As this could be time intensive, a thorough study based on one scenario with a sensitivity study based on a worst case and best-case climate change scenario could already provide relevant information about the most sensitive components of the building LCA model.

Secondly, it is unsure when certain shifts (e.g. higher cooling than heating load or shift from gas to electricity) will happen and this might highly depend on the building characteristics and location. Multi-year dynamic simulations are recommended to get insights in these dynamics.

Lastly, evolutions in energy mixes and energy efficiencies are often driven by policy goals. It is however uncertain if these will evolve linearly towards those goals or not and whether they will be reached within the foreseen timeframe. If the goal of the LCA study is to get insights in the influence of changes, the authors recommend to assume linear trends. If the goal is to see which reductions in GHG emissions are needed by when to avoid further climate change, a sensitivity study on time steps is recommended to identify the necessary changes and their time steps.

4. Conclusion

This paper investigates changes in operational energy use and related emissions caused by climate change and how these are currently considered in building LCA studies. Three aspects are focused on during a literature review: (1) changes in operational energy use (heating and cooling) due to changes in the climatic context of the building during its service life, (2) changes in operational energy use due to technological evolution or climate regulations and (3) changes in energy mix (increase of renewable energy) due to climate regulations. All three were found to have an important influence on the energy use and related emissions, though the extent of influence depends on the considered region, time step and environmental indicators. The authors recommend to choose an appropriate time step for the investigated influences and to allow for changes within different time steps by means of dynamic building simulations (preferable multi-year simulation) or correction. Further a holistic approach is recommended to avoid burden shifting and to make well-founded decisions. Lastly, uncertainties are inherently linked with future projections. Therefore, sensitivity analysis with at least best- and worst-case scenarios is recommended for the studied parameters to obtain robust design decisions.

Abstract. Due to energy, environmental, and social benefits, green roofs are recognized as a bioclimatic technology and sustainable construction systems and are becoming a predominant solution in connection with urban planning and building envelope retrofitting. To support design and marketing of Urbanscape® lightweight extensive green roofs a special software tool was developed, which is presented in the paper. Performance evaluation tool (PET tool) is validated based on extensive and continuous 5-years in-situ monitoring of thermal and hydrological response of different Urbanscape green roofs. The key performance indicators of Urbanscape green roofs are evaluated based on calculated thermal and hydrological response. To emphasize the advantages of green roofs thermal response and performance indicators are determined also for non-vegetated roof for the same boundary conditions. PET tool enables i) evaluation of Urbanscape green roofs' whole year thermal and hydrological response, ii) to search for the optimal design of the Urbanscape green roof system in terms of energy and water performance, iii) evaluation of comparative advantages compared to non-vegetated roof, iv) energy savings and CO_2 emission reduction analyses for heating and cooling season. Analyses can be made for arbitrary worldwide climate conditions since meteorological parameters are gathered from Meteonorm database.

1. Introduction

In the past, the primary role of greenery on the building envelopes – green roofs and green facades – was its aesthetics, while their impact on the building and the external environment has become the subject of research in the last decade [1]. Nowadays, green building envelopes are recognized as having a high positive influence on urban microclimate and living comfort in cities, since they address many environmental issues, such as urban heat island mitigation, water retention and detention, sink of CO_2 and other pollutants [2-3], all resulting from the impact of global climate change and urbanization [4]. The survey of research activities and state of the market reveilles that among green building envelope technologies green roofs (both extensive and intensive) are the most developed and established technology. Due to energy, environmental, and social benefits, green roofs are recognized as a bioclimatic technology and sustainable construction systems [2, 5] and are becoming a predominant solution in urban planning and an increasingly used alternative at building envelope retrofitting especially in the form of extensive green roofs because of low additional structural load, low maintenance and low cost in comparison to intensive solutions [2, 6]. Green building envelopes are part of the green infrastructure, which is quoted in numerous strategic documents, initiatives and directives of the European institutions [7-10] and city administrations, where they are recognized as technology that contributes: to improving the energy performance of buildings, to stormwater and water resource management, to achieving greater biodiversity and to the transition to a climate change neutral Europe.

Green roofs are adaptive (and even multifunctional) building envelope constructions, so their characterization, selection and evaluation of thermal performance can not be based on standard/basic building construction thermal performance metrics e.g. steady-state thermal transmittance (U-value), which is easily recognized by building designers, stakeholders and experts [11]. Due to lack of suitable performance metrics for static and adaptive building constructions the advantages of green roofs, in comparison to non-vegetated roofs are most commonly studied experimentally or numerically using developed numerical models [12] and considering equal boundary conditions. Green roof models were also developed for building energy simulation tools EnergyPlus and TRNSYS [12] however they firstly do not consider latent heat of water at water freezing ambient conditions, which considerably influence green roof thermal response and secondly they are not adapted to lightweight mineral wool growing media, which has a very high water retention capacity and low thermal conductivity and density (equal to mineral wool thermal insulation) in a dry state.

Due to limitations of existing green roof models in building energy simulation (BES) tools a software tool named 'PET tool' was developed to enable yearly thermal and hydrological response analysis for arbitrary climate boundary conditions. Software tool was made based on the developed and thoroughly validated green roof and non-vegetated roof numerical models. PET tool is designed in a way to support design and marketing of Urbanscape® lightweight extensive green roofs. It's functionality and performance metrics are presented in this paper.

2. Green roof performance evaluation tool

PET tool is a user-friendly software tool, developed within MS Excel, intended for comprehensive analyses of Urbanscape green roofs' thermal and hydrological performance and presentation of their advantages compared to existing non-vegetated flat roofs. PET tool, its features, functionalities, performance and analyses are the result of collaboration between Knauf Insulation, Urbanscape Green Solution Team experts and stuff of Laboratory for Sustainable Technologies in Buildings, Faculty of Mechanical Engineering, University of Ljubljana. PET tool is one of the results of a five-year industrial research project [13-14] financed by Knauf Insulation, Škofja Loka, Slovenia.

Instructions for proper use of PET tool and correct interpretation of presented results can be accessed from the PET tool welcome screen (figure 1a). Instructions (figure 1b) provide also further calculation examples and interpretations of results according to frequently asked questions of customers.

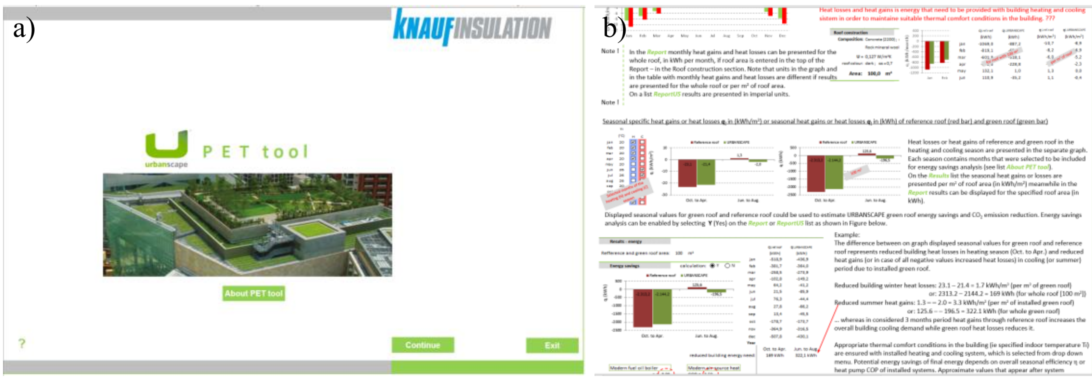

Figure 1. 'PET tool' welcome screen (a) and screenshot of PET tool instructions for use and results interpretation (b).

2.1. Numerical model and model validation

Green roof energy and hydrological performance is determined with developed one-dimensional transient heat and mass transfer numerical model, which considers main heat fluxes that influence green roof thermal response as well as green roof's water balance. The green roof model is presented in detail in [12]. Compared to existing green roof models it also takes into account heat transfer phenomena at freezing temperature conditions – a latent heat accumulation in green roof's lightweight mineral wool growing media. As demonstrated in [12], latent heat accumulation considerably alters the green roof's thermal response; peak heat flux as well as heat losses are also reduced. Green roof's numerical model equations are solved within MS Excel environment using the matrix inversion method. Number of temperature nodes is fixed to 32, where 6 of them are being used for the green roof growing media. Specially developed algorithm determines optimal number of nodes for each roof layer, according to the layer thermal resistance, in order to achieve optimal accuracy of numerical calculations. Thermal and hydrological response of the green roof is determined using a time step of one hour, which equals the time step of meteorological data, which are obtained from Meteonorm 7 software [15]. Alongside with the green roof numerical model also a numerical model of reference (non-vegetated) roof was developed in order to enable comparative green and reference roof performance analysis.

PET tool was validated based on extensive and continuous 5-years in-situ monitoring of thermal and hydrological responses of different compositions of Urbanscape Green Roof Systems performed on Faculty of Mechanical Engineering, University of Ljubljana. Experimental green roofs were installed on a flat roof of a laboratory test building presented in figure 2. There are four modules, each with dimensions of 1 × 3 m, one of them representing the reference non-vegetated roof. Until now 8 different Urbanscape green roof compositions were tested, each with in-situ monitoring period of at least 1 year. One green roof composition remains unchanged since 2013 for evaluation of long-term effects on thermal and hydrological response. Results of PET tool numerical model validation are presented in yearly reports [13-14] and published research papers [12].

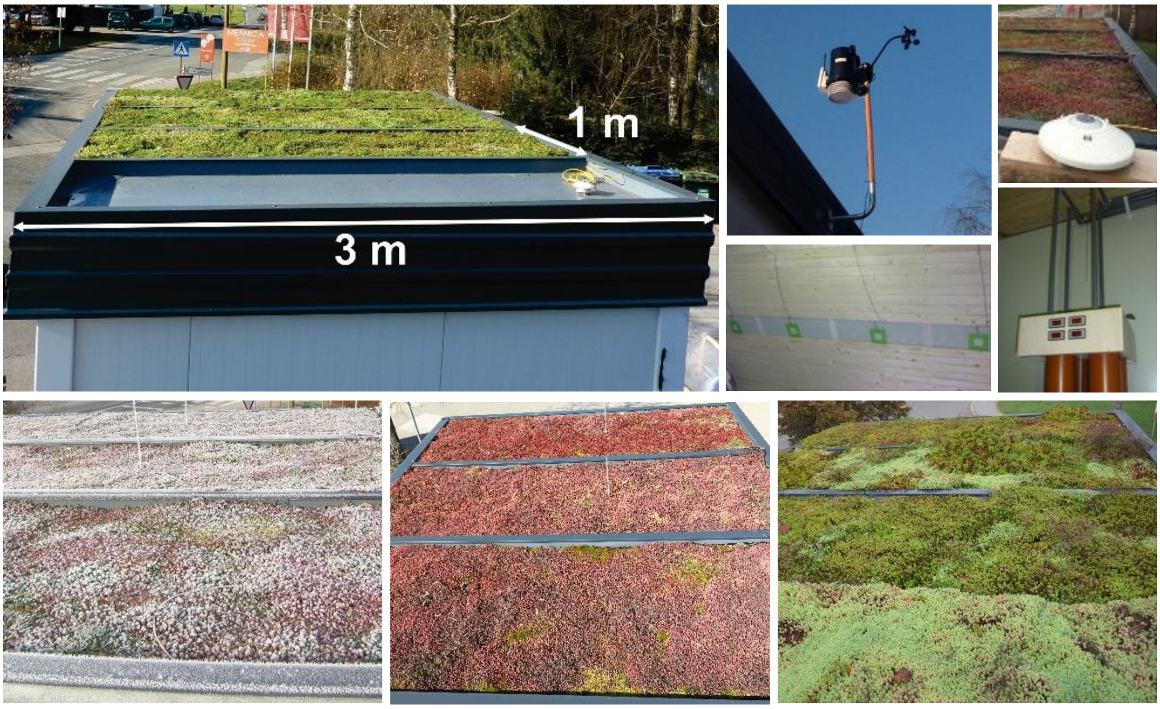

Figure 2. Lightweight extensive green roof modules on a roof of the laboratory test building after installation in 2013 (top left), some used measurement equipment (weather station Vantage Pro 2, pyrgeometer Kipp&Zonnen CG1, heat flux meters, developed outflow volume-flow meters) (top right) and green roof vegetation (Sedum-mix) appearance in different periods of the year (bottom).

2.2. Definition of roof compositions and boundary conditions

PET tool is a MS Excel .xlsm file with separate .xlsx file with Meteonorm meteorological data for several worldwide locations. The screen that appears after the welcome screen is shown in figure 3a. At first, the composition of a loadbearing construction (i.e. the ‘Reference roof’), on which Urbanscape Green Roof System is placed, is defined. Up to 6 layers can be defined, from drop-down boxes where materials are organized in groups. For each layer thickness needs to be specified and U-value is displayed at the top of the screen. For the reference roof the absorptivity of solar radiation also need to be selected. Follows the selection of Urbanscape lightweight extensive green roof system composition. As a vegetation layer a Sedum-mix blanket with 2 cm soil layer is added automatically. For the green roof the overall thickness and maximum water content are displayed on screen. Irrigation scenario – N/Y and at which water content green roof is irrigated – needs to be also specified. In the numerical model it is set that at each irrigation event 30% of maximum water content is added. At the end the climate conditions are specified by firstly selecting the country and then the city. Data that are imported in PET tool and are needed in numerical model are hourly values of ambient air temperature and relative humidity, wind speed, rainfall and solar and incoming longwave radiation on horizontal plane.

The second PET tool screen presents graphically and numerically meteorological parameters (figure 3b) what helps the green roof expert to define indoor temperature in heating (winter) and cooling (summer) season and to select months that are going to be included into seasonal energy savings analysis. Months that are not selected are not considered in seasonal energy performance analysis. Displayed meteorological data are valuable also for optimization of green roof composition and irrigation scenario.

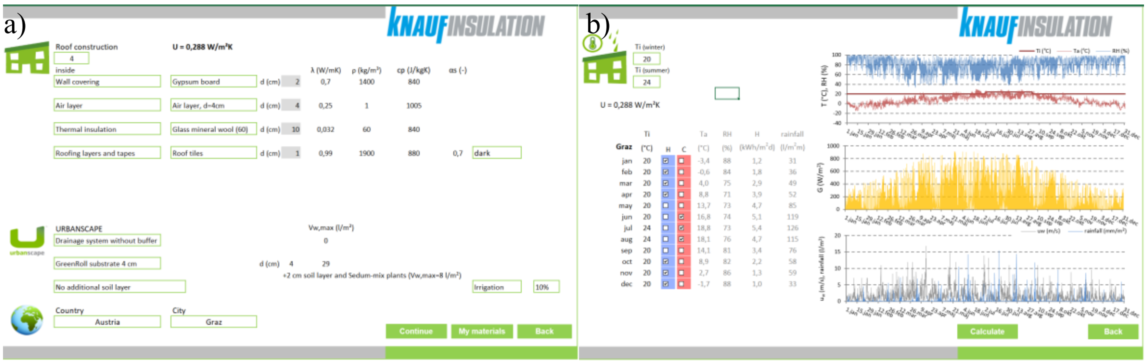

Figure 3. Screenshots of ‘PET tool’; definition of reference roof composition and lightweight extensive green roof composition and irrigation and selection of site meteorological parameters (a) and indoor boundary conditions definition and selection of months for seasonal analysis and graphs presenting meteorological parameters (b).

2.3. Presentation of performance indicators

When boundary conditions as well as heating and cooling season are defined thermal and hydrological response is calculated with validated numerical models of lightweight extensive green roof and reference roof. In the PET tool calculation progress is shown by displaying calculated monthly values. Thermal and hydrological response calculations do not end at the end of the year. Calculations are repeated in order to balance initial conditions. Calculations stop when calculated values does not differ from those obtained in the first run. Figure 4 presents screen with displayed results where hourly, monthly, seasonal and yearly values are presented for the green and the reference roof. The first graph (top-right) presents hourly values of specific heat flux $\dot{q}i$ in (W/m²) on inner surface of reference roof (red line) and green roof (green line). It enables comparison of peak heat fluxes which directly influences required heating and cooling power. Graph also visualizes green roof heat flux attenuation due to increased roof heat capacity, shading and evapotranspiration as well as due to latent heat accumulation in green roof substrate caused by water freezing and melting at freezing ambient conditions. On the left hand side of the screen monthly average specific heat values are presented as an indicator of monthly heat losses and gains. The difference between reference and green roof value indicates the potential monthly energy savings. The same graph presents also monthly peak heat fluxes what indicates the expected peak heat losses and gains in each month. Numeric values are listed in the report (section 2.4).

For the months that were selected for heating and cooling season the seasonal specific heat gains or heat losses qi in (kWh/m²) are presented for the reference roof (red bar) and for the green roof (green bar). These values can be used to evaluate Urbanscape lightweight extensive green roof energy savings as well as for green roof composition optimization.

One of the recognized advantages of green roofs is also urban heat island mitigation. This benefit of green roof in comparison to the reference roof can be evaluated from the graph in the middle of the screen (figure 4), which presents hourly values of calculated outdoor surface temperatures of both roofs. Lower outer surface temperatures indicate other environmental and social benefits of green roofs. This graph also enables evaluation of water stress conditions on temperatures and heat transfer.

Green roof water balance is presented at the bottom of the screen with presented results (figure 4). Right graph shows hourly values of green roof substrate water content (orange line), outflow from green roof (green line) and green roof irrigation (blue line). From this graph green roof expert can analyse influence of different irrigation scenarios and different drainage systems (with/without water storage) on retained water and water for irrigation. One can evaluate green roof also regarding to the stormwater management.

Yearly hydrological performance of Urbanscape green roof system (on the bottom left graph in figure 4) presents dark blue bar showing yearly rainfall from meteorological data what in analysis equals the outflow from the reference roof. Next to outflow from Urbanscape green roof is presented with green bar and above both bars the share of retained water in case of green roof installation. Estimated amount of water for irrigation of each m² of green roof is shown in light blue bar.

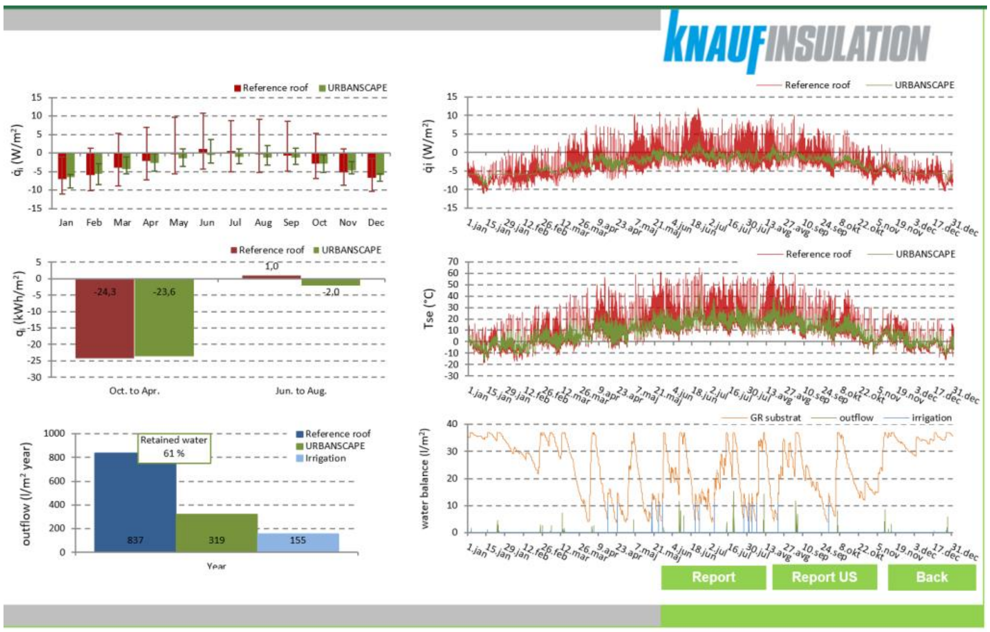

Figure 4. Screen with results of numerical calculations in the form of graphs presenting hourly, monthly, seasonal and yearly values of calculated parameters.

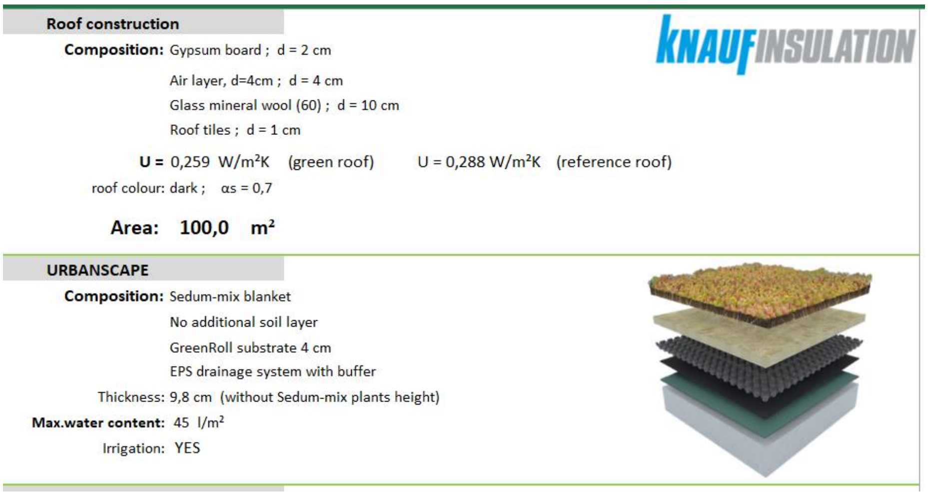
2.4. Report

PET tool report enables further analysis and presentation of additional results like numerical average monthly heat flux values and monthly water balance results. The report can be saved as a separate pdf file. As one of the purposes of PET tool is to support marketing, the results in the report can be presented in imperial units. There are also two tailored versions of PET tool in French and German language.

Report contains the information on reference and green roof composition and their U-value. In case when expanded polystyrene (EPS) drainage layer with water storage is used in green roof, also informative U-value of green roof, determined considering the calculation methodology for inverted roofs, is displayed as shown in figure 5. In case when green roof area is specified all graphs and numerical values are presented for specified roof area and not as specific values for each m^2 of green and/or reference roof.



Roof construction

Composition: Gypsum board ; d = 2 cm
Air layer, d=4cm ; d = 4 cm
Glass mineral wool (60) ; d = 10 cm
Roof tiles ; d = 1 cm

U = 0,259 W/m²K (green roof) U = 0,288 W/m²K (reference roof)

roof colour: dark ; αs = 0,7

Area: 100,0 m²

URBANSCAPE

Composition: Sedum-mix blanket
No additional soil layer
GreenRoll substrate 4 cm
EPS drainage system with buffer

Thickness: 9,8 cm (without Sedum-mix plants height)

Max.water content: 45 l/m²

Irrigation: YES

Figure 5. Part of the report presenting reference and Urbanscape green roof composition and basic characteristics; in case of used EPS drainage layer U-value of green roof differ from U-value of reference roof.

Figure 6. Part of the report where energy savings and CO_2 emission reduction (environmental indicator) due to green roof installation can be determined.

In the energy section of the report the building heating and cooling system, their seasonal efficiency and energy carrier can be specified. Based on selected or entered values the reduced final energy use for heating and cooling is presented as well as energy savings per energy carrier for each season. Additional yearly reduction of CO_2 emissions due to installed green roof is presented.

3. Upgrades and additional functionalities

With constant development of Urbanscape green roof solutions also the PET tool is being constantly upgraded. New drainage systems and new lightweight growing media solutions are added to the drop down list, while their thermo-physical properties are determined with laboratory experiments and validated with green roof in-situ thermal and hydrological response measurement results. New materials for loadbearing (reference) roof construction and meteorological data can also be added to enable analysis for specified reference roof design and location.

Further more advanced analyses are also possible with an open version of PET tool. As an example of such analysis the influence of historical weather data (observed climate changes) on green roof hydrological response is presented below. Namely, often raised question is how representative are the weather data, which are typical years for selected location. Results obtained using historical data for the period from 1985 to 2016 was statistically analysed and compared with results obtained with Meteonorm typical year for case study green roof in Mexico City. Figure 7 presents some of the obtained results. From the hydrological response graphs for selected years (typical year, 2016 extremely high and 1990 low precipitation amount) it can be concluded that typical year suitable covers the rainy periods in Mexico City.

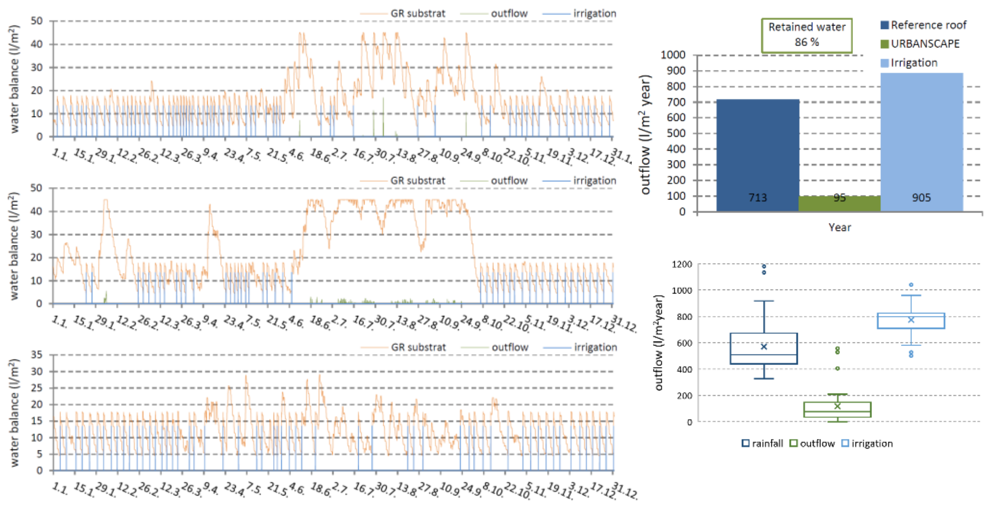

Figure 7. Results of green roof hydrological response analysis considering weather data from 1985 to 2016; water balance graph in case of typical year (top), 2010 and 1990 (bottom); yearly balance in case of typical year and box plot considering all 33 sets of meteorological data.

Box plot in figure 7, which covers all weather data sets further reveal wide range of yearly rainfall where more than ¾ of the years had a rainfall below that of a typical year. Historical data show that the amount of precipitation is increasing. Two outliers indicate two years with extreme rainfall, both appearing in last decade. One additional outlier in green roof outflow indicates that there was also one another year with high rainfall in a short period (month with extremely high rainfall). Low outflow for other years indicate high water retention capacity of case study green roof. Obtained results for required irrigation water gives indication on range that is expected regarding to the variations of meteorological conditions in the Mexico City.

4. Conclusions

Due to the lack of suitable thermal performance metrics for green roofs and limitations of BES tools that do not enable thermal response analysis of lightweight extensive green roofs with lightweight mineral wool growing media a ‘PET tool’ was developed and presented in this paper. In comparison to existing models the PET tool green roof model additionally considers different heat and mass transfer at water stress conditions and at freezing temperature conditions. As it was shown the PET tool enables: a) evaluation of Urbanscape green roofs’ thermal and hydrological response, b) to find the optimal green roof composition in terms of energy and water management performance, c) evaluation of the comparative advantages of green roof compared to existing reference flat roof and d) energy savings and CO_2 emission reduction analysis for heating and cooling season. Analyses can be made for: i) arbitrary composition of lightweight or massive reference flat roof – on which Urbanscape system is installed, ii) different composition of Urbanscape green roof system and irrigation scenarios and iii) different worldwide climate conditions.

Abstract. The rise of grid electricity price and a growing awareness of climate change is resulting in an increasing number of photovoltaic facilities installed in buildings. Electricity market regulation and climatic conditions, in particular solar radiation, are the main factors that determine the economic viability of a photovoltaic facility. This paper describes a method for evaluating the potential for photovoltaic (PV) production and self-consumption for the building stock of a particular city. A GIS 3D city map is used to calculate solar irradiation. Building-level electricity use is calculated based on building type, geometry and other characteristic inferred from building age, taking the cadastre GIS as main input. The methodology identifies the realistic potential for rooftop photovoltaic installations, as well as the optimum size to be installed from an economic perspective. To represent different regulations that can affect economic viability of PV installations, calculations should adapt for the specific installation conditions and regulatory situation, as for example self-consumption and net metering. The proposed methodology is applied to a case study in Irun (Spain), where results for potential of PV generation and self-consumption for the building stock are presented. The results offer public administration a realistic view of economically viable PV potential for the city and allow to analyse different mechanisms to promote their installations. It also serves for individual electricity consumers to evaluate and optimize new photovoltaic energy facilities. Finally, it serves policy makers to estimate the repercussion of electricity market regulations on the economic viability of PV systems.

1. Introduction

Energy consumption in cities currently represents between 60% and 80% [1] of the global energy use. As the population living in cities increases worldwide, this percentage is bound to increase in the future. The expected trends for progressive electrification of heating loads and transportation, will also mean that electricity use in cities is likely to rapidly increase in the coming years, and consequently the energy supply and demand profiles in the cities will evolve.

Cities will generally need to upgrade grid and infrastructures to be able to cope with these increasing electricity demands, and this infrastructure should allow to increasingly deliver renewable electricity, if climate change objectives are to be achieved. Generation of renewable electricity on-site within the city is becoming a priority in many cities, as a solution to reduce electricity transportation and distribution losses and potentially reduce investments in grid infrastructure. From all the renewable electricity generation technologies, PV has emerged in recent years as arguably the most competitive and adequate technology for urban areas, due to its good economic and environmental performance. Costs have reduced [2] and levelized costs of PV electricity has reached grid parity in many countries [3].

Environmental benefits of PV installations are also nearly indisputable [4], as long service lives and low maintenance result on a nearly-zero impacts for their operation, and life cycle impacts have greatly reduced due to improved manufacturing processes [5].

Distributed PV electricity generation and consumption is therefore a subject of major interest for most cities, and methodologies and tools for estimation of its potential are needed to facilitate this task. This paper proposes a method for evaluation of PV potential, departing from cadastre data for the cities to create a 3D GIS map, estimate the available solar radiation, and calculate the solar PV electricity production.

As economic viability of PVs largely depends on the specific electricity market, this paper presents an evaluation for the different regulatory approaches, including economic evaluation if self-consumption or net metering schemes are applied.

2. Methodology

2.1 Calculation of building stock energy demand

The calculation of the energy demand of the building stock for the city of Irun has been done through *Enerkad,* software developed by Tecnalia in the European research project PlanHeat [6], completed and improved to allow the electricity energy consumption analysis.

The *Enerkad* tool is a QGIS based software which calculates the energy demand and consumption at the building, district or city level based on cadastral data. *Enerkad* performs a static calculation, based on the degree-day method, and obtains the energy demand for each final use: heating, cooling, Domestic Hot Water (DHW), lighting and equipment, allowing energy consumption to be obtained by type of fuel for each building. Given that the study carried out focuses on the potential of PV generation, the analysis will focus on the electricity consumption. Due to the unavailability of a representative sample of hourly electricity profiles, the national electricity consumption curve for the residential sector has been used for residential buildings [7], and an alternative profile for non-residential buildings [8].

For residential buildings the heating system is introduced in the model (gas boiler, diesel boiler, electric boiler, heat pump, etc.), in case there is an electricity need associated to heating purposes it will be considered in the electricity consumption curve.

For non-residential buildings, it is particularly relevant the fraction of electricity used for heating and cooling, which will largely vary between buildings depending on their use, age and the outside air temperature during each day.

Electricity consumption profiles are defined based on 5 main uses: cooling, lighting, equipment, heating and domestic hot water. Each one of the uses has its own characteristics:

- **Electricity for Cooling**: Covers all the cooling demand supplied by air to air heat pumps, will be mainly found in tertiary buildings.
- **Electricity for Lighting and equipment:** Covers all the electricity demand for equipment and lighting uses. The consumption profile will vary depending on the building use and the day of the week (workday, Saturday, Sunday).
- **Electricity for Heating:** Covers all the heating demand supplied by air to air heat pumps (mainly tertiary buildings) and electric boilers (some residential buildings).
- **Electricity for DHW:** Covers the domestic hot water demand met by electric boilers.
-

A complete description of the energy demand analysis methodology is presented in European projects' public reports[9] and conference papers[10].

2.2 Calculation of solar irradiation

The objective of the solar potential analysis is to quantify the potential for the integration of solar technologies on the roof surfaces of the buildings in the Municipality of Irun, considering orography, urban framework and shading resulting from constructive and natural elements

The climatic file and the Digital Surface Model (DSM) must be modified in order to adapt it to the requirements of the used tool. It is necessary a filtered DSM file, containing only the points corresponding to the roofs of the buildings and the ground. The rest of the points in the file are deleted.

The annual solar radiation per square meter (resolution of the DSM model) is obtained for any point of the municipality (roofs and urban spaces) by means of the UMEP plugin [11] for QGIS[12]. The solar map is bounded to the municipality limits using the administrative boundary layer of the municipality.

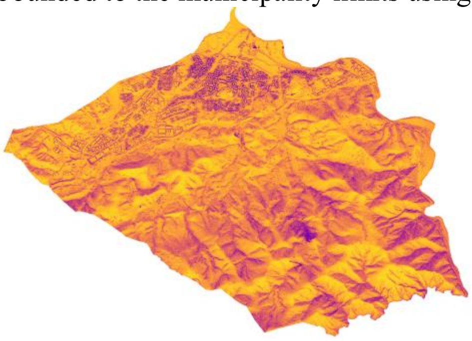

Figure 1. Annual solar radiation map of the municipality of Irun

In the solar radiation map (figure 1) all radiation levels are shown. The areas selected to study the potential PV production will have to meet several requirements and filters, as being part of the building roof and exceeding a specific irradiance threshold. To calculate surfaces where PV could be installed with a minimum economic performance (e.g. maximum return of investment period), minimum irradiance thresholds have been set and are specified in section 3.3.

2.3 Economic performance evaluation of PV installations

The economic performance of PV installations profitability and its relation with different regulations has been calculated considering that the consumer will be connected to the electricity grid, and assuming that the power term tariff will not vary when installing the PV modules. Therefore, all the economic savings quantified correspond to the energy term of the electricity bill.

For the actual electricity production, the calculation method presented in EN 15316-4-6:2007 [13] and the specification of technical conditions of installations connected to the network [14] have been used. PV production is hourly calculated for 12 days each one representing one month of the year. Irradiation values have been taken from PVGis database for the city of Irun [15].

Table 1 shows details of parameters that are used to calculate economic performance of PV installations.

Table 1. Summary of the parameters used for the economic

Parameter	Value
PV module efficiency [16]	16 (%)
Inverter efficiency [17]	95 (%)
Miscellaneous losses [18]	13%
Electricity base price for the first period [19]	0,1347(€/kWh)
Taxes on electricity (VAT) [20]	21 (%)
Annual electricity price variation rate[1]	2 (%)
Interest rate [7]	6.7 (%)
Power density of PV modules [16]	164.95 (W/m^2)

[1] Reports from the European Commission [26] show 4% annual price growth for the past years. A more conservative approach has been taken for this study. Note that higher electricity price variation rates would reduce the return period of the PV modules.

Total installation costs [21]	1.465 (€/W)
O&M costs [21]	0.02 (€/W.year)
PV modules service life [4]	25 (years)
Inverter service life	15 (years)

2.4 Economic evaluation of PV generation and consumption under different policies

There is a large degree of variations and uncertainty on the evolution of regulations for on-site PV production and self-consumption throughout the world. This paper explores three different scenarios which correspond to specific energy policies carried out or proposed in different parts of the world [22].

- **Solely self-consumption (SC)**, this first scenario reflects the current regulation system in Spain where the surplus of small PV producers is not remunerated at all. Consequently, the obligation to feed the grid with free electricity when the production exceeds the producer's energy demand stimulates smaller distributed generation facilities with no surplus electricity production and whose profitability is exclusively based on reducing the electricity bill. This approach brings on a smaller reduction of the greenhouse gas (GHG) emissions associated to electricity savings and is not able to decouple from a fossil-fuel dependent economy.
- **Net-metering,** this regulation has already been put into practice in places like California. In this study, surplus electricity is valued at retail price. Therefore, all the electricity produced with solar panels can be consumed at any other time, using the grid as a storage system. This legislation could consider different periods where the energy fed into the grid can be retrieved, daily net metering, monthly net metering, annual net metering. **Annual net metering (ANM)** is the modality chosen for the present evaluation.
- Finally, a third scenario has been represented, **"theoretical maximum potential"**. This scenario assumes that all the surface available for PV installation within the chosen irradiation threshold could be installed, and the economic return for injecting to the grid will be equal to the economic return for self-consumption. This scenario could represent regulations where electricity transactions with nearby buildings or electricity users could be allowed, or some regulations with feed-in tariffs.

3. Case study characterisation

Irun is the second largest city in the province of Gipuzkoa in the Basque Autonomous Community, Spain. It is located in the border between Spain and France and inhabits 59.508 citizens [23]. The municipality takes part in several sustainability programs and has already published its second sustainability action plan.

3.1 Origin of the data

To carry out the analysis of the potential of solar energy implementation on the roof surfaces in Irun, the following geospatial data are used:

- Digital Surface Model (DSM): 1m^2 resolution, from Geoeuskadi ftp download service [19].
- Climatic information of the study area: The climate model of the city of Donostia (15km west) available in Energy plus format (epw) with hourly resolution [24] has been used.
- Reference cartography: Cadastral basis of the buildings for the municipality of Irun, provided by the City Council of the locality and layer of administrative limits of the Basque Country obtained from Geoeuskadi [25]

3.2 Building stock electricity consumption characterisation

Based on the GIS built from cadastral data, the total rooftop area has been obtained and is shown in Table 2. As this study focuses on the study residential and tertiary buildings' energy consumption, the industrial rooftop area will be neglected. Nevertheless, it represents a significant potential area for PV installations.

Table 2. Rooftop area by building type in the city of Irun

	Rooftop area (residential and tertiary)	Industrial and other rooftop area	Total
Total	774.336,70 m^2	428.017,64 m^2	1.186.305,93 m^2

Table 3 presents the results from the electricity consumption simulation done with *Enerkad* tool [9], [10], as explained in section 2.1.

Table 3. Building stock energy characterisation for the city of Irun

	Unit	Value
Total electricity consumption	kWh/year	124.050.535,95
Cooling	kWh/year	1.145.746,85
Lighting and equipment	kWh/year	71.174.294,34
Heating + Domestic Hot Water	kWh/year	51.730.494,76

3.3 Calculation of surfaces with a minimum solar irradiation threshold

To determine PV installations that would have a minimum economic return under optimum circumstances (all electricity used or sold at cost price) two different irradiation thresholds have been selected. Table 4 shows the thresholds and their estimated return of investment, considering energy savings, installation and maintenance costs,

Table 4. Return of investment periods for different irradiance thresholds

Irradiance threshold (kWh/ m^2 year)	Return of investment (years)
1100 (kWh/ m^2 year)	<10 years
925 (kWh/ m^2 year)	<12 years

As it can be seen in figure 2, most roofs with North and even with west slopes are automatically dismissed in the upper threshold, due to the shades associated to their orientation.

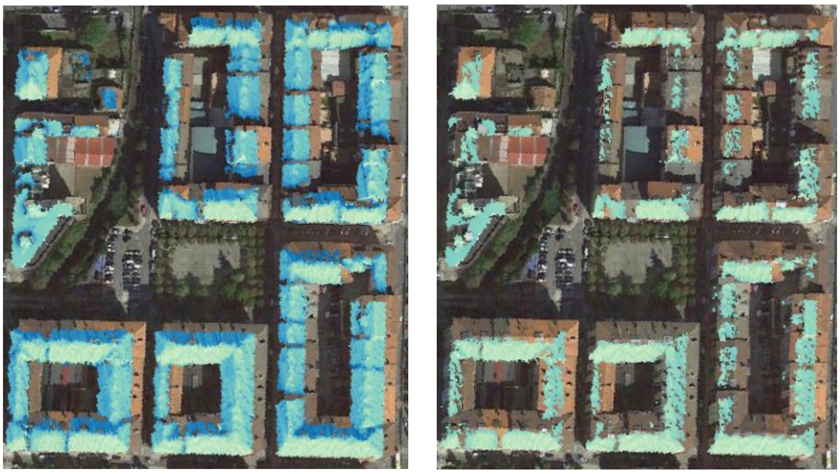

Figure 2. Solar radiation considering different thresholds (left: 925 kWh/m^2 and right: 1100 kWh/m^2)

Crossing this data with the cadastral base layer of the municipality, 2 parameters will be calculated: the roof surface with a radiation greater than the established threshold and the average radiation in the surface in which the radiation is greater than the stablished threshold. Based on the average solar irradiation and available roof surface, solar production potential will be calculated building by building.

3.4 PV optimization based on economic performance and possible legislations

Since solar resource is not available on demand and must be exploited during a limited period of time, the correct planification and dimensioning of the facility is of great importance to pursue its maximum profitability. National regulation for distributed generation plants has a direct impact on the design of the facility, as it determines the economic revenue of the installation, or the size of installation to achieve a minimum profitability.

For the calculation of the energy balance to determine the optimum profitability of a PV installation, a standard building, representative for Irun has been used as a reference. The building consists of 32 dwellings divided into 5 floors and it is oriented north to south with a flat rooftop. For the purpose of this study, the solar electricity production will be shared by all the dwellings in the building.

Taking such building as a reference, the energy consumption and PV production curves have been calculated for each month of the year. Then, the costs and savings for the PV facility have been calculated and a sensitivity analysis performed to find the optimum peak power of the PV installation.

When considering the legislation in the calculation of costs and savings, it is necessary to study the coupling of the electricity production and consumption, especially in the "self-consumption only" case, where all the surplus electricity would be lost without obtaining any profitability. In figure 3 the generation and consumption coupling can be seen for two PV installations cost-optimized for both regulations (optimized based on the results from the sensitivity analysis shown in figure 4).

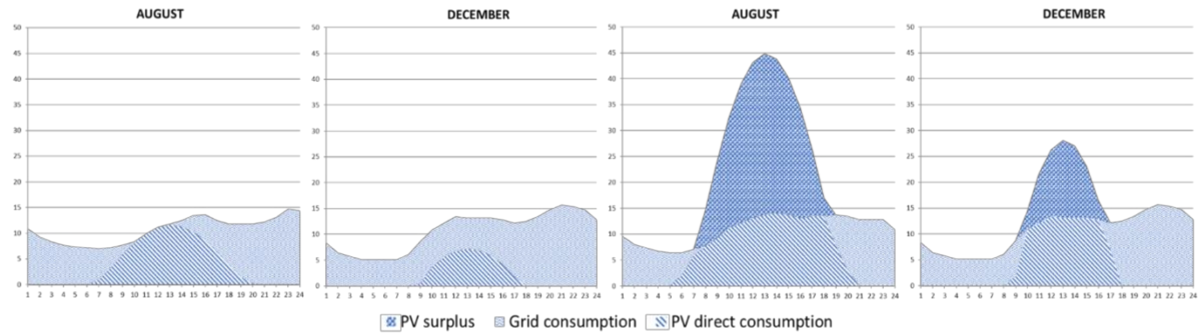

Figure 3 Comparison between the month with the highest electricity surplus (August) and the month with lowest electricity production (December). Installation designed for an optimum profitability under Self-Consumption and Annual net Metering regulation according to results from figure 4.

As the installed power of a PV facility increases or decreases, the energy balance pictured above varies, consequently varying the amount of surplus electricity and savings. In Figure 4 it can be seen how this modification on the size affects the benefits and how the profitability starts dropping once the energy surplus increases. The optimum point for a PV power plant stands as for 1kW per dwelling in case of self-consumption regulation and about 2,25 kW per dwelling in case of annual net metering regulation.

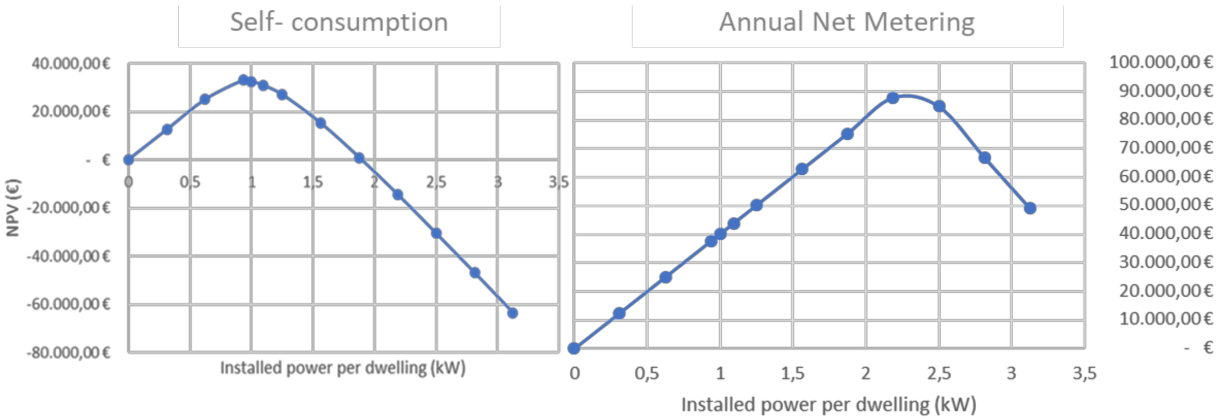

Figure 4. PV plant dimensioning NPV curve for Self-consumption and Annual Net metering regulations.

The optimum points from the NPV curves presented above follow the next behaviour:

- **Self-consumption:** the optimum case consumes 100% of the electricity consumption. No electricity in injected into the grid and **29,23%** of the annual electricity demand is met by PV panels.
- **Net metering:** In this case the grid is used as a storage and the optimum PV installation should be able to feed a **100% of the total annual electricity demand** of the dwelling, even if only **48,90%** of the electricity produced by the PV panels is **instantaneously consumed**.
- **Theoretical maximum potential: 100%** of the electricity produced by the panels could be indistinctly used and sold, with the same economic return.

For the analysis of the economic profitability of PV installations, maximum size of PV installation will be therefore determined as follows, for the different irradiation thresholds:

- Self-consumption: 29% building demand
- Net metering: 100% building demand
- Theoretical maximum potential: 100% available building roof surface

4. Results

Combining the calculations presented in the previous sections the optimized PV potential of the city of Irun has been calculated. These results show the available area which complies with good solar irradiance and sufficient economic profitability, considering also the current legislation.

Table 5. Installable surface for investment return period under 10 years

	Theoretical maximum	Self-consumption only	Annual net metering
Installable surface	269.822 m^2	149.039 m^2	248.452 m^2
Percentage of rooftop surface in the city	35%	19%	32%
Approximate installable power	44,50 MW	29,73MW	40,99 MW

Table 6. Installable surface for investment return period under 12 years

	Theoretical maximum	Self-consumption only	Annual net metering
Installable surface	550.287 m^2	207.098 m^2	439.466 m^2
Percentage of rooftop surface in the city	71%	27%	57%
Approximate installable power	90,79 MW	34,17MW	72,51 MW

In the following table the energy share of PV power in the city is calculated.

Table 7. Solar power energy share. Percentage of building stock electricity consumption fed by solar PV.

Threshold	Theoretical maximum	Self-consumption only	Annual net metering
1100 kWh/m^2.year	32%	17%	29%
925 kWh/m^2.year	59%	24%	48%

For PV installations to have a return of investment below 10 years (irradiation above 1100 kWh/m^2.year), with current regulation in Irun (self-consumption), only 19% of the roof surface could be installed, and 17% of the total electricity use of the building stock could be produced and consumed. If regulation would evolve to an annual net-metering scheme, 32% of the available roof surface and up to 29% of the electricity use in buildings could be supplied by PV. The theoretical maximum potential of PV installations in the city for this 10-year return of investment could reach 35% of the roof area and provide 32% of the total electricity use.

These numbers largely increase if the return of investment is extended to 12 years (irradiation above 925 kWh/m^2.year, as many other roof surfaces would become available. As it can be seen in Table 7, for this case up to 24% of the total building electricity use could be supplied under self-consumption scheme, 48% for annual net metering, and 59% for the theoretical maximum production.

5. Discussion and conclusions

This study has shown a methodology to calculate the potential for PV electricity generation and consumption in cities. The methodology allows the calculation of potential for installation of economically viable PV generation systems in buildings across a city, under different regulatory schemes such as self-consumption or net metering. This type of study is expected to be very useful for city energy planning, as it allows to estimate PV generation potential in roofs, which could represent a significant share of the total building energy use in the cities.

For the presented sample case of Irun city, located of North Spain with an average annual radiation of 1,300 kWh [15], which is one of the lowest for a Spanish city, up to 24% of the total building electricity use in the city could be supplied by PV panels under current self-consumption regulation. This percentage of building electricity supply would rise up to 48% if annual net metering were in place, and to 59% for the theoretical maximum production of PV panels in roofs. These calculations are for profitable installations with a return of investment of 12 years, which equals a IRR of 7%, taking into account that these installations have a service life of 25 years. With this attractive economic performance, business models and financial schemes should be explored to promote the progressive and rapid deployment of installations and make use of this solar resource currently unexploited.

Even though cities embark in sustainable energy strategies and climate change mitigation action plans, it is important to note that in coming years building electricity use is expected to increase, due to the progressive electrification of transport and heating loads. It can be expected that a larger share of the available solar PV surfaces in the roofs in the city could be used for building self-consumption. The implications of this PV generation on the electricity grid would in principle be beneficial, as would mean practically no changes to the current electricity grid and can reduce new infrastructure requirements for the grid.

Abstract. Structural-spatial form and urban land use are among the main transformative fields of action of cities. Quality of life and environment, identity and individuality as well as participation in local society are significantly influenced by urban surfaces. Most urban surfaces have so far been designed for the long-term fulfilment of individual purposes, but offer greater scope for design in terms of functionality and adaptability, quality and efficiency. It therefore makes sense to develop, evaluate, technologically expand and test the potential of urban surfaces in terms of building physics as a whole. In view of growing stress on urban structures due to climate-induced influences, such as flooding, extreme weather conditions or heat islands, new possibilities, processes, systems or materials are needed to improve resilience. The article presents exemplary developments that can be supplemented and combined. Hydroactive surfaces can buffer rainwater and release it with a time delay to reduce heat and flooding equally. Green façades improve city climate and air quality. Sound-absorbing façades reduce inner-city noise. Innovative transparent foil enclosures provide equally visibility and an optimum weather protection of objects to be protected throughout the year.

1. Introduction

Essential transformative fields of action for cities are their structural-spatial design and urban land use. They are of particular relevance for the sustainable development of cities and urban districts, as they have a decisive influence on the quality of life and environment, on the identity and the participation in local society. At the same time, there are inseparable interactions between the design and use of urban areas and other fields of action, including resource and energy efficiency, climate resilience and mobility. The focus of most settlement, traffic and, above all, building surfaces has so far been solely on the long-term fulfilment of individual purposes. For the exploitation of a multitude of further design and action options, it is necessary to unite the aspects and actors that originate from all parts of urban society in a structured and moderated interdisciplinary and interest-spanning process. The fact that local authorities are highly affected by permanent climate changes and extreme weather events alone makes it clear that these challenges can only be met with coordinated contributions. These contributions include the holistic development and technological expansion of the building physics potential of urban surfaces. Figure 1 illustrates the effects and interactions in the context of the current situation and design goals.

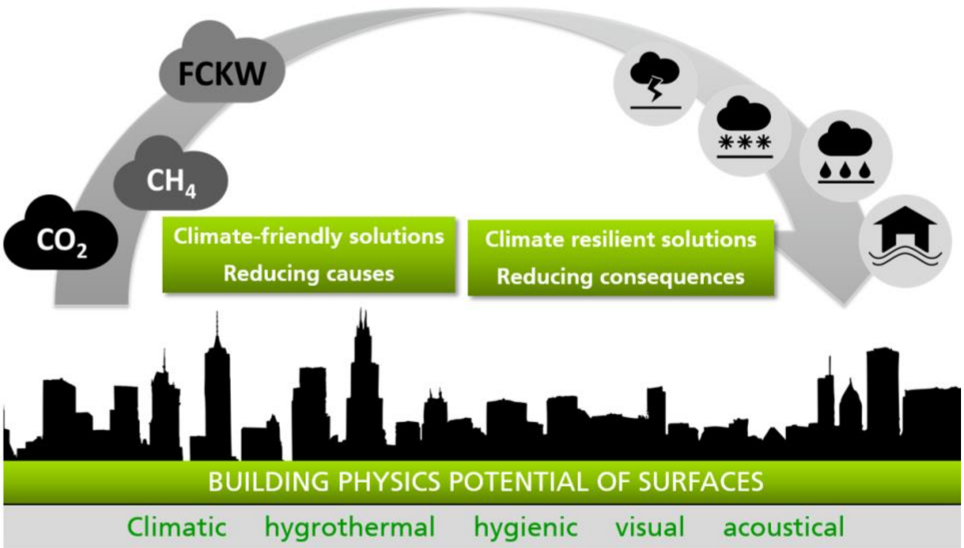

Figure 1. Building physics potential for the design of urban surfaces with climate relevance and for sustainable quality of life and environment in cities.

The current state of knowledge clearly and frequently demonstrates the need for action, but also shows concrete options for action that can be used effectively and economically, e.g. to react to specific consequences of climate change and to the increased dynamics of weather phenomena (water, snow, temperature). In practice, however, there are often barriers that are cross-use, cross-interest and cross-disciplinary. In order to be able to extend the system concept to large urban surfaces, e.g. to include aspects of urban safety (disaster and fire protection), systematic physical land management is necessary, as illustrated in Figure 2. Sustainability is the basic principle and standard of the design.

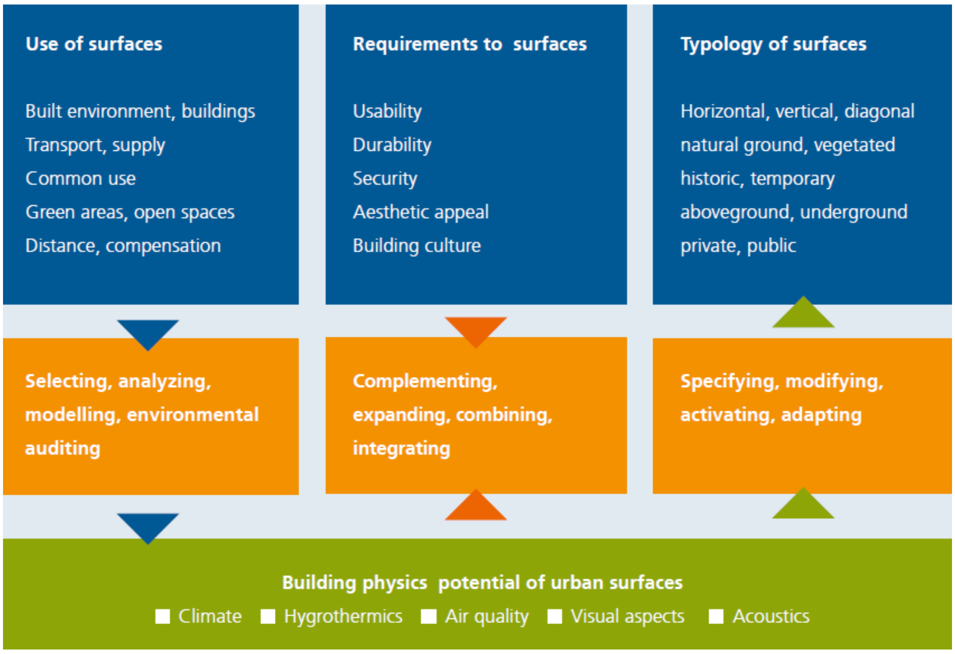

Figure 2. Systematic consideration and treatment of urban surfaces in the sense of physical land management.

The experimental determination of the properties of urban surfaces, the (quarter and city) model description with planning tools and, of course, the evaluation were and are the subject of research and development in order to develop the building physics potential. The Fraunhofer IBP is working on these topics since a couple of years in several projects. Currently there is a comprehensive project running at the IBP to develop both solutions for an enhanced climatic resilience and an improved sustainability of urban surfaces. Exemplary results of the IBP developments and their interrelated consideration are reported here. The examples given are chosen to show the wide scope of options.

2. Hydroactive traffic and open spaces

In metropolitan areas, the proportion of sealing increased to over 90 percent of the total area, which increases and accelerates precipitation runoff on the one hand and reduces the amount of water available for evaporation, latent cooling and groundwater recharge on the other hand. Since the lack of buffer areas leads to overloading of the sewer system, municipalities can limit the maximum discharge donations from properties and, for example, prescribe retention options on the property [1]. However, particularly in highly dense settlement structures there is often no space for open indentations, e.g. trough-trench systems with high infiltration and evaporation rates. Therefore, urban surfaces are in demand which serve to prevent heat and flooding equally [2]. One approach is the so-called "sponge city" principle [2] [3], in which urban surfaces are increasingly used for the intermediate storage of precipitation. The aim is to approximate the water balance of built-up areas to that of undeveloped areas, i.e. essentially to reduce the peak discharge values after heavy rainfall events and to increase the proportion of local evaporation and infiltration for groundwater recharge in the urban water cycle.

The horizontal roof and traffic areas, which have so far been largely fallow, as well as selected façades are of particular importance for potentially hydroactive areas [4] [5].

For decades, paving surfaces have also been able to be designed as infiltrable coverings. Usually, paving structures with a porous structure or seepage openings with a regular profile are considered. Alternatively, the joint between the paving stones is filled with coarse-grained material. In order to enable complete drainage in the vertical direction, all layers in the substructure must be permanently permeable in addition to the surface layer. Due to the resulting lower mechanical load-bearing capacity, it is only used on traffic areas with low loads, e.g. service roads, pedestrian zones and permanently used parking areas with low truck and bus traffic [6] [7]. So far, initiatives to use traffic areas as summer urban heat sinks have been rare [8]. While commercial products are not yet available, field measurements show that a temperature reduction of the order of ten Kelvin is possible, depending on the boundary conditions. This corresponds approximately to the temperature difference between a dry concrete surface and a grass area at noon. Figure 3 shows a field test with different water-storing concrete pavements.

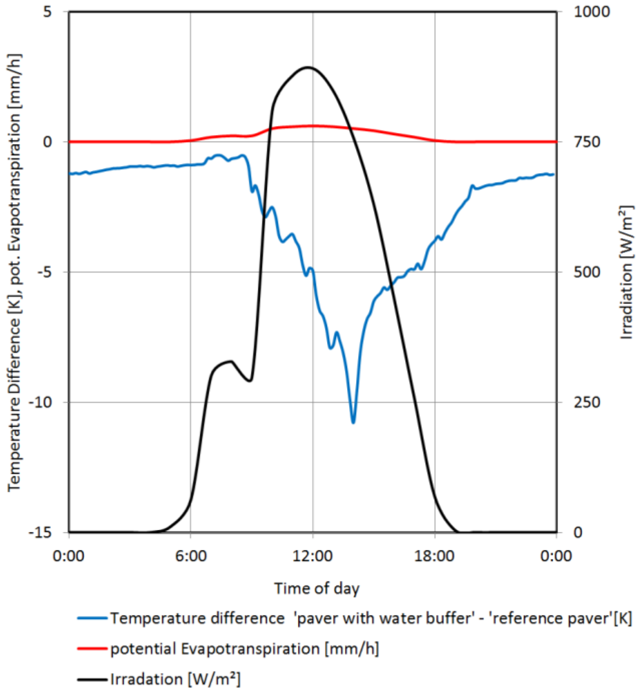

Figure 3. Field test with different water-storing concrete pavements (left: test field, right: measured temperature reduction of a storage stone compared to a standard concrete paving under summer conditions [8]).

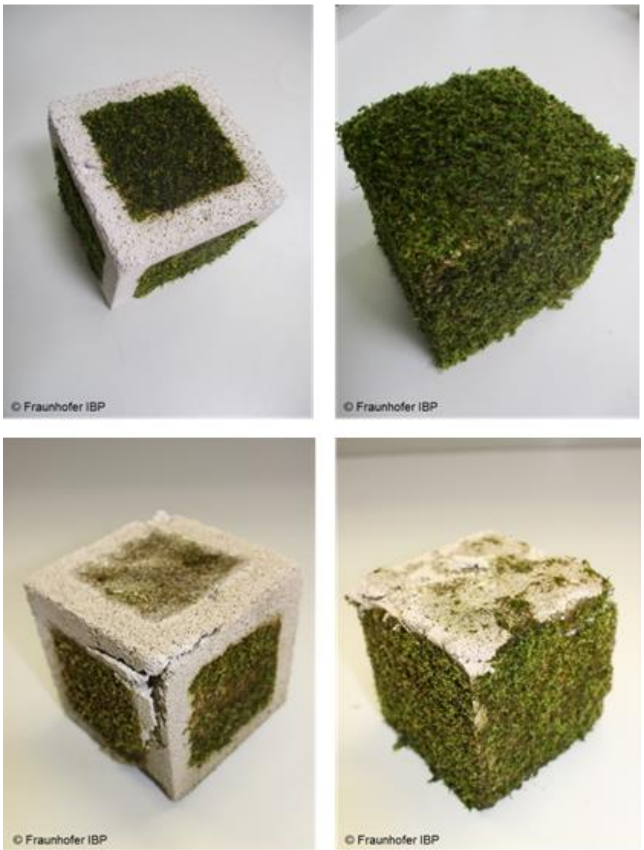
3. Greening of façades

With the "Weißbuch Stadtgrün" [9] the political goal is pursued to promote green in the city and thus also green buildings and façades. An obvious argument is the effective medium to long-term CO_2 binding and thus the contribution to climate protection.

In the manner of a "natural air-conditioning system", evapotranspiration through vegetation can have a cooling effect in the sense of reduced summer heating, sort of reducing heat stress in urban areas [10]. Comparative measurements of conventional and greened façades show that the latter have a cooling effect in summer and an insulating effect in winter, as well as balancing the humidity directly in front of the wall. For example, the evapotranspiration of an 850 square metre "living wall" is approx. 1,800 liters with the corresponding cooling capacity [11]. Façade-bound greenery thus reduces the effort required for air-conditioning of the buildings because it keeps them cooler.

In terms of air quality, model observations [12] show a reduction of nine percent NO2 and 13 percent PM10 (Particulate Matter $\leq$ 10 µm) in incoming air pollution when large-area green walls are placed in street canyons under average conditions. Within a street canyon, reduction values of up to 15 percent NO2 or 23 percent PM10 are possible, which can increase by up to 40 percent for NO2 and 60 percent for PM10 at low wind speeds. Data on concrete filtering performance of climbing plants are only available in isolated cases. In the case of ivy (Hedera Helix), for example, this is four to 8.4 percent of the total dust in the vegetation period or 1.8 to 3.6 percent per year. Of these, 71 percent are smaller than 15 micrometers and only ten percent smaller than 5 micrometers [13] [14]. With the Boston ivy (Parthenocissus tricuspidata) a binding of up to 80 percent of metals from the coarse dust was determined [15]. All these results prove that green façades can cause a local reduction of dust pollution. The examples also show, however, that systematic investigations with practical relevance are urgently required in view of still incomplete information on the potential effects.

While green roofs are already comparatively well developed and numerous systems for the most varied tasks and requirements are already established on the market, there is still a need for optimization for green façades. Many systems are fragile and also costly to install and maintain. Extensive greening must be carried out with site-specific plants, e.g. for certain mosses, and must include targeted control and promotion of surface colonization. This is the only way to achieve a visually appealing growth that is regularly and homogeneously distributed. At the same time it promotes the native flora and expands the niche offer for numerous animal species.



In addition to innovative design and implementation, a key to success also lies in selecting the right plants for the respective application and planning situation. For example, mosses with up to 30 times larger surface areas have a higher fine dust binding potential than many grasses.

Since further investigations are necessary, a new method is currently being developed to settle moss on building surfaces. First results are both promising and essential for future development steps. The condition of the test specimens in Figure 4 after winter weathering in the open shows that the moss was able to establish itself on the surfaces protected from driving rain. The used building material, on the other hand, has obviously been strongly affected by frost-thaw changes, which is why further investigations with different building materials are necessary in order to find an optimal correlation here.

Figure 4. Three-dimensional test specimens of 10 by 10 by 10 cm AAC block and planted with moss (two different shapes). Test specimens before (top) and after winter weathering (bottom).

4. Sound absorbing façades

The unchanged high attractiveness of cities also leads to increasing acoustic demands on urban systems and structures. With regard to the perception of sound in an urban context, the reflective behavior of façades is the main focus. In distinct street canyons, the hard building surfaces amplify all sound events, but of course the shielding effect of buildings is also perceived. Before functionally extending façades to influence acoustics, especially in noisy urban spaces, it is important to emphasize that this should never be at the expense of their function as sound-insulating building envelopes. In practice, there are still deficits and development needs. The acoustic functionalization of façades certainly cannot solve urban problems on its own. In order to take up the proof and the economic efficiency of acoustic façade functions for urban areas, a systematic consideration is the first step. The practically relevant acoustic categories can be summarized as follows:

- Sound generation / sound radiation: Today, façades emit considerable and above all completely expendable noises. Ventilation openings, movable sun protection systems or wind noises on acoustically sensitive façade elements are just a few examples of avoidable noise exposure.

- Sound screening / sound diffraction: These terms are essential for the already mentioned shielding effect of buildings in urban environments. There is the possibility of a targeted influence on the propagation of urban sound through structured façades, balconies, overhangs, roof connections and the like.
- Sound reflection / sound diffusion: Together with shielding and diffraction, they contribute to the amplification and distribution of sound. On the other hand, however, there is a great variety of elements, structures and urban design scope to consciously direct sound into less sensitive areas, even if it cannot be stopped or absorbed.
- Sound absorption: The actual reduction of sound energy once generated only is possible by absorption or dissipation of sound waves. Materials, layers and structures as well as openings and gaps offer numerous possibilities without having to invent a new façade. Almost all façade types can be functionally upgraded or converted to achieve high sound absorption levels.

A concrete example of a possible modification is the "rear-ventilated curtain façade". The system has been established for a long time and proven in practice, is characterized by a high degree of design diversity, is accepted by building owners and architects and is in itself unproblematic in terms of building physics functionality (moisture, heat and fire protection). However, the goal-oriented implementation in practice requires knowledge of the optimum relationship between flow resistance and other properties of the (outer) layers. Figure 5 schematically shows a façade structure with a sound-permeable (e.g. perforated) outer layer and its sound absorption if three different underlay sheets are used in front of the insulating material. The main difference is the flow resistance of the underlay variants, which certainly still meet the requirements of DIN EN ISO 13859 [16]. The sound absorption coefficients show the effect of clever modification of individual parameters. If typical inner-city noise spectra are used, highly absorbent noise protection façades can be achieved with variant 3 in Figure 5.

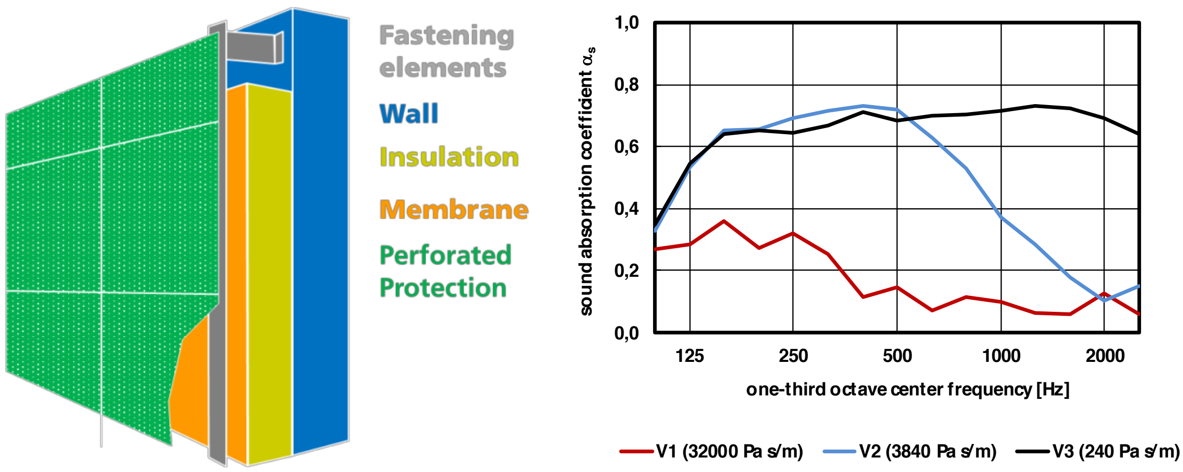


Figure 5. Acoustically modified, rear-ventilated curtain façade (left: schematic structure, right: measured sound absorption coefficient at vertical sound incidence and use of 3 underlays with very different flow resistances).

Based on this sound absorption effect, its impact on the urban environment can be calculated and evaluated. For the exemplary quantification of the potential, Figure 6 shows the building situation with buildings aligned parallel to the source (motorway, dark blue area on the bottom right), flanked by vertically positioned buildings and a side street. The standardized frequency-dependent calculations were carried out according to DIN ISO 9613-2 [17], the street (traffic figures) was characterized as a line source in octave bands with noise spectra from pass-by measurements. Geometry and topology are based on real, in detail simplified data and the façades were mathematically clad with sound-absorbing material. The results allow the comparison of weak absorption effect, e.g. a normal exterior plaster (Figure 6, left), and highly absorbing ($\alpha_w \geq 0,75$) material (Figure 6, right), as e.g. with the layer variant 3 according to Figure 5. The level differences are clearly recognizable and concern not only the individual points (figured level values), but considerable zones of the area.

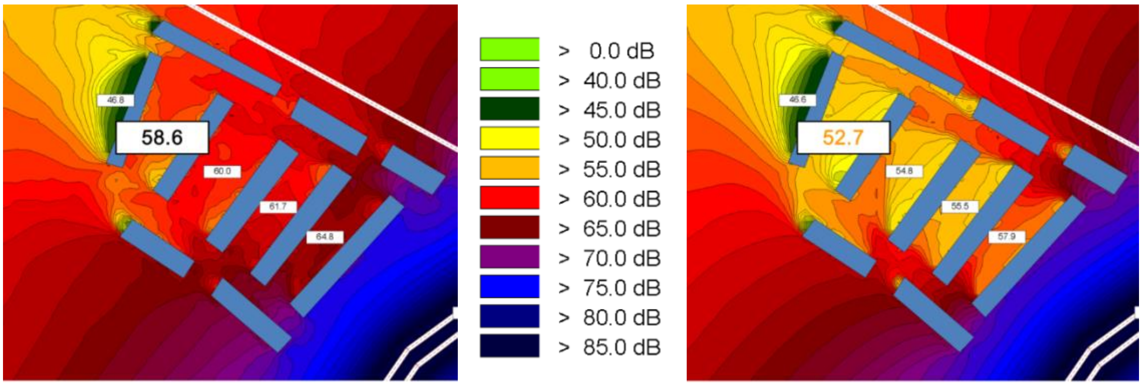

Figure 6. Sound immission calculation with low (left) and high (right) sound absorbing façades of the buildings. The single values in the maps are sound pressure levels (sum levels in dB(A)) at selected points.

Of course there are still some questions, e.g. after the comparison with noise barriers or after the additional costs. The answers will be differentiated and will lead to concrete advantages and disadvantages depending on the situation. With a view to the future, it is therefore important to recognize, evaluate and treat the acoustic environmental influences in almost all, including urban, living spaces.

5. Transparent enclosure systems

Every autumn thousands of fountains or stone sculptures are hidden, mostly under wooden enclosures, to protect them from the winter climatic conditions. However, this measure makes a large number of culturally valuable objects invisible for almost half the year. These temperature-damping opaque enclosures offer a comparatively constant indoor climate, but with a consistently high level of air and material humidity and without completely preventing frost-thaw changes, which contributes to the damage to the cultural assets. The solution of using transparent enclosures made of a steel and glass construction to ensure the visibility of the objects to be protected enhances the quality of the urban space. Nevertheless, on the one hand these constructions are associated with increased costs due to the choice of materials and the logistical effort involved, on the other hand the combination of glass housing and solar input creates a "greenhouse effect" which results in high fluctuations in temperature and humidity and puts considerable strain on the object to be protected [18], not to mention possible glass breakage.

Scientists from the Fraunhofer Institute for Building Physics IBP and the Technical University of Munich have therefore developed and investigated an enclosure system made of transparent membranes which, by damping the amplitudes of temperature and relative humidity, enables a climate favourable to the object to be protected [19]. Further goals of this system are, among other things, the avoidance of the essential damage mechanisms for stone objects, especially frost-thaw changes at high material moisture levels, thermohygric deconsolidation and organic growth as well as favourable assembly, transport and storage properties and sufficient durability. In addition, the design should pay attention to optimum regulation of the ventilation system. When the ventilation is too high, the external climate also becomes apparent in the interior and leads to moisture ingress and condensation on the stone, whereas too little air exchange can trigger a permanently high air humidity and consequently frost splitting and organism growth.

The transparent enclosure system under investigation consists of a framework with braced stainless steel profiles, into which a prefabricated polyvinyl chloride foil cover is suspended. This system is characterized by various advantages. On the one hand, it can be easily dismantled into its individual parts and reduced to a small storage volume, and on the other hand, the support frame has good durability. In addition, the film is easy to replace in the event of attrition and, among other things, offers high tear and UV resistance combined with "non-crease" transparency even after repeated construction and dismantling. In addition, the high moisture content of the material at the time of enclosure can be dissipated to the outside via heating due to solar radiation in conjunction with controlled air exchange, while moisture entry by re-condensation is prevented.

Figure 7. Newly developed foil enclosure in field test.

The results of the measurements carried out prove that with these systems a faster material drying is achieved than with previously used opaque wood enclosures. In addition, organic growth is largely avoided and the material to be protected is kept dry. The innovative transparent foil enclosures with controlled ventilation are an interesting alternative to the opaque wooden enclosures currently in use especially because they provide equally visibility and optimum weather protection of the fountains or stone sculptures that characterize the cityscape throughout the year.

6. Outlook

Although the challenges of urban systems are not equally distinct in all cities, the impact of elementary urban structures can be found everywhere. This also includes the chronic and acute consequences of climate change at the local level, such as water shortages or flooding, unusually hot and cold weather conditions, heat islands and haze bells. Urban surfaces will play a major role in the reaction and transformation of cities, and their building physics efficiency is significantly higher than it has been exploited yet. In the future, innovations and investments will be just as necessary as regulations, incentives and information. The aspects and examples presented show that the building physics of urban surfaces can make valuable contributions to this.

KristinaHenzler@gmx.de

Abstract. The physical design of urban surfaces determines the management processes that are required to ensure that their intended functions are fulfilled within a set period of time and influences their linked material flows. Those flows are causing numerous environmental, economic, and social impacts. In the field of urban surfaces, there is a broad variety of innovations available that has the potential to contribute to a more sustainable environment and quality of life in cities. However, before implementing any kind of innovation, it is important to quantitatively and qualitatively assess its sustainability impacts in a holistic manner. While current assessment methods provide a suitable framework for the sustainability assessment of products and services, without modification, they cannot be applied to urban surfaces and related management processes.

The herein introduced methodological approach is designed to overcome this problem by not only being tailored to the sustainability assessment of innovations in the field of urban surfaces but also by combining life cycle thinking with a holistic approach. By integrating SDGs, it will provide insight into the possible impacts of an innovation in all three dimensions of sustainability at the municipal level. This knowledge can be used to support the municipality in its decision on the design of urban surfaces and management processes by showing whether or not it is advisable to implement an innovation from a sustainability point of view. The focus of this publication is on the development of a general life cycle of urban surfaces and its interaction with product innovations.

1. Introduction

Leistner et al. [1] highlight the importance of the design of urban surfaces for the environmental quality in cities and their resilience to climate change. They show that urban surfaces have a considerable building physical and sustainability related potential and that innovations are essential for realising it [1]. It is pointed out by Leistner et al. that by conducting a Life Cycle Assessment (LCA) on the various management processes of urban surfaces, it is possible to determine their sustainability and to identify potential starting points for the optimisation of the partly large quantity of material flows in cities [1]. By systematically assessing the sustainability of urban surfaces, another perspective is taken as usually complete sustainability assessments of cities overlook their potential. All three dimensions of sustainability are essential for sustainable development [2], and not only environmental but also economic and social impacts are expected from the implementation of the aforementioned product innovations. Current sustainability assessment methods cannot unmodified be used for the analysis of innovations in the field of urban surfaces, as, e.g., they do not allow the practitioner to take into account the comprehensive use phase of the urban surface and the interaction of the life cycle of the innovation and the surface. Therefore here, a holistic approach for the sustainability assessment of innovations in the field of urban surfaces is proposed, using life-cycle thinking and indicators in line with and based on the Sustainable Development Goals (SDGs). Thus, such a method can be used to support municipal decision-makers with regard to potential sustainability impacts before implementing innovations for urban surfaces. The SDGs are accepted as a basis for the development of sustainability assessment methods and are used on a municipal level, e.g., by Maier et al. [3] and Wang et al. [4].

2. State-of-the-art of sustainability assessment methods

Several existing methods have been analysed regarding their suitability for the assessment of innovations in the field of urban surfaces.

The LCA uses the concept of life-cycle thinking [5], however, attempts to apply this to urban surfaces have shown that it is not sufficient to take into account the multitude of processes that occur during the use phase of urban surfaces. This leads to an entanglement of different processes and therefore, life cycles. This requires a new approach, different from the establishment of one general life cycle. Besides, various requirements are placed on urban surfaces concurrently [1], yet they cannot be considered with the concept of the functional unit provided in the ISO-LCA. Moreover, different stakeholder perspectives can be taken when assessing innovations in the field of urban surfaces, as, e.g., in the case of costs: on the one hand, there is the municipal budget and on the other hand, the income of the workers. Besides, as the LCA only allows for an assessment of possible environmental impacts [6], it is inevitable to go beyond this concept for a holistic assessment. Therefore, indicators must also be selected and adapted to the system of the urban surface to be investigated.

The concept of Life Cycle Sustainability Assessment (LCSA) presented by Klöpffer [7] allows the three dimensions of sustainability to be taken into account by combining the methods of LCA, LCC, and SCLA [6]. However, for the social dimension, there is no scientific agreement on indicators [8]. Hence, here, the SDGs are used to select indicators for a holistic assessment. Moreover, the methods of LCA, LCC, and SCLA are developed to different degrees, which can cause difficulties in the application of this approach [8]. Wang et al. [4] have shown that rather than the LCSA as presented by Klöpffer [7], the Life Cycle Sustainability Analysis (LCSA) Framework (hereinafter: LCSA Framework), which is one of the results of the CALCAS project [9], provides a good foundation for the development of a holistic sustainability assessment method.

The LCSA Framework builds on the ISO 14040-standardised LCA, but goes beyond it in three dimensions of broadening and deepening, thus enabling the practitioner to conduct an assessment of impacts in the environmental, economic, and social dimension of sustainability [9]. However, it must be noted that it is not a guide [10]. Rather, it is described as "[. . .] *a transdisciplinary integration framework of models rather than a model in itself*" [9]. Consequently, it first needs to be made operational [9]. So far, the LCSA Framework has not been used for the evaluation of urban surfaces. Hence, the herein presented method adopts the fundamental structure of the LCSA Framework but relies on other methods and concepts in order to make it applicable to the case of urban surfaces.

The ex-ante sustainability assessment methodology for municipal solid waste management innovations developed by Wang et al. [4] provides a sound basis for the development of the new method. Its appealing features are the operationalisation of the LCSA Framework, the integration of the SDGs in the assessment, based on the approach by Maier et al. [3], and the sustainability assessment of innovations in a specific field before their implementation [4]. Thus the method of Wang et al. [4] plays a decisive role in the operationalisation of the LCSA Framework for innovations in the field of urban surfaces: its way of implementing the Framework and making it applicable to innovations serves as a basis for the design of the individual phases of the new approach. It needs to be modified to fit innovations in the field of urban surfaces and related management processes.

In conclusion, there is currently no method available that can directly be used for the sustainability assessment of innovations in the field of urban surfaces prior to their implementation. As has been shown above, not only the scope of application of existing methods but also the special features of urban surfaces, such as their extensive use phase, make it necessary to develop a new holistic methodological approach, which is tailored to the analysis of product innovations in this area. The method of Wang et al. [4] is used as a starting point for the development of the new approach. By this, the LCSA Framework is made operable for the assessment of urban surfaces. One of the main challenges in developing the new approach is the lack of application of life cycle thinking to the concept of urban surfaces. Thus, this newly developed framework serves as the underlying basis for the sustainability assessment of urban surfaces based on life cycle thinking and the SDGs.

3. Methodological Approach

The methodological approach for the sustainability assessment of urban surfaces is based on [3] and [4], depicted in figure 1. The adaptation of this framework allows the indirect assessment of SDGs across different impact category groups, including the selection and definition of appropriate SDG-based indicators. As the new methodological approach will allow a sustainability assessment of innovations in the field of urban surfaces, firstly the terms *urban surface* and *innovation* have to be defined in the context of sustainability assessments and life cycle thinking, and secondly, a general life cycle of urban surfaces must be developed. Thus the focus of this publication is on the introduction of a life cycle of urban surfaces and accordingly on the first stage of the methodology, the goal and scope definition. The generalised life cycle will make it possible to identify possible starting points for an innovation. Building on this first stage, a holistic sustainability assessment of an innovation can be conducted by proceeding with the phases of modelling and interpretation.

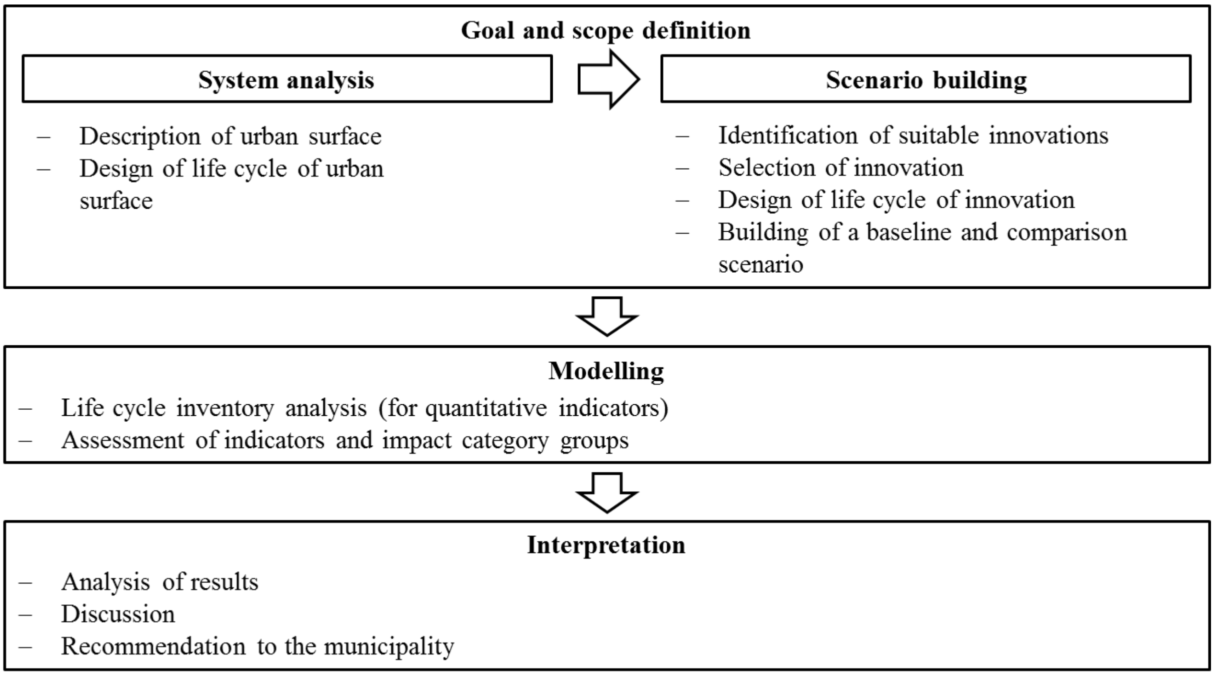

Figure 1. Sustainability assessment of innovations in the field of urban surfaces, based on [3] and [4].

3.1. System analysis

3.1.1. Urban surfaces, management processes and material flows. The term urban surfaces was coined by Leistner et al. [1]. This paper attempts to refine this concept by specifying the scope of its applicability and proposing a general categorisation of urban surfaces suitable for the herein proposed methodological approach for sustainability assessments of urban surfaces based on life cycle thinking.

Here urban surfaces are defined as surfaces that interact in public outdoor spaces within an urban context. Therefore areas such as public parks, streets, and facades are regarded as urban surfaces while indoor spaces and underground infrastructure, e.g., the municipal sewage system, are not included within this concept. A surface is considered as an urban surface as long as it keeps interacting in the same way as at the point under consideration, regardless of its geometrical dimension. As Leistner et al. [1] have shown, areas in cities are used for numerous purposes, amongst others, for buildings, traffic, and green spaces. Therefore urban surfaces are made of a variety of materials, such as concrete, grass, and cobblestone. Different requirements are placed on them, e.g., accessibility, usability, safety, and aesthetics [1]. Hence the combination of surface material, function, and requirements imposed on the surface by users or legal regulations is used here to differentiate between different types of urban surfaces. Figure 2 shows the combination of material, function, and requirements for the case of streets.

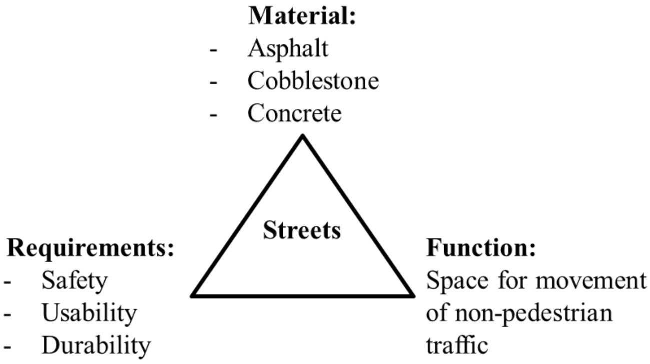

Figure 2. Triangular categorisation of streets.

From this, a categorization of urban surfaces is derived. For example, the categories of green spaces, building spaces (roofs/ facades), traffic areas, squares, and barriers are distinguished. Those can be further disaggregated into subcategories, e.g., in the case of green spaces into playgrounds, parks, and nature reserves or in the case of traffic areas into roads, cycleways, and footways. Thorough management is required in order to ensure that urban surfaces fulfil their functions within a set period. While the necessary management processes depend on the type of surface, it is common that most surfaces require several processes with varying frequencies during a year. The following is a brief, non-exhaustive overview of management processes in the field of urban surfaces. The maintenance of green spaces involves processes such as the removal of weed and foliage, watering, fertilising, and lawn mowing. Traffic areas require processes such as cleaning, winter service (gritting and snow clearance), and road marking works as well as repair, replacement, and modernisation processes. For other surfaces, e.g., barriers, repair and cleaning processes need to be performed. Derived from Leistner et al. [1], material flows that are applied to a surface during a management process, such as gritting salt, water, and fertiliser, are called input flows. Output flows are considered in this paper as a result of management processes and include, e.g., green waste and dust.

3.1.2. Life cycle of urban surfaces. As urban surfaces are considered as infrastructure, the building life cycle in DIN EN 15978 [11] is transferred to urban surfaces to design their life cycle. For this purpose, a building is considered as consisting of several urban surfaces. Consequently, the surface material is understood as equivalent to the construction product/ component in the standard DIN EN 15978 [11] and the surface as equivalent to a part of a building. The adapted life cycle does justice to the complex use phase of urban surfaces, in which, as is the case with buildings, several management processes for their maintenance, repair, and so on are carried out. It should be noted that for the assessment of urban surfaces a functional equivalent shall be formulated in accordance with DIN EN 15978 [11] in order to be able to take into account the fact that as aforementioned several requirements are placed on urban surfaces simultaneously, such as usability, safety, and aesthetics, and to ensure the comparability of the assessment results [1, 11]. It could be defined, e.g., as ‘Providing 1m^2 of footway for 1 year that meets its functional and technical requirements', with the reference unit [m^{2}a]. It reflects the previously introduced categorisation of urban surfaces based on their material, function, and requirements. Figure 3 shows, based on DIN EN 15978 [11], a proposal for the modules of the life cycle of a new urban surface, for which information should be provided to assess its sustainability. The four phases of its life cycle are briefly explained below.

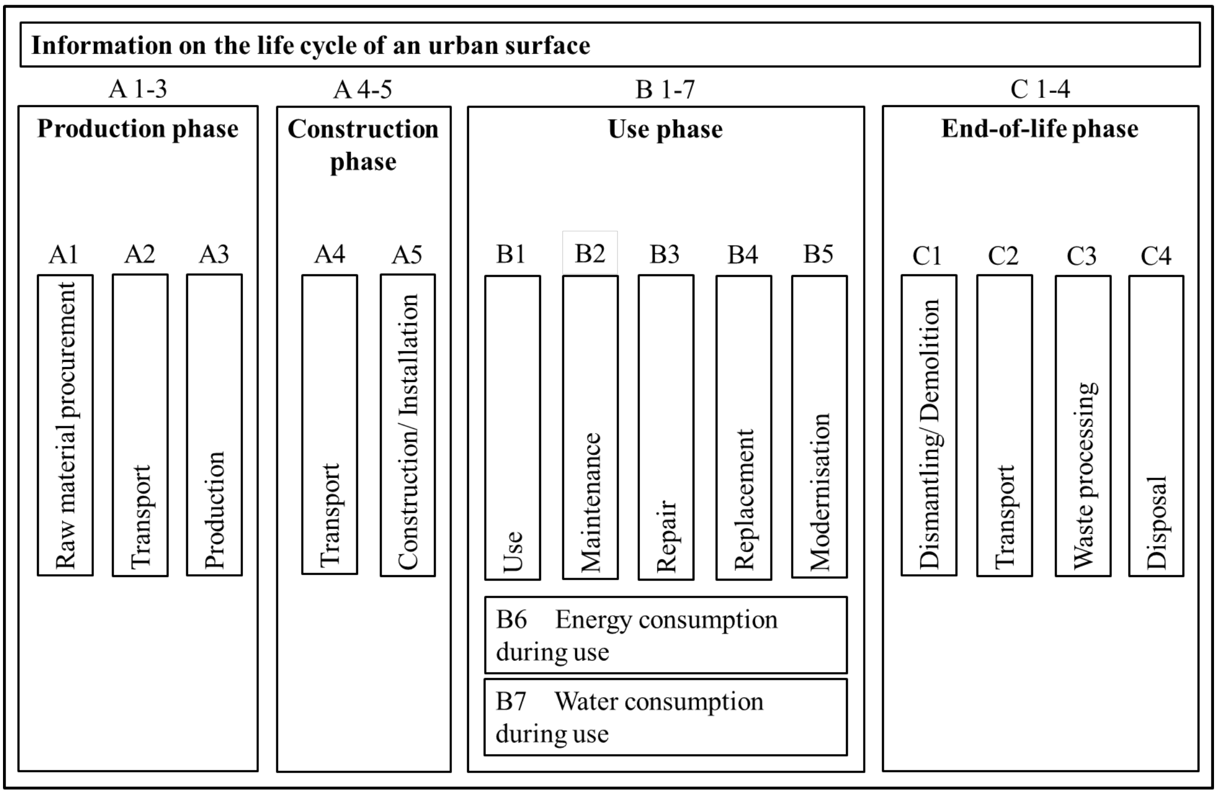

Figure 3. Information on the life cycle of an urban surface, based on DIN EN 15978 [11], technical terms adapted from [12].

A 1-5: Analogous to DIN EN 15978 [11], the processes leading to the installable surface product, e.g., wooden battens, should be taken into account in the production phase. The construction phase should contain processes for the surface materials from their production site to the completion of the construction of the surface, such as the transport of the wooden battens to the construction site and their installation [11].

B 1-7: Adapting the boundaries set in DIN EN 15978 [11], here the use phase comprises the time between the construction and the dismantling/ demolition of the urban surface. In module B1, it is taken into account that substances can be released into the environment during the use of the urban surface [11]. As previously pointed out, various management processes are performed in the use phase of an urban surface. These processes can be assigned to different modules within this phase. Following the standard DIN EN 15978 [11], the boundary of the module B2 should contain processes such as street cleaning, and lawn mowing. The repair processes necessary in the event of damage are considered in the module B3 [11]. While a replacement with the same surface material (even if it is undamaged) is taken into account in module B4, a replacement with another material should be considered in module B5 [11]. Analogous to DIN EN 15978 [11], energy and water flows that occur in the use phase of the surface, e.g., in the process cleaning, are assessed in the modules B6 and B7.

C 1-4: For buildings, the begin of their end-of-life phase is considered to have been reached as soon as they are getting decommissioned, and no further use is planned for them [11]. For urban surfaces, e.g., the end-of-life of a park which is being transformed into a residential area, the disposal of parts of a surface and waste such as lawn cuttings are considered in the modules C 1-4.

The four-phase structure that is suggested here for the life cycle of urban surfaces is, in principle, the same for different types of surfaces; however, their modules differ concerning the processes they contain. For this reason, the life cycle needs to be adapted to the surface to be assessed.

3.2 Scenario building

3.2.1. Innovations for urban surfaces. In order to optimise urban surfaces from a sustainability point of view, different types of innovations can be introduced in the city. This study relies on Rogers [13] to define an innovation as: "[. . .] *an idea, practice, or object that is perceived as new by an individual or other unit of adoption*". With regard to urban surfaces, the *idea, practice or object* is related to an innovation that has the potential to optimize urban surfaces and the *unit of adoption* refers to the municipality. Thus, based on the work done by Leistner et al. [1], in this publication we differentiate between three different types of innovations in the field of urban surfaces: a) innovative surface materials, e.g., sound-absorbing facades [1]. This type of innovation directly influences the material composition and structure of the urban surface itself; b) innovative machines/ technologies, such as gritting vehicles with a hybrid drive or battery-powered hedge trimmers. This type of innovation is related to the technology that is used to manage an urban surface; c) innovations regarding the management processes of urban surfaces, e.g., a new weed removal process. This type of innovation refers to an innovative way in which a particular management process is carried out. In any case, it is necessary to assess the potential sustainability impacts of an innovation before its implementation to facilitate an informed decision regarding its introduction [4]. In this paper, the focus is on the assessment of surface material innovations and innovative machines, both product innovations, since process innovations are not considered as tangible. The innovations are used for designing a comparison scenario which can be compared to a baseline scenario reflecting the state of the art of the urban surface and its management in the respective municipality [4]. The delta between the baseline scenario and the comparison scenario is calculated to assess the sustainability impact.

3.2.2. Life cycles of innovations. Depending on the type, the innovations intervene in different modules within the use phase of an urban surface. As in Maier et al. [3], the system boundary of the innovation is based on the concept of life cycle thinking in order to be able to consider the sustainability impacts along the entire life cycle of the innovation – this makes it possible to identify a shift of burden in all three dimensions of sustainability between the life cycle phases or processes and to take countermeasures prior to their implementation [5]. Therefore, the life cycle of a surface material innovation or innovative machine, both product innovations, should be designed after ISO 14040 [5]. For the life cycle of products and their innovative versions, respectively, a cradle-to-grave approach is chosen; consequently, impacts are assessed in the raw material and fuel acquisition, the production of precursors and the final product as well as in its use and end-of-life phases [6, 14].
An (innovative) machine is used in the respective management process of the urban surface, which in turn is performed in the use phase of the surface. For example, a common gritting vehicle and an innovative road sweeper would be used in module B2 (maintenance) of the urban surface. An innovative surface material, such as easy-to-clean cladding, would be installed in module B5 (modernisation) of the surface. As a result, the life cycle of a product and product innovation, respectively, and the life cycle of the urban surface interact. This finding is illustrated in a greatly simplified manner in figure 4. This relation reminds of the interactive life cycles introduced by Labuschagne and Brent [15]. Figure 4 shows that in the use phase of an urban surface, in addition to modernisation processes, such as process 2, also several other management processes, for example, the maintenance processes 1 and 3, are carried out, in which different products or product innovations can be used.

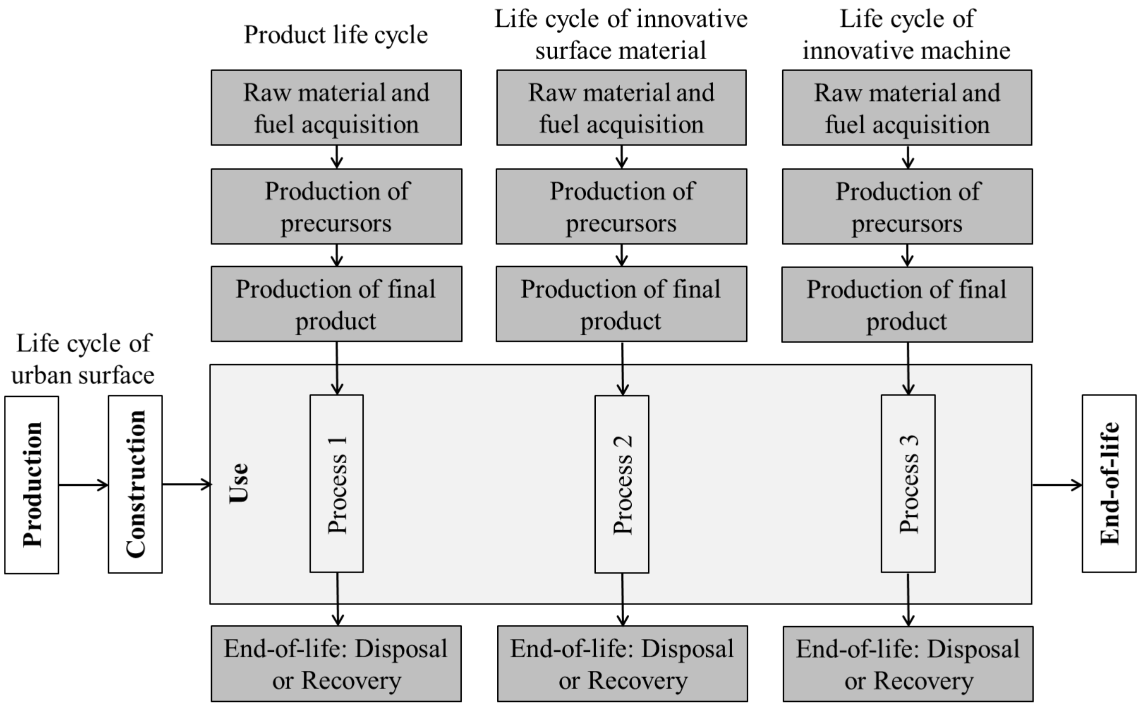

Figure 4. Exemplary illustration of the interaction between the life cycle of an urban surface and the life cycles of products and product innovations, respectively.

Based on the approach of Wang et al. [4], this exemplary, simplified scheme should be modified and tailored to the urban surface, its management processes and innovation in question to model a baseline and comparison scenario for the ex-ante sustainability assessment. In the modelling phase, it should be taken into account that, e.g., a surface material innovation can not only impact on the management process and material or energy flows it is aimed at, but also on linked processes and flows. Consequently, in addition to the other life cycle stages, all management processes and flows occurring in the use phase must be included in the sustainability assessment to grasp the full impact of the innovation. It should be noted that this methodology is designed for the assessment of innovations that optimise existing functions, but not, e.g., innovations that change functions of an urban surface.

4. Application

This section gives an example of the application of the sustainability assessment framework and the life cycles shown in figures 3 and 4 to a highway. It also makes clear how the SDGs are integrated into the assessment. In the first step of the goal and scope definition, the road is characterised, following figure 2. The highway is made of concrete and serves as a space for movement of non-pedestrian traffic. It needs to meet requirements such as safety, usability, and durability. Based on this information, it is possible to design the life cycle of the highway in question. Following figure 3, the phases of production and construction contain processes concerning the provision of concrete and the building of the road. In the use phase, maintenance processes such as winter service (gritting and snow clearance), road cleaning and repair processes are carried out (non-exhaustive list). In the end-of-life phase, besides the demolition of the highway itself, the processing and final disposal or recovery of the demolition waste and output flows, e.g., sweepings and dust, need to be included. In the scenario building, suitable innovations are identified and selected for the assessment. An innovative snow plough was chosen to improve the sustainability of the process of *snow clearance*. The life cycle of the innovation is built using the life cycle thinking in ISO 14040. Then the interacting life cycles of the highway and the currently used and innovative snow plough, respectively, are designed.

Figure 5 illustrates for the case of the innovative snow plough the embedding of the introduced life cycle scheme in an LCSA Framework operationalising assessment system and the integration of the SDGs into the latter. Thus it is possible to conduct a holistic sustainability assessment of the innovative snow plough. To make the assessment system easier to follow, the life cycle of the highway is not fully depicted in this figure. Looking at figure 5, it is essential that the practitioner analyses the sustainability impacts of the highway's use phase with (comparison scenario) and without (baseline scenario) the application of the innovation and additionally the entire life cycle of both ploughs. In this way, it can be determined if the potential advantages of the innovation regarding the sustainability impacts of the road's use phase outweigh the impacts linked to the innovation's provision. As shown in figure 5, the herein presented assessment system is built on the SDG-integrating approaches by Maier et al. [3] and Wang et al. [4]. Their SDG-based indicator systems are adapted to the assessment of innovations in the field of urban surfaces because as Maier et al. [3] point out, it is crucial that the indicators fit the innovation under question. Hence impact category groups from the indicator systems of Maier et al. and Wang et al. that are thematically uniting the SDGs, e.g., *poverty*, *climate* and *health and safety*, as well as suitable indicators are used to assess the potential impacts of an innovation in the three dimensions of sustainability [3, 4]. Amongst the criteria guiding the selection process of the indicators is their ability to assess likely impacts caused by innovations in the field of urban surfaces.

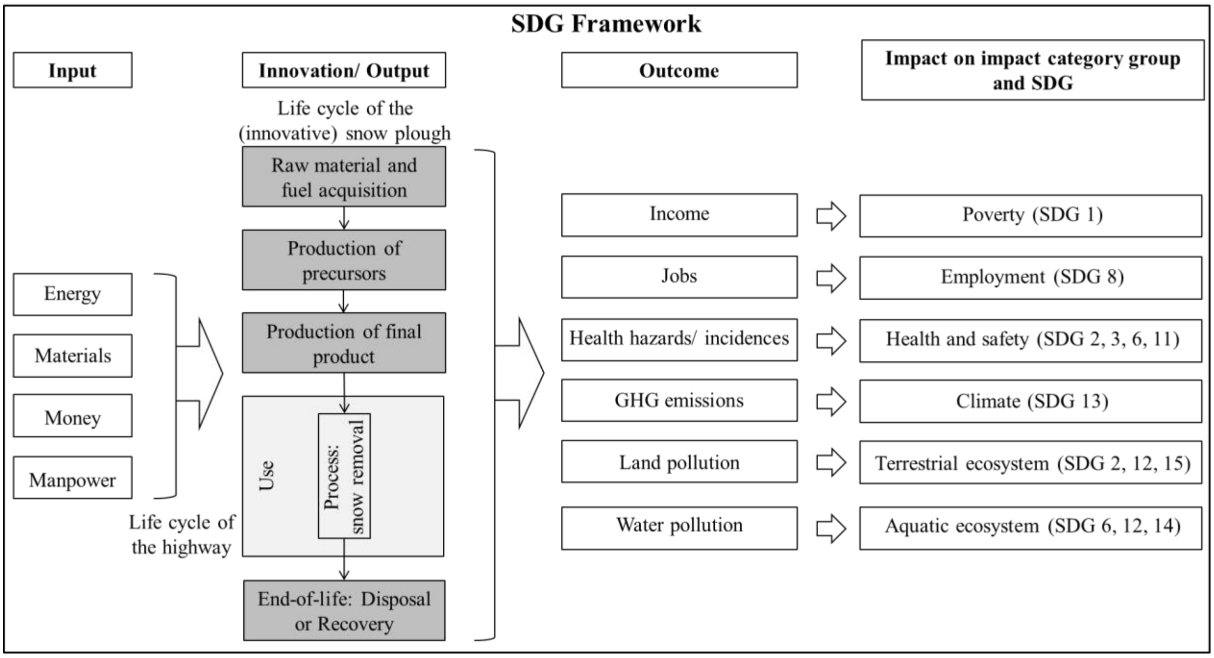

Figure 5. Embedding of the life cycle of the (innovative) snow plough in the SDG-integrating sustainability assessment system, adapted from Maier [16].

5. Discussion and conclusions

The herein introduced generalised life cycle of urban surfaces and its proposed interaction with the life cycles of product innovations provide a good starting point for a life-cycle based sustainability assessment of innovations in the field of urban surfaces. However, there is still a need to extend the proposed life cycles to make it possible to assess process innovations and to consider potential interdependencies between different management processes. Furthermore, while the methodology can be used for the assessment of innovations that optimise existing functions, it needs to be further developed so that it can be used, e.g., for the evaluation of innovations that change the functions of an urban surface, such as multifunctional materials. The next steps are to select and adapt indicators from the SDG framework to the urban surface system and to illustrate the practical applicability of the newly developed methodology by applying it to a case study concerning a specific innovation.

Abstract. Indian coastal cities, enriched with a variety of marine resources, are a major driver of economic growth where the Indian coast provides shelter to a large part (~49%) of the total population in India. Proper planning of coastal resources is crucial for sustainable development, which can be achieved through advanced planning methods. Current methods for the planning of coastal landscapes in Indian coastal cities are ineffective in sustainable utilization of coastal resources and need improvements. This paper evaluates the application of the new planning method for classification of coastal landscapes in Mumbai city. The new method incorporates geospatial technology and multicriteria decision-making approach. The existing method of coastal area classification is based on Coastal Regulation Zone (CRZ) notifications by the central government, which has ambiguities in implementation. In the new method, coastal areas of Mumbai city are classified based on the physical eligibility of the coast for management of coastal resources and spatially compared with prevailing unscientific classification of coastal areas. The most dense urban area is considered for quantitative comparison of prevailing and new classification approach. Results of coastal area classifications by both methods disclosed the significant differences among different classes of coastal land. The results are validated with field visits and ground truthing along the coast of Mumbai. The findings of this study will enable the stakeholders to utilize available coastal land resources in an efficient manner for developmental and conservational activities at regional and neighborhood scale.

1. Introduction

Coastal areas are recognized as vital support to the regional and global economy around the world. Researchers are emphasizing the challenges of coastal resource planning at present due to the continuous increase in anthropogenic pressure along the global coastline [1]. Dynamics of geomorphological, climatic, and socioeconomic changes are altering the coastal system at spatial and temporal scale resulting in degradation of ecosystem services, biodiversity, and infrastructure [2]. Similarly, the Indian coast is also exposed to natural hazards like tsunamis, cyclones, extreme rainfall, coastal flooding and pressure of allied developmental activities along 7200 km of shoreline [3]. Indian coastal zone is managed to control the physical and socioeconomic vulnerability with the help of coastal regulations at the central and state level. According to Coastal Regulation Zone (CRZ) notification, eco-sensitive areas are classified into four different categories, but the distinction of these categories is based on the coastal boundary of different distances (500 m or 100 m) from the High Tide Line (HTL) towards the landward side. The CRZ notification is a strategic planning method of integrated coastal governance but unable to deliver the expected because of subjectivity and ambiguity at both fundamental and implementation level [4]. Current CRZ method is inconsistent and empirical, which does not consider the physical eligibility of different coastal features at spatial and temporal scale. Coastal planning and management is a challenge for other developing countries as well due to similar unclear policies like CRZ in India [5]. CRZ method of coastal land classification tries to deliver sustainable coastal governance for land management with limited capability. However, this CRZ method has been ineffective and failed in the past to achieve the aim of integrated coastal management at the Indian coast [6,7]. Therefore, an objective based robust classification approach for coastal areas is required to improve the coastal planning in India. It is essential to have a robust solution to address the conflicting interests of associated stakeholders during coastal land classification.

In this study, we demonstrated the application of Coastal Area Index (CAI) method, which is quantitative and capable of addressing the current challenges in existing CRZ method [8]. CAI method is applied to the coastal area of Mumbai city in India. Furthermore, a comparative assessment of the spatial extent of different categories classified by the existing CRZ method with the CAI method is carried out. Feasibility and advancement of the CAI method over CRZ method are validated by field visits and ground truthing at the selected location.

2. Methods

This study presents the application of a newly established quantitative method (CAI) for the classification of coastal land, which is based on geospatial science and multicriteria decision-making approach. We selected the coastal stretch of Mumbai city for classification into different categories based on the CAI method. Mumbai city in India is a coastal megacity of regional and global importance, located at the west coast of India and the unique dynamic coastal environment of the city represent all important geomorphological features [9]. Mumbai, an Island city, is surrounded by the Arabian Sea along the west coast and a large Thane creek in the east representing a large natural mangrove cover and associated biodiversity. Additionally, key reason for selecting this study area is the availability of signatures of ecosystem degradation related to coastal pollution, coastal flooding, the significant increase in urban development along the coast and violation of current existing CRZ method [10,11].

This study uses primary remote sensing data for quantification of physical coastal features. Important geomorphological variables representing physical coastal features are pre-processed and converted into raster format at 30m pixel level, as shown in Table 1. Land Use Land Cover (LULC), Digital Elevation Model (DEM), Normalized Difference Vegetation Index (NDVI) and coastal slope (%) are processed and classified using remote sensing data whereas soil and geology types are processed based on secondary data from central agencies namely Survey of India (SOI) and Geological Survey of India (GSI) respectively. CRZ areas are digitized using digital vector maps sourced from the State Coastal Zone Management Authority (SCZMA).

2.1. Comparative assessment of CRZ and CAI method

CAI method is developed by coupling GIS and multicriteria decision-making techniques; these techniques are well recognized and accepted in literature for land classification and policy-oriented conflict resolution among decision makers [12]. According to the CAI method, subclasses of physical coastal features are converted into utility functions based on the relative importance of particular feature towards environmental sensitivity followed by overall weight assignment to an individual layer of a coastal feature. Linear weighted sum method is used to generate the CAI by multiplying the layer weights with the respective utility value of the particular feature. Final CAI is obtained on a scale of 0-10 and classified in three distinct categories representing low, moderate, and high sensitive areas for developmental activities. CRZ classes are also demarcated according to the digital maps and converted into vector graphics in GIS tool for quantitative comparison with the areal extent of classes derived by

CAI as shown in Figure 1.This selected area is a predominantly urban area having inhabitants and commercial activities in 90% of the total area.

Table 1. Description of data types and processing.

Data layer	Source	Sub-classes
Land Use Land Cover	LANDSAT 8 (30 m)	built-up and fellow land, saltpans, vegetation, cropland, mudflats, marshes, mangroves, water bodies
Coastal slope (%)	SRTM (30 m)	< 25, 25-50, 50-75, <75
Elevation (m)	SRTM (30 m)	<1, 1-5, 5-10, >10
NDVI	LANDSAT 8 (30 m)	water, barren land, sparse and dense vegetation
Geology	GSI	rhyolite, trachyte, AA and compound flows, intertrappean, alluvium, agglomerates tuff, mud
Soil	SOI	backfilled, fine, clay, mud
CRZ classes	SCZMA	CRZ I, CRZ II, CRZ III

2.2. Validation method

Field visits are conducted at the selected site for validation of different classes by CAI and CRZ method. For this, a small area of 0.2 km^2 at the mouth of Mahim Bay, Mumbai is selected by considering the physical access to the site. This area is visited personally during clear weather. Visual observations are documented, and geotagged pictures are captured for meaningful interpretations.

3. Results

The coastal area along the coast of Mumbai city is classified and compared using CAI and CRZ approach to identify the better and more appropriate land classification method as presented in Figure 1.

3.1. Validation

Selected location near Mahim Bay in Mumbai is considered and visited for field validation, as shown in Figure 2. The visited area is demarcated with a white box in Figure 2, and satellite imagery of a particular area is shown. In Figure 2, the CAI classifies this area as low to moderately sensitive, whereas presently, this area is in CRZ II. This area is fully urbanized, and validation exercise shows the agreement between both methods. We observed the open defecation and solid waste pollution activities along the HTL which need immediate interventions from governing authorities.

3.2. Spatial extent comparison of classified areas by CRZ and CAI approach

Field visits combined with CAI and CRZ classification presented the effectiveness of CAI method for coastal land classification. Comparative results of the spatial extent of different classes are presented in Table 2.

Table 2. Spatial extent comparison of classes in CRZ and CAI for the selected site.

Classes	CRZ Area		CAI Area	
	km^2	(%)	km^2	(%)
I	1.6	7.8	0.9	4.6
II	18.5	92.0	8.1	40.1
III	0	0	11.1	55.3
Total	20.1	100	20.1	100

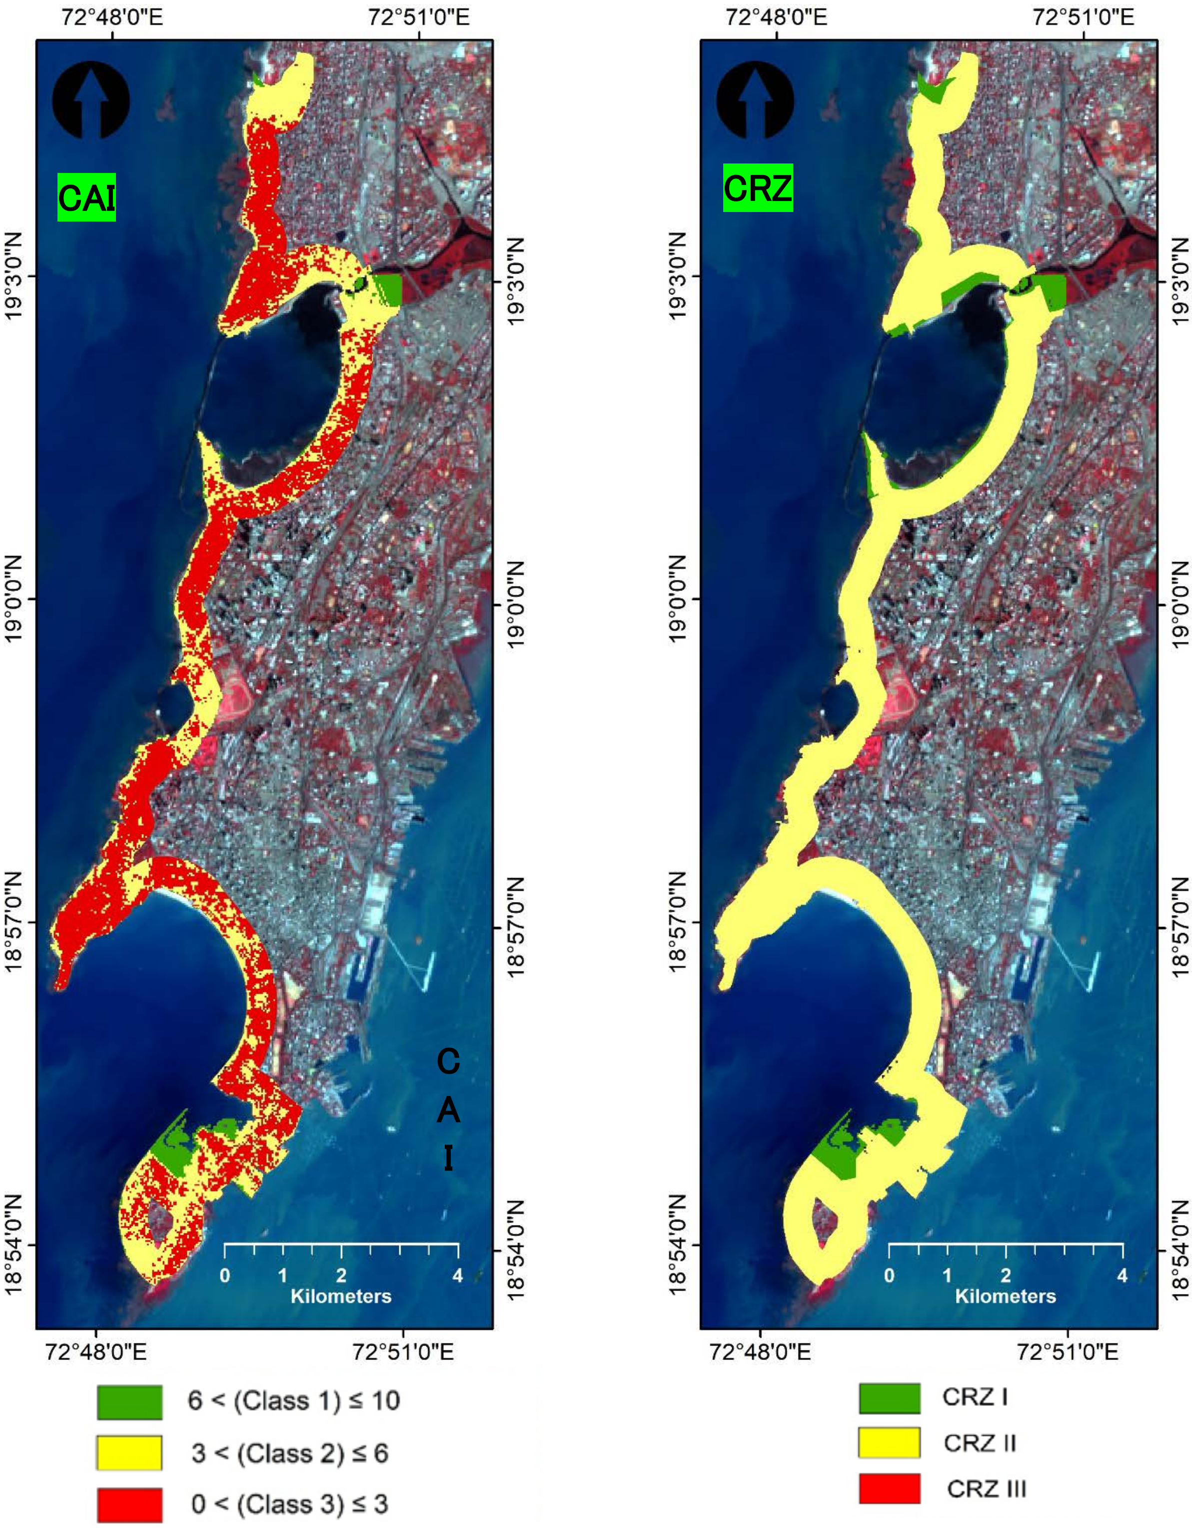

Figure 1. CAI and CRZ classification at the coast of Mumbai city for quantitative comparison.

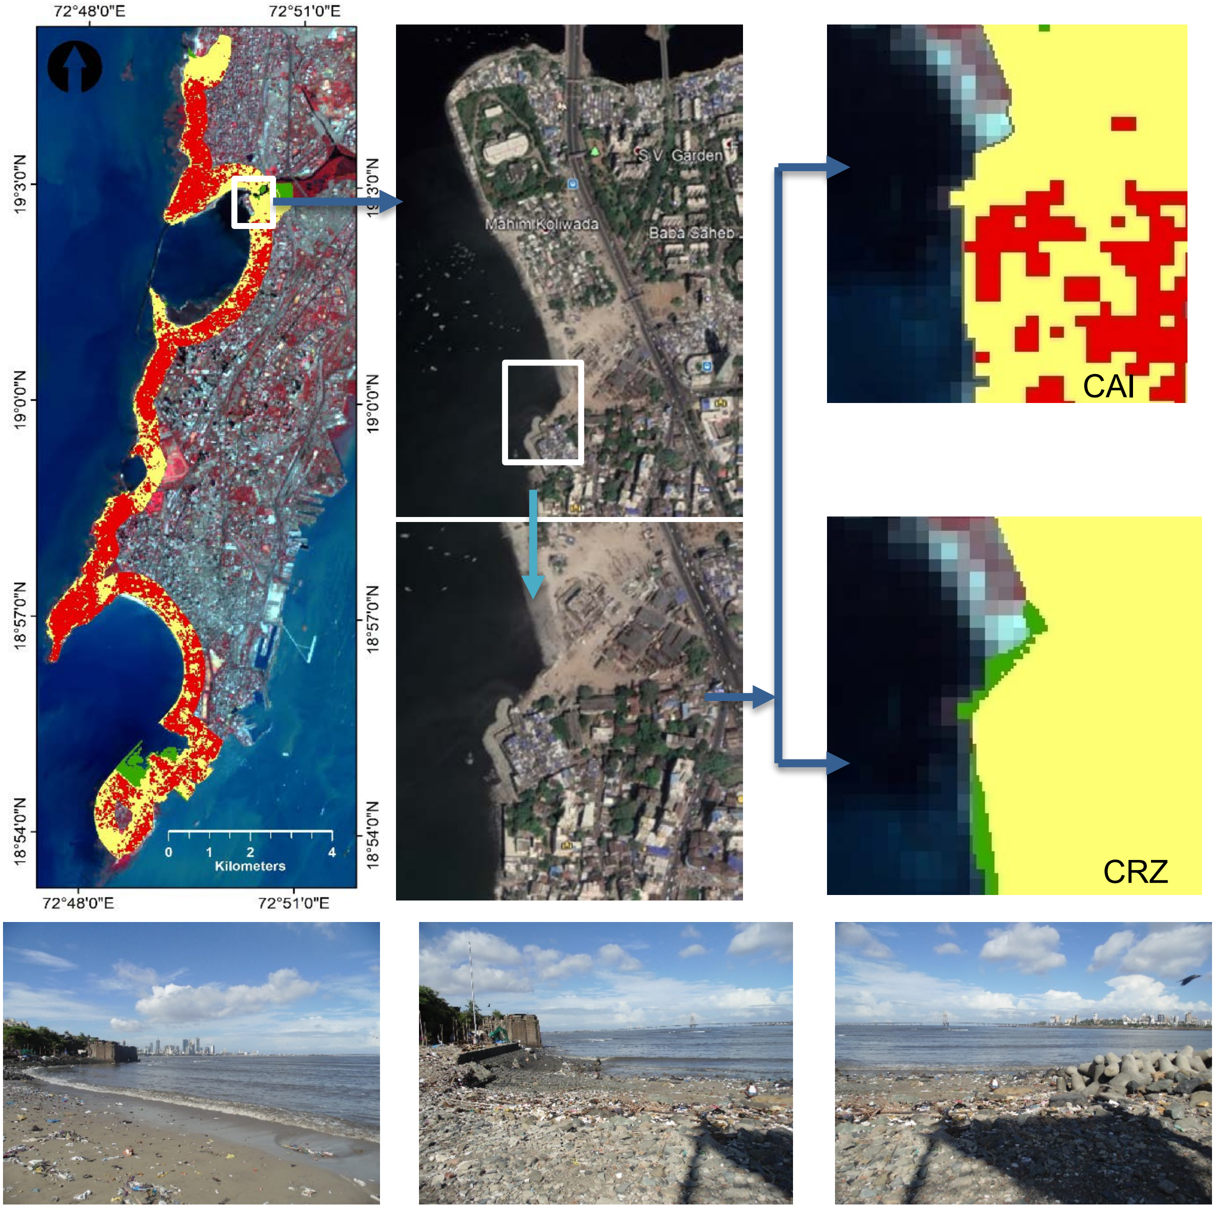

Figure 2. Validation of CAI based on ground-truthing at three selected sites along the Mumbai coast.

CAI method classifies 3.4% less coastal land in highly sensitive class compared to CRZ method as given in Table 2. The spatial extent in class two, which is moderately sensitive according to CRZ method is 52% more compared with the CAI method. Class 3, which is less sensitive in CAI, is measured 55% higher compared with CRZ. Comparison of CRZ and CAI extent shows that around 90% area is classified in a similar category of less to moderately sensitive, and the results of both methods are aligned with each other.

Results of the comparative assessment show the ability of the CAI method to classify coastal areas quantitatively at the pixel level by incorporating the physical characteristics, whereas CRZ method demarcates the fixed boundary at any given geographical location. CAI is a more robust decision-making method for coastal land classification, and the potential of this method for integrated coastal management in coastal urban areas is demonstrated in this study. Suitable applicability of CAI method will synergize the coastal protection and development by addressing the limits of current prevailing CRZ method.

4. Conclusion

The current method of coastal land classification needs to be replaced by a coherent solution to achieve effective planning of built environment from available coastal land resources. Demonstrated method of CAI is quantitative and suitable for land classification in coastal cities. Proposed CAI approach is efficient, robust, and easy to implement at a city scale. The classification differences of the spatial extent by CAI and CRZ method might be useful for coastal managers and researchers as the potential areas for development, built environment and environmental management are evaluated. CAI method allows the land classification at a precise scale in a transparent manner and addresses the subjectivity of existing CRZ method.

Acknowledgment

The Authors thank the anonymous referees for their useful suggestions. Turning the existing building stock into a resource mine: proposal for a new method to develop building stock models

Lismont A, Allacker K

KU Leuven, Faculty of Engineering Science, Department of Architecture, Kasteelpark Arenberg 1 – box 2431, 3001 Leuven, Belgium

karen.allacker@kuleuven.be

Abstract. The construction sector is facing an important challenge to reduce its resource consumption. A promising strategy is to reduce the need of virgin resources by using the existing building stock as a resource mine. Various insights are needed to enable this. It should be clear how many materials are in the stock, when these will become available and to what extent these can be reclaimed in an environmentally and economically viable way. For this purpose a spatio-temporal building stock model is being developed and tested on the city of Leuven, Belgium. In a next step it will be assessed how these flows can be reclaimed in an environmentally and economically viable way. This paper provides a review on the methods used for building stock modelling and proposes improvements on the bottom-up archetypes scaling method. Building parameters relevant to material reuse and are introduced and a new methodology for upscaling is presented, using two data analysis techniques: a clustering algorithm and an artificial neural network.

1. Introduction

The construction industry is responsible for over 40% of the total European energy and resource use [1] and 25-30% of all generated waste [2]. The European Commission (EC) has therefore labelled construction and demolition waste (C&DW) a priority waste stream [3] and put a directive into place to increase its reuse and recycling [4]. Waste management is also one of the areas in its EU Action Plan for the Circular Economy [5]. In Belgium, there already is an effective C&DW recycling scheme, keeping over 90% off landfills [6, 7]. This however mainly consists of energy intensive recycling processes such as melting of metals and grinding of mineral waste (e.g. bricks, concrete, ceramics) into aggregates. The latter is especially wasteful as it degrades high-grade materials into low-grade variants [8]. According to the NGO Rotor DC, reuse of deconstructed building components is limited to about 1% of all material. Deconstruction (rather than demolition) is a logistically, economically and legally complex process [9, 10] and hence only a few companies offer this service. To scale the current initiatives from the small markets to a more significant part of the construction industry in a sustainable way, knowledge about the material flows resulting from deconstruction and refurbishment is needed. This requires insights in the material composition of the existing building stock, the demolition and refurbishment activities and related material flows and the environmental benefits related to potential recycling or reuse paths. This is a complex topic with highly disaggregated data that need to be connected to identify opportunities for a circular economy. Insights in the current state of the art regarding the main methodological aspects (environmental modelling of the building stock, urban mining and geographical data analysis) are elaborated in the subsequent section. Based on these insights a new modelling approach is presented in section 3. In a final section conclusions are drawn and the further outlook is described.

2. Building stock modelling - state of the art

2.1. Building stock modelling and urban environmental impact

Two main approaches can be distinguished in the field of building stock modelling: top-down and bottom-up approaches. Top-down approaches, such as input/output modelling and urban metabolism studies [11, 12] allow to gain global insight in the systems at work, but are unable to uncover the mechanisms of its subsystems (essentially keeping the city as a "black box") [13]. Bottom-up approaches [13, 14, 15] subdivide a city in its various components which are assessed separately and then aggregated to obtain the full picture. In literature, two bottom-up approaches can be identified to assess building stocks: the archetypes approach and the building-by-building approach [14]. The former makes use of a limited set of archetypes, each representing a subset of the building stock. This trades off the benefits of a detailed analysis of these archetypes for a simplified depiction of the heterogeneous stock. The building-by-building approach models each building individually, but usually means a lower level of detail and a lower scale level (i.e. neighbourhoods) because of practical limitations.

Geographical Information Systems (GIS) provide additional insights by making the data spatially explicit. GIS allows to assess local opportunities and impacts [13, 16] and to refine the bottom-up model through a more accurate inventory of the characteristics of all buildings [14, 17].

Where earlier studies on urban systems were limited in scope (limited to material flow analysis, or greenhouse gas (GHG) emissions), more recent studies have adopted a more holistic approach using life cycle assessment (LCA) [11, 12]. The LCA method allows to account for a wide range of environmental impacts (including GHGs, human toxicity and land use) and considers all life cycle stages (production, use and end-of-life), thereby avoiding burden shifting [18].

2.2. Materiality of building stock / urban mining

As resources are becoming more scarce and environmental burdens from the production of construction materials are increasing, attention is turning towards the existing building stock as a resource mine [19, 20]. Insight in the materials available in the building stock and the related environmental implications have become important. Mastrucci et al. [21] attempted to assess the resources in an urban area through a GIS-enhanced archetype model, derived from the European TABULA project on building typologies [22]. An LCA was made for the end-of-life stage, comparing current construction waste treatment with a higher recycling fraction for concrete. The study did not include an assessment of upscaled recycling opportunities. Other studies focussed on dynamic life cycle inventory (LCI) in LCA and on temporal changes in the building stock, identifying the release of materials and volume of recycling from building demolition [23], but without considering waste flows from refurbishments and without assessing environmental impacts.

The approach is also used to assess changes in the stock due to maintenance and refurbishments [24], or due to shifts in energy supply or climate change [25]. The ongoing BBSM project includes a limited material flow model for Brussels as part of their research in urban mining, taking into account three renovation scenarios [26]. More detailed studies on the environmental impact of demolition practice and recycling potential are available at the building level [8] without providing insights in urban stocks. Innovative recovery methods for C&DW were for example investigated in HISER and an integrated approach to a circular building sector was strived for in BAMB [27, 28]. A holistic building stock model incorporating circular principles should include these developing techniques.

2.3. Data analysis in GIS

The amount and complexity of building stock and GIS data require sophisticated techniques for data analysis [29]. In that regard cluster analysis, a type of data mining, has been successfully applied to partition and analyse a heterogeneous building stock regarding its energetic characteristics [30]. While data mining is used to uncover existing patterns from data, machine learning, which is a branch of artificial intelligence (AI) and a different method of data analysis, goes beyond this and can be used to build predictive models. Applications relevant for urban mining are still scarce, but the method has recently been applied to predict the energy performance of a building stock [31]. This study used artificial neural networks (ANN), a popular method of machine learning. The benefits of this non-parametric approach over statistical prediction models (e.g. as used by Mastrucci et al. for energy use predictions [32]) are a better representation of complex relations, the ability of the model to self-correct when more data becomes available and a lower sensitivity to researcher-induced bias by pre-programmed rules [29].

3. New spatio-temporal building stock model for Leuven

3.1. Goal of the new building stock model

The aim of the spatio-temporal model of the building stock is to gain insight in which building materials can be reclaimed at what time and how this is possible in an environmentally sound way. This model should hence allow to predict future material flows and anticipate on resulting opportunities and challenges concerning their reuse and impacts. As the model should allow to simultaneously assess material flows coming from the existing stock and material needs for refurbishments and new buildings, the model should go beyond identifying quantities of flows and facilitate a high-level recovery of materials. In order to achieve this goal a bottom-up model is proposed, validated by top-down data and combined with LCA for the environmental assessment. This is further described in the subsequent section.

3.2. Case Study

The method is developed using the city of Leuven (BE) as case study. Leuven has become an internationally recognised frontrunner in the sustainability debate and in this context, various data have been collected during the past decade which are valuable inputs for this research. Moreover, the mobilisation of citizens and enterprises alongside research institutions in Leuven 2030 shows potential for the aggregation of more data and application of the study results. The datasets that will be integrated for the research are listed in Table 1, but might be further extended with additional data sources during the research.

Table 1. Available data for Leuven

Dataset	Content

3.3. Categorization of buildings
To model the building stock, a set of representative buildings for both the existing stock and new buildings has been defined. In a next stepan inventory of the quantity of (reusable) materials will be made for each of these representative buildings.

3.3.1. Selection of representative building types for the stock. The various representative buildings had to cover variations in construction period, as this influences the materials used, and variations in building types, as this influences the amount of materials in a building. A literature review on archetypes of buildings identified two useful studies: the TABULA project [22] and the SuFiQuaD project [33] which provided a good basis for the characterization of the building stock. Both studies defined archetypes for the Belgian context, categorizing the stock by construction period and building typology. The archetypes have been described in detail with the aim of assessing energy use (TABULA) or environmental impact and renovation strategies (SuFiQuaD).

To define the set of representative buildings, a statistical analysis of the building stock in Leuven was made. This analysis supported the use of the five construction periods (before 1945, 1945-1970, 1971-1990, 1991-2005 and after 2005) and four main typologies (terraced, detached, semi-detached, multi-family buildings) used by both earlier mentioned studies. The results of the statistical analysis are presented in Figure 1. The four main typologies represent a more or less even share of the housing stock. The figure reveals that while terraced houses were historically more popular, this has shifted to detached houses and multi-family dwellings. For the aim of our research, the roof type of the stock was analysed to investigate if a further division of the archetypes distinguishing roof types is needed. The analysis of the data shows that the amount of flat-roofed buildings is negligible, unless for the most recent time period and the multi-family dwellings as a whole. Accounting for these, the set of archetypes has been expanded from 20 to 28 archetypes.

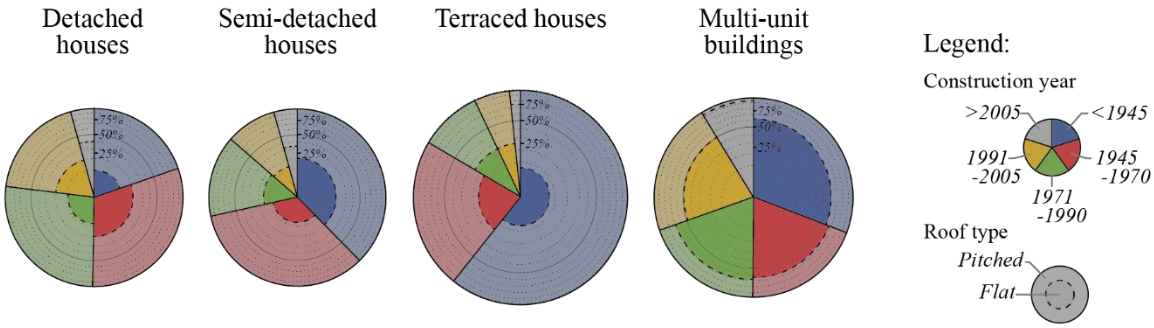

Figure 1. Categorisation of building stock in Leuven (chart sizes are weighted by total floor area)

3.3.2. Material inventory of selected types. To assess which of the materials in the archetypes can be reused, parameters are defined that determine the reusability [34], the environmental impact and economic value of materials based on a literature study and expertise of the authors. Examples of parameters are the material age, fixation method, location in the building (accessibility), embodied environmental impact and remaining technical service life. These parameters will be applied to the material inventory of each of the archetypes to determine the amount of reusable materials.

3.4. Clustering algorithm
In parallel to the manual categorization under paragraph 3.3.1, a clustering algorithm has been applied to attempt the same. A k-means clustering has been selected, where four parameters are considered: construction year, total floor area, share of exposed façades and share of pitched roofs. The algorithm defines a set amount of “k” clusters of buildings based on their similarity, as determined in the four-dimensional space defined by the considered parameters. It results in clusters of a relatively equal internal variance, which makes it a good fit for the data extrapolation. The results are shown in figure 2 and accompanied by a semantic interpretation of these results in table 2.

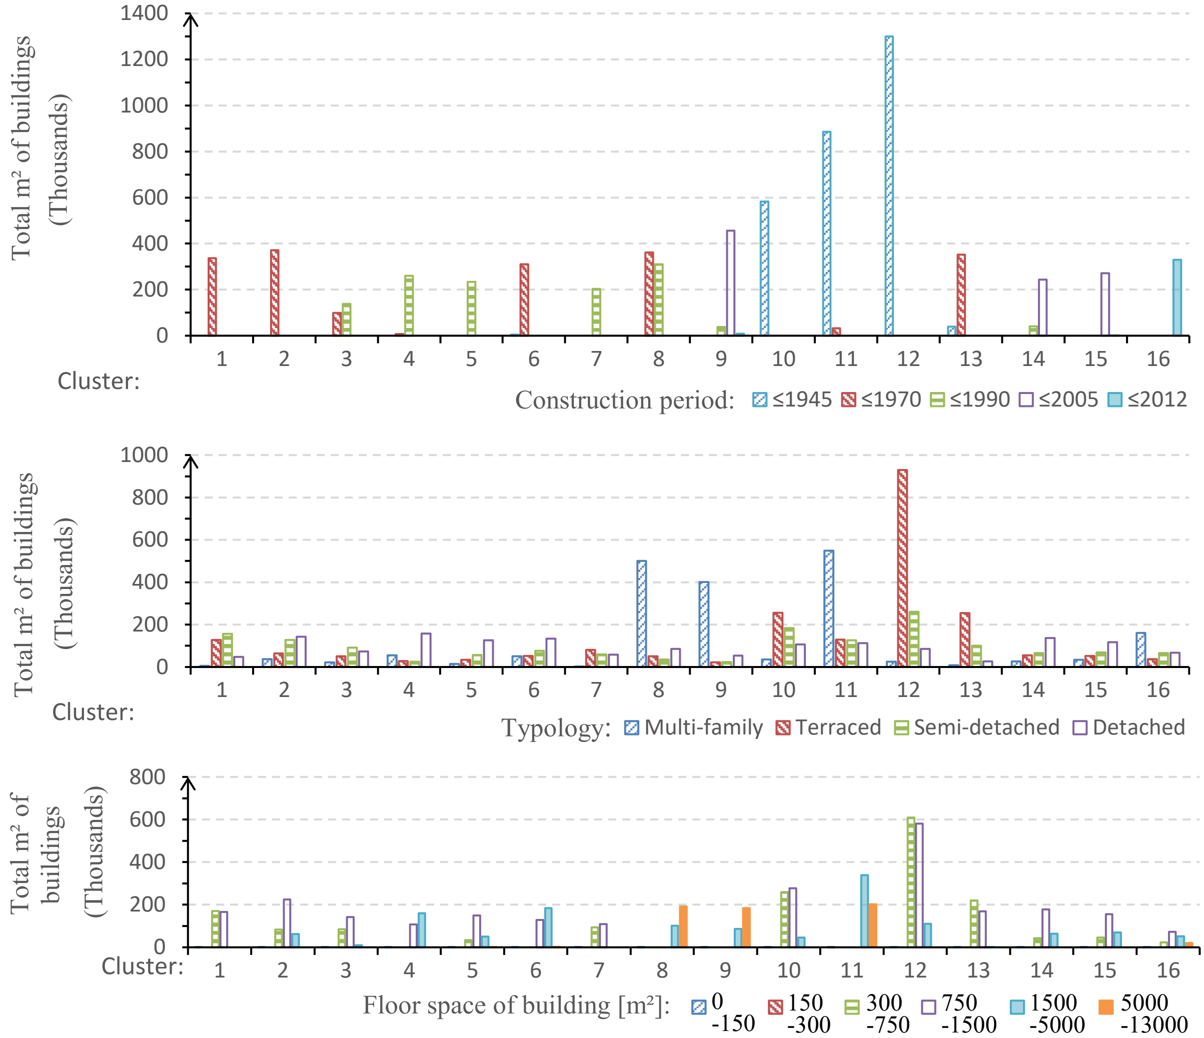

Figure 2. 16-means clustering of the building stock. The internal distribution within each cluster is shown for three parameters: the construction period, typology and floor space.

Table 2. Semantic interpretation of the clusters defined by the k=16-means clustering algorithm. Note that they are in no particular order.

Cluster	Time period	Typologies
1	1956-1970	Small, compact single-family buildings (<300 m²)
2	1946-1970	Medium single-family buildings (ca. 300 m²)
3	Ca. 1970	Small, compact single-family buildings
4	1971-1990	Large “single-family buildings” (ca. 750 m²), likely multi-family buildings
5	1971-1990	Medium single-family buildings (ca. 300 m²)
6	1946-1970	Large single-family buildings (ca. 750 m²)
7	1971-1990	Small single-family buildings (<300 m²)
8	Ca. 1970	Multi-family buildings
9	1991-2005	Multi-family buildings
10	Pre 1945	Small single-family buildings (<300 m²)
11	1921-1945	Very large buildings (>750 m²), likely multi-family buildings
12	Pre 1920	Small single-family buildings (<300 m²)
13	1940-1955	Small, compact single-family buildings (<300 m²)
14	1991-2005	Large single-family buildings (>300 m²)
15	1991-2005	Large single-family buildings (>300 m²), more pitched roofs
16	2006 and later	(Almost) all typologies

The number of clusters was determined empirically. Because of the low number of flat-roofed single-family dwellings, pitched-roofed multi-family dwellings and generally post-2005 buildings, the algorithm did not recognize these as separate clusters. Because of this the algorithm was reduced from a k=28-means clustering to a k=16-means clustering. It should be noted that there is now one post-2005 cluster (cluster 16) and that clusters 14 and 15 are similar except for their roof type.

The 16 clusters determined by the algorithm are almost completely in line with the suggested partition of construction periods, with the exception of clusters 3 and 8. Given the lack of formal delineation between these partitions, this is remarkable.

The distinction is less clear for the typologies. It should be noted that these categories in the second graph are taken from the classification by the city of Leuven. At first it would seem that the parameters of floor space, ratio of exposed façade and ratio of pitched roof do not characterize the typologies well, but the final graph adds an important nuance. It shows that floor space is an important characteristic. In fact, in the case of cluster 11, the algorithm arguably has done a better job of identifying the multi-family buildings, as buildings with a floor space above 750m² are very likely to be an apartment building instead of a single-family typology.

4. Future outlook

In a next step of the research, the inventory from the representative buildings will be upscaled to the entire urban building stock based on GIS data. In existing studies the upscaling is most often done by linking an archetype to each single building in the stock based on its characteristics. All data is then scaled linearly based on the archetype and a weighing factor, e.g. floor area. Our study proposes a new approach using data analysis algorithms. Compared to the traditional expert-based models, which use hard-coded rules, data analysis algorithms by design allow for more complex and flexible models, being able to self-adjust their criteria when more data samples are added, or when the algorithm is applied to an entirely new data set. More specifically our proposal is to support the extrapolation of the single building data through two machine learning methods: a k-nearest neighbours classification and an artificial neural networks (ANN).

4.1. K-nearest neighbours classification (kNN)

A kNN is loosely related to the k-means clustering algorithm used under 3.4, but instead of defining clusters within a set, this method works in the opposite direction: it classifies elements into categories based on the category of similar elements. This similarity is calculated in the same way as in k-means. This way it will categorize buildings under the most similar archetype. If the archetypes were to match the centroids of the earlier defined k-means clusters, the kNN classification will return categories identical to the 16 clusters. If the archetypes don't match these centroids or a different amount of archetypes is selected, the kNN adjusts, demonstrating its flexibility.

After the classification, the data obtained for the archetypes under section 3.3.2 will be extrapolated for all buildings based on their category and weighing factors determined on the available GIS-data.

4.2. Artificial neural network (ANN)

Besides the clustering approach, a second approach, i.e. ANN, will be used for the upscaling of the material inventory of the representative buildings to the full building stock. An ANN is a computing system which can learn to perform a task (e.g. extrapolate data) without using a pre-programmed instruction set [35]. There are several learning paradigms which can be employed depending on the kind of task the ANN is expected to perform. In this case, a supervised learning paradigm is selected which uses a set of training data (i.e. the cases as basis for the archetypes) to predict values for a new set of data (i.e. the remainder of the building stock). For this, inputs (known data like floor area), intermediary nodes and outputs (unknown data like present materials) form a network connected through synapses (Figure 3). Each connection represents a random non-linear transformation of the signal. These are weighted and summed to obtain an output value. Based on the feedback from the training data, these weights are then iteratively adjusted in order to obtain a good approximation of the actual output signal.

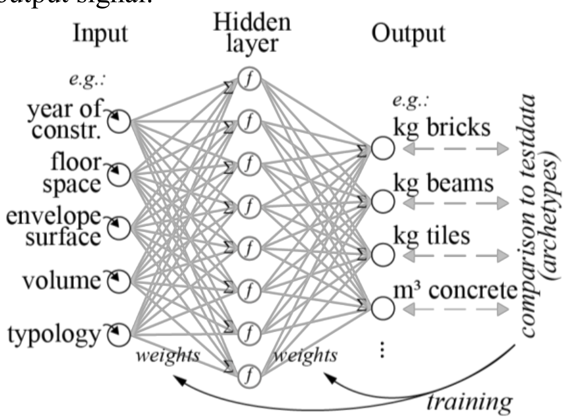

Figure 3. Concept for the proposed ANN. Data that is available for all buildings serve as input to extrapolate the unknown parameters. The network is trained on known data from the archetypes.

4.3. Interpretation of models

In the models obtained through the cluster analysis and ANN, buildings are not a priori categorised in a set of predefined archetypes, but are rather brought into relation to an expandable number of samples through their known variables. In this way, the unknown variables, i.e. quantities for the building elements, will be expressed as a sum of fractions of the inventories of representative buildings. The accuracy of these estimations can be improved through systematic interpretative workflows. The required steps will be specific to the resulting application. Relevant and feasible distinctions will be different for resource management on regional or urban scale, or even the scale of districts or building sites.

It is important to separate these interpretative steps from the development of the models themselves to assure flexibility and scalability and minimize bias.

4.4. Validation of the results of the various approaches

The results obtained through the scaling and interpretation will be validated by comparing the predictions with the reality of the building stock through test samples. Based on the outcomes of this comparison it might appear that the models require further improvements. Through an iterative process the models will be improved and more case studies will be added until the models perform well enough.

Besides validation through comparison with a random sample of buildings, the predictions of the models will also be validated by comparing these with top-down statistical data. This comparison might also reveal that one method is preferred over the other: the ANN might prove impractical in that it requires too much training data to become reliable or on the contrary demonstrates an important level of detail in its predictions. The cluster model could prove robust, but to what level it becomes inflexible for other applications because of programmed rules, remains to be seen.

4.5. Application

4.5.1. Scenario modelling. A temporal resource flow model, incorporating renewal rates of buildings and building components, allows to assess the influence of different future scenarios of expected changes in the building stock on the amount of (reusable) materials that will become available in time. These scenarios could for example represent increasing insulation levels, accelerated renovation rates or a gradual change towards the use of other construction methods (e.g. timber frame construction). The scenarios themselves will be defined based on expected future situations, covering ‘business-as-usual’, ‘targeted refurbishments’, ‘zero-energy standard’ and ‘reduced life cycle environmental impact’.

4.5.2. Quantification of building material flows. In a more straightforward application of the building stock models, near-future macro or meso-scale flows can be anticipated and the material stock on building sites can be estimated.

5. Conclusion

In the context of using the existing building stock as a resource mine, insights are needed regarding the amount of materials in the stock, their location and when these will become available. Such insights can be derived from building stock models. For this paper a spatio-temporal building stock model is being developed. The model builds upon previous research on stock modelling using a bottom-up approach. Based on a literature review, this approach was preferred over a top-down approach as the level of granularity of the latter is too low for the aim of our research. The approach proposed departs from existing approaches using building typologies which are upscaled to model the full stock. In contrast to existing studies that use a manual categorization of the buildings, a clustering algorithm is used to allow for managing the large amounts of data in an efficient way. The approach was tested on the city of Leuven to cluster the various buildings in the stock and it could be concluded that the method is deemed adequate for this use case as it aids in interpreting the large amounts of data and complex interrelations between them.

Modelling the building stock remains a challenging task as reliable information can't be obtained for all buildings. The application of our clustering analysis exposed that there can be important semantic differences to data as was the case for the typological classification. The interpretation of intermediary forms, e.g. those between an apartment block and a terraced house, can lead to very different results depending on how they are treated in the scaling from the archetypes to the rest of the stock. In the next step of this research, a better scaling method will be pursued through two machine learning techniques: a k-nearest neighbour algorithm and an artificial neural network.

Acknowledgements

The authors would like to thank predoctoral researcher Evelien Verellen for sharing her insights in building stock modelling and the building stock data of the city of Leuven.

Abstract. The understanding of the global performance of a historical city is a complex balance of several specific issues and requires a multi-disciplinary approach to face with actual urban phenomena and challenges, such as the seismic risk and energy efficiency, that are strongly influenced by urban form. This paper focuses on the potential of urban metrics and typological indicators for describing the seismic vulnerability and the solar radiation availability of distinct urban textures, and the correlation between the two aspects. Comparative analysis at fabric scale was conducted on the historical centre of Rieti (Latium, Italy), to underline the main seismic and solar indicators. In the last decade, we witnessed the spreading of urban scale assessment and analysis tools, but seldom using an integrated approach to face the complexity of the historical city. Relying on morpho-typological indicators, the proposed method characterizes the fabrics in terms of seismic vulnerability and solar availability through a multicriteria analysis. The analysis reveals substantial differences between fabrics using three groups of indicators: *Plan*, *Space* and *Analysis-oriented*. Each group describes different features of the urban fabrics that affect seismic and solar performance and suggests improvement strategies. The purpose is to support policymaker and designer in the urban renovation process.

1. Introduction

The historical city is a complex system, and the understanding of its evolution requires specific attention to face urban actual phenomena and challenges, as natural disasters and climate changes. Nowadays, several studies in the field make use of approaches at the urban scale, rather than the building scale, in order to consider and explore all the elements that affect the functioning of a city [1–4]. Moreover, different urban forms correspond to different performances among which the seismic and the solar performances must resort to the analysis of the physical features of basic components of the built environment. In this framework, our study explores the causal relation urban form/seismic vulnerability/solar energy in the historical city through a multicriteria analysis, based on physical indicators - Urban Metrics (UM) and Morpho-Typological Indicators (MTI). The aim is to ease planning decisions for sustainable renovation processes.

The Mediterranean city represents a significant example of urban system, based on masonry construction and characterized by typological processes of growth, closely related to climate conditions and seismic events that defined its history. In terms of seismic risk, the analysis of the urban fabric focuses on the mechanical behaviour at the scale of the building aggregate [5], defined as a complex system of interrelated parts, structural units that are interconnected or in contact, which may interact under a seismic or dynamic action in general. Building aggregates generally have non-homogeneous and stratified constructive features, with different level of effectiveness of structural links between different parts. The research aimed at understanding the seismic performance of the city has developed the following approaches: on the one hand the structural-constructive approach focused on the analytical-mechanical understanding of masonry construction [6,7] and the identification of constructive characteristics linked to the reduction of vulnerability on an urban scale [1,2]; on the other hand the urban-systemic one [8,9] focused on risk assessment for the functional systems in which the city is organized. The shift of attention from the scale of the building to the aggregate and urban fabric one revolves around the morpho-typological parameters, which together with the constructive ones, are the basis for expeditious assessments of vulnerability on the urban [2,10] and territorial scale [11].

Solar energy availability is a key variable to assess buildings energy performance in the urban environment. On one hand, building's solar gains account for a significant part of the energy balance during both winter and summer; on the other hand, the potential for harvest solar energy in the urban context is directly connected to the potential for renewable energy systems to enhance energy efficiency at urban scale. Several studies reported the effect of urban metrics on solar performance [12,13]. Some of them consider real urban areas and related data in order to predict their solar potential using UM to better characterize the layout of the case studies [14,15]. Other studies focused on understanding the influence of urban morphology, described and controlled through UM, to optimize the solar potential of urban areas. The latter use normalised models derived from representative urban textures [16,17]. To perform solar energy analysis at urban scale, experts use specialised tools recently developed for the purpose, i.e. *Radiance*, *DIVA*, *CitySim* and *SUNtool*. These tools fostered the implementation of solar analysis in design practice. However, two factors still limit their widespread to urban planning and design: the specialist knowledge required to set up the simulation and the amount of time needed to realize the model at urban scale. For these reasons, this study uses the capability of UM to predict solar energy availability at urban scale. The method, based on a previous study reduces time and data necessary to carry out solar analyses, useful in the early stage of the design process [18]; this method is intended for architects and decision makers since do not require specialist knowledge and data required for the calculation are generally used in urban planning practice and are easily accessible for many cities.

In the last years, the importance of integrated approaches between energy and seismic analysis is testified by a growing number of studies. The relevance is particularly highlighted regarding the retrofit of the built heritage, implementing building envelope systems for energy, structural, and user-oriented retrofit that would significantly increase the commercial value and the life cycle of buildings, involve the users in attractive and visible solutions and, reduce the costs of energy [19]. Other studies regard the renovation of a high-rise building, focusing on the architectural quality to demonstrate the cost-effective evaluation of the convenience of the integrated approach in supporting public administration in social housing renovation [20]. On the one hand, the importance of the urban scale is nowadays recognized and investigated in several types of research for both the energy and the seismic performance, focusing the influence of urban morphology on these features [21]. On the other hand, the integration of the approaches is still focused on the building scale. The aim of this research paper is to overcome this compartmentation of knowledge, proposing a preliminary approach on integrated multicriteria analysis for the historical city, based on morpho-typological indicators in order to describe the seismic vulnerability and the solar radiation availability.

2. Methodology

2.1. The city of Rieti

The city of Rieti, located in Central Italy, is the ideal urban environment to test seismic and solar performance of historical urban form. Rieti concerned with the category of medium sized (between 5,000 and 60,000 inhabitants) local council areas, which make up about 30% of the total of Italian local government bodies and concern over 50% of the population - Ancitel on Istat database (01/01/2018).

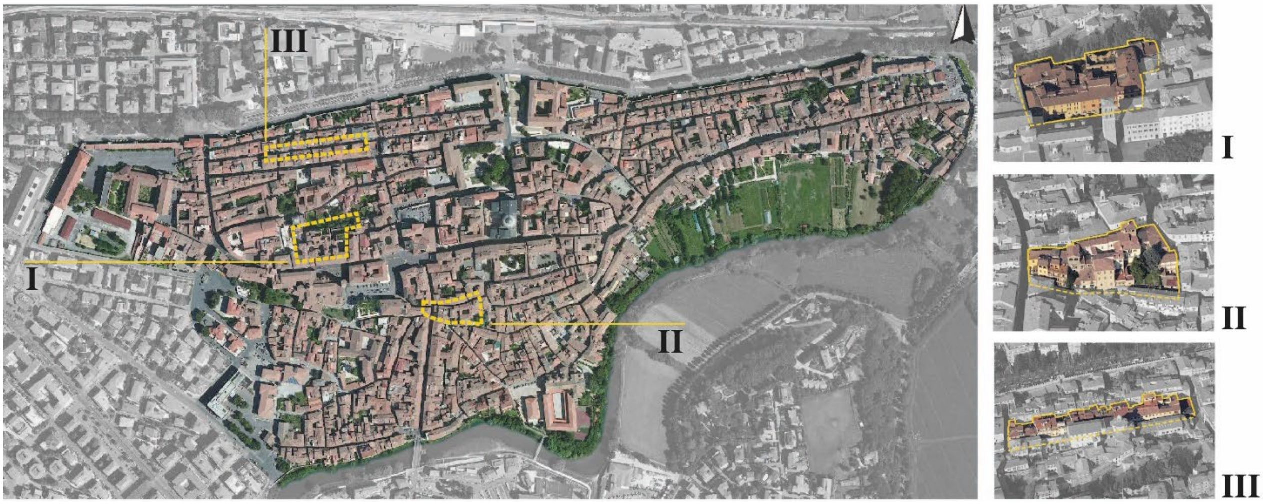

Figure 1 Aerial view of the city of Rieti and case studies identification.

The municipality of Rieti is characterized by well-conserved historic centre covering an area in proportion to its population and which falls in an area of medium-high seismic risk (zone 2), the area recently stroke by the 2016 Central Italy Earthquake. Case studies are three representative aggregates of typical urban texture of Rieti: case **I** is located in the core of the roman town, following the ancient settlement, along the *decumanus*; the aggregate, as a portion of an urban texture characterized by a clear hierarchy of streets and public space, is the result of stratification and alteration of the original seventieth century buildings; case **II**, close to the medieval walls, is part of a more articulated urban fabric with narrow streets; case **III** is located in the first medieval expansion, with a regular street pattern and mainly based on row houses, partially modified or replaced in recent times.

2.2. Metrics for urban form analysis

The range of variation of several Urban Metrics (UM) and Morpho-Typological Indicators (MTI) have been calculated. The formers have been derived from three-dimensional models of the urban textures with a level of detail LoD1 [22]. The latter have been derived from typological-observational methods, based on data of damage and vulnerability observed on previous earthquakes and normally calibrated on the use of existing databases with a level of accuracy 1 [7]. The UM taken into account have been derived from eight basic variables, widely common in urban and building studies and easily accessible (Table 1). Each metric gives information on some qualitative aspects of the urban form, such as the shape of the buildings, the plot patterns or the street network. It has been already proven that UM have a causal relation with energy performance at the urban scale [3,23]. Morpho-typological indicators are derived from the observational approach on the damage of similar structures, common in vulnerability studies for expeditious assessment at urban and territorial scale. Each indicator gives information on some qualitative aspects of the urban form and structural behaviour of the aggregate, such regularity of shape, interactions with existing buildings, transformations and interventions (Fig. 2 Table 2). The MTI analyzed are derived from the studies conducted on the case study of Nocera Umbra [24] and from the studies of Borri and Avorio, carried out on the masonry construction. In analogy with Fazzio's studies [24], qualitative indicators have a variable weight ranging from 3 to 10.

Both UM and MTI have been divided into three groups, considering their peculiarities in describing urban form: *Plan, Space* and *Analysis-oriented*. Besides, in order to facilitate the understanding and of the results, a comparison between cases has been conducted by means of normalization (Table 2). The groups collect UM and MTI with similar properties in terms of description of different features of the aggregates: *Plan* indicators are able to represent the main features on the horizontal plan; *Space* indicators describe the three-dimensional complexity; *Analysis-oriented* indicators are useful to predict solar and seismic performance at early stage of analysis.

2.3. Aggregate seismic and solar performance

The "vulnerability of the aggregates" is defined as the susceptibility to damage and loss of organization due to the complex of risk factors to which individual blocks are subjected, deriving from typo-morphological, structural and functional aspects [24]. In this study, we refer to “relative vulnerability” of the aggregates, because the normalization is carried out on the dataset of each city. Given the typological-observational nature of the vulnerability assessment methodology, the results have a greater relevance for the urban management in order to understand the vulnerability level of different portion of the urban texture.

Analogous to the cited studies, the seismic performance has been analysed thought two group of indicators, as part of a wider research [10]: descriptor parameters of the morphological and typological characteristics of the aggregate, related to the overall configuration; descriptor parameters of the general structural characteristics, related to the average characteristics of building components and aggregation methods. In this paper the first group of indicators have been considered (Figure 2).

The solar irradiation on building façades has been assessed for the selected urban aggregates of each digital model, considering urban obstructions during the whole year. We focus on the solar performance of the vertical surfaces since they are directly related to the building's solar gains which account for the most part of the energy demand in the Mediterranean latitudes. *Heliodon2* software and *Heliodon2plus* data post-processor have been used for simulations. *Heliodon2* calculates the spatial and temporal distribution of solar energy on building façades, considering a cloudless sky condition during a given period; the associated post-processor use climate data to obtain direct and diffuse solar radiation. Calculations have been carried out on the base of the latitude of the city of Rieti (42°24' N 12°51' E).

3. Results and discussion

The main results, with regards to solar irradiation on building façades and seismic performance, UM and TI evaluation are here presented and discussed in two separate subsections. The results have general implications to seismic and solar performance at urban scale in the historical city of Mediterranean climate.

3.1. Seismic and solar performance

The assessment of seismic vulnerability for the aggregates shows the most critical situations for the cases with higher Sd or TAd, which is usually reflected also on articulated geometric configurations (**I**), and for irregular aggregates with high values of PT, PTis and AT, located in complex urban fabric. The latter due to the relation with the surrounding aggregates (rSA) increasing the induced vulnerability (**II**). On the contrary, case **III** emerges as relatively less vulnerable as described by lower PT (regular linear trend) and lower TAd (mainly composed of building with a high degree of typological homogeneity). In order to complete the seismic analysis and to evaluate the relative vulnerability index, indicators based on structural characteristics are reported in Table 3.

Global façade energy density	kWh/m^2	193,5	191,4	237,8
Direct solar radiation fraction		33%	40%	37%

* *Considering cloudless sky condition*

Concerning solar energy, irradiation on façades ($kWhm^{-2}y$) is directly related to a combination of high-density-related values (GSI, VOSR, Vd) and low SF/SVF values. In historical urban textures, reasons for better solar access compared to observed tendencies, are due to specific morphological features: lower urban density combined with optimal façades orientation (**III**). Instead, solar performance is in general poor for cases with high urban density (as described by each UM). Even though similar surface exposure and lower SF/SVF, case **II** receives more solar radiation compared to **I**. This result is reliably represented by UM (FSI, GSI, VOSR and VAr). Comparing fractions of direct and diffuse irradiation for case studies, we notice that differences between **I** and **III** are almost levelled by increasing of diffuse radiation (Table 4). Based on these results, it can be argued that, considering the most reliable metrics for solar analysis as indicated in previous studies [18], **II** and **III** performs better than the average. The former, due to the presence of several courtyards and higher ratios of façade surface/built volume. The latter thanks to favourable texture orientation in relation to façade exposure.

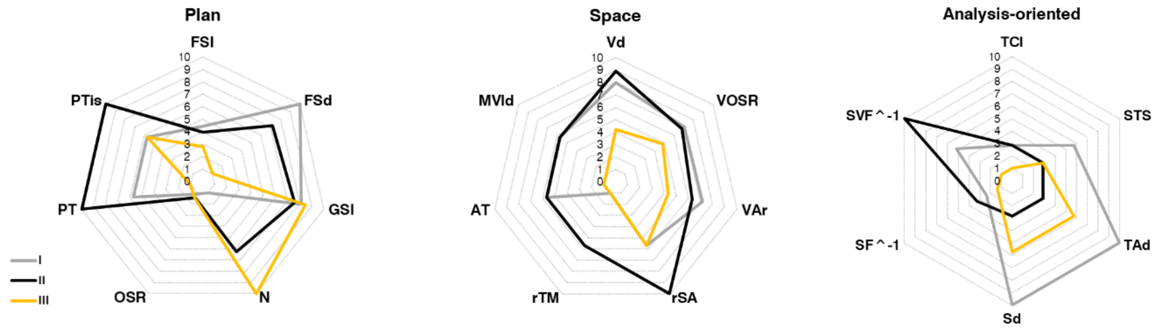

Figure 3 Comparison of normalized UM and MTI (grouped into Plan, Space and Analysis-oriented)

3.2. Urban form metrics and typological indicators
