Table 2 and Figure 3 show respectively the computation of UM and MTI and the corresponding normalized values for case studies (decimal scale). The purpose of the diagrams is to visualize the urban scale performance: the higher the value of an indicator, the worse the behaviour of the aggregate in term of solar availability and seismic vulnerability. For this reason, we use reciprocal value for SF and SVF. In general, to combine different indicators helps clearly understand building density and compactness of urban fabric: compared to cases **I** and **II**, we can observe that case **III** is more compact and have less building intensity, producing openness in the urban form. By grouping different types of UM and MTI is possible to highlight urban form features of each case as shown in Figure 3. Case **III** values clearly reflect differences in urban layout and morphology of the island. Moreover, the difference between **I** and **II** appears: **II** has higher values in most of the *Plan* and *Space* metrics, while **I** has higher values in all the *Analysis-oriented* metrics. The case **I** and **II** are the aggregates with lower performances, while case **III** always covers the smaller areas of the graphs, showing as in a regular urban texture exist more favourable condition.

First-stage evaluation of seismic vulnerability and façade solar availability at urban scale can be obtained making use of the diagrams: the smaller the area on the proposed diagrams, the greater are the intrinsic capacities of the urban aggregate to perform at both levels.

4. Conclusion

Our paper presents an investigation on the capability of a multi-criteria analysis based on UM and MTI to predict urban seismic vulnerability and solar availability in the historical city located in Mediterranean climate. The Plan indicators highlight intrinsic criticalities of urban texture regarding the horizontal plan, therefore strictly related to urban form and very hard to transform without invasive action that could compromise the historical value. The Space indicators, due to their three-dimensional definitions are suitable to describe renovation strategies based on urban acupuncture and geometric regularity, taking into account the interaction with the urban surroundings. The Analysis-oriented indicators are suitable to control urban form and typology implications of solar and seismic performance and to improve them through solar and seismic sensitive design.

The proposed multi-criteria analysis model has been structured with several purposes. On one hand, it can support policy maker decisions according to the performances of urban aggregates, in order to differentiate public investments and incentives; on the other hand, it should be integrated in the early stage of design process, taking into account the solar façade availability and seismic vulnerability of urban areas to guide urban renovation strategies.

2 DEGREES – understanding the contribution of cities to a carbon neutral society

Wittstock B, Goerke J, Blumberg M

thinkstep AG, Hauptstr. 111-113, 70771 Leinfelden-Echterdingen, Germany

bastian.wittstock@thinkstep.com

Abstract. Climate change is understood to be a factual situation to deal with and the world community has agreed with the Paris agreement of 2015 to limiting global warming to 2 °C above the pre-industrial state. Cities and urban areas are at the core of anthropogenic climate emissions. So far, however, cities are not generally recognized as major action fields for a climate neutral society. Yet, individual examples of cities with a strong climate neutral agenda prove the overall societal and economic advantage of their actions.

This study analyses 15 European cities to understand the influence and potentials, local actions and political activities as well as targets that cities can take and define to mitigate climate change and contribute to the global 2-degree goal. The empirical evaluation of the cities was conducted in 2017, using the science-based targets approach on public buildings as initial pilot. The study identifies critical internal and external success factors for effective climate engagements, particularly from the 1/3 of the cities whose strategies comply with the 2-degrees target. Criteria and levers are derived that help cities transform into low carbon communities. From that, a framework model and operational guidance are developed, binging cities in the position to develop their individual path towards the 2-degree goal.

The results of the study are demonstrated by the case of the Swedish community of Växjö, showcasing how the early and broad adoption of low carbon policies and actions results in overall economic growth and prosperity as a 'green community'.

1. Background and Introduction

The summer of 2018 lead to a fundamental change in the broad public reception of the subject of climate change. To broad parts of society in Central Europe, it became evident that climate change does already take place [1]. The global climate has warmed since the beginning of the industrial revolution of the 18th century by about 1 degree Celsius. Also, until 2013, 12 of the 14 highest annual average temperatures occurred in the time frame from 2000 to 2013 [2]. Overall, a broad consensus has been found on the need for action against climate change and even the youth increasingly raise their voice to demand for action [3].

In 2015, the parties of the Paris COP 21 conference (United Nations Framework Convention on Climate Change, 21st Conference of the Parties) agreed to limit global warming to below 2°C, or even 1,5°C compared to the pre-industrial state [4]. With ¾ of the world's population soon living in urban areas, cities are a major player for effectively mitigating climate change. For municipal administrations, however, effectively acting against climate change is a major challenge, as conventional mechanisms of administrating a city fall short for doing what needs to be done to save the climate.

This study analyzed the activities of 15 European cities to understand their current activities towards mitigating climate change. From this analysis, mechanisms were derived to help municipalities be successful in working against climate change. Obviously, cities and municipalities have a broad range of action fields to engage in working against climate change. This study explicitly focuses on the municipal building stock, as this is one of the common fields for all municipalities. Also, the municipal building stock is of special interest due to it's potential or actual function as a role model for the private real estate industry. With this focus, the relevance of other sectors like mobility and transportation should not be negated, but here, a more city-wise view into municipal activities is required. Also, some findings are believed to be applicable or transferable to other municipal activities, without further elaboration of this point in the study.

2. Empirical analysis of municipal activities

To gather information on how cities and municipalities[1] act against climate change, data from several European cities is assessed. Both, by means of a questionnaire based inquiry with the cities and by applying the Science Based Target (SBT) method [5] to understand the contributions of cities to the 2°C-target.

2.1. Methodology

Quantifying the carbon emissions of a city or municipality forms the basis for understanding or even defining a carbon reduction target for the city or municipality. The quantification of carbon emissions follows the Greenhouse Gas Protocol, more specifically the Global Protocol for Community-Scale Greenhouse Gas Emission Inventories [6].

This protocol defines three different scopes for emissions. Scope 1 refers to direct emissions from activities and operations within the city boundaries. Scope 2 denotes emissions from Energy production and distribution, both in- and outside the city boundaries and Scope 3 relates to upstream emissions for any goods or services imported into the city boundaries. For municipalities, the three scopes analogously relate to activities and operations that are directly associated with municipal buildings and facilities or that are imported directly to municipal facilities.

For the purpose of this study, the focus lies on municipal buildings. Municipal administrations generally serve as local role models for their cities so that any climate change actions of municipalities most likely relate to their buildings and facilities. In addition to that, municipal buildings are directly available for local administrations to establish climate actions.

With the help of a questionnaire, information was collected from the involved municipalities on their approach to climate action for municipal buildings. The survey covered both, a section on a municipality's perspective on climate change and a section on their actual carbon reduction targets. The aim of the survey was particularly to understand whether the cities' current engagement in climate actions (in the municipal building sector) conforms with the 2-degree target and to identify critical success factors and barriers towards successful climate mitigation actions.

For this, the Science Based Targets method framework [5] is used. It provides a set of mechanisms that allow to derive sectoral, company- or city-specific greenhouse gas emission budgets and reduction pathways from the 2-degree target from Paris. To calculate the required changes in emissions for each of the study cities, the Sectoral Decarbonization Approach (SDA) [7] is used. This method breaks down the overall carbon emission budgets to sectors and finally to individual companies or cities.

The required emission reduction based on the SDA calculations are compared with (partially estimated) current reduction targets that the respective municipalities have defined.

2.2. Results and findings

The survey and the subsequent calculations of the required emission reductions for the cities present a diverse landscape. Some cities have actively used the Science Based Target method before to define

[1] In this article, 'city' refers to the geographical boundaries for a dedicated urban area (and this can also include an entire metropolitan area), while 'municipality' denotes the administrative bodies of a city government.

their individual 2-degree targets and act accordingly. Other cities have no targets in place that exceed national legal requirements and correspondingly have no dedicated climate actions planned.

2.2.1. Cities' current engagement in climate action. A total of 42% of the participating cities with enough data (n=12) have targets defined that comply with the 2-degree target. A much larger portion of the participating cities – 73,3% - however, consider their carbon reduction targets to be very ambitious and only 1/3 of the participants have faith in meeting the targets in the defined time frame. This also stands in some contrast to the finding that all cities state that their city is already affected by the consequences of climate change and that the effects of global warming are a relevant issue for their city.

The carbon reduction targets that cities have defined typically are derived from the current situation and are defined in a way that reaching these targets can be achieved with small or reasonable effort. Two thirds of the cities adopt targets from national or EU-targets, and 1/3 of the cities have targets that reach beyond national targets. Only 10% of the participating cities align their targets with IPCC indications.

The survey also concluded that Scope 1 and 2 emissions from cities particularly stem from fossil fuel. This leads to the conclusion that increased energy efficiency for buildings, optimizing energy systems and grids for the entire city, changing energy sources, e.g. towards biomass, and working to influence citizen behavior are among the most effective mechanisms to mitigate climate change.

In addition to that, the survey also made very clear that cities also highly depend on external factors, particularly the decarbonization of external energy supply. While some cities actively work on reducing dependency from external energy sources, for other cities, this appears to be a significant obstacle towards carbon reduction.

2.2.2. Findings from applying the Science Based Targets model. As said, the carbon emission reduction targets of 42% of the cities are aligned with the 2-degrees target. For this alignment, the cities' building sector requires an average emission reduction of 26% by 2030.

Table 1 sets the required emission reduction targets that have been calculated for each city (if enough data was available) with the Sectoral Decarbonization Approach (SDA) in relation to the cities' actual reduction targets for 2030.

Table 1. Cities' required emission reduction according to SDA & estimated current reduction pathways for 2030.

City	Required emission change (negative = reduction), based on SDA	Current reduction target (estimate) (positive = reduction)
Aachen	-32%	< 32%
Aberdeen	n/a	n/a
Aarhus	-22%	100%
Bergen	-3%	100%
Bremen	-50%	< 60%
Erlangen	-18%	7%
Glasgow	-64%	< 64%
Helsinki	-34%	< 34%
Karlsruhe	-37%	16%
Leeds	n/a	n/a
Limerick	-10%	35%

City	Required emission change (negative = reduction), based on SDA	Current reduction target (estimate) (positive = reduction)
Munich	n/a	n/a
Pamplona	-1%	8%
Plock	-55%	< 55%
Växjö	+21%	100%
Average	**-26%**	**n/a**

Table 1 (cont'd). Cities' required emission reduction according to SDA & estimated current reduction pathways for 2030.

The table shows clearly that the current ambitions of cities are higly diverse – from a 7% reduction target (Erlangen) to a complete decarbonization (Aarhus, Bergen, Växjö). One exceptional case is the one of Växjö. Due to their very early adoption of climate change mitigation actions – see section 3 – Växjö currently has a lower carbon emission profile than what would be required for a reduction path for 2030. This leads to a hypothetical additional emission budget, which is reflected by the positive number for the required emission change. Obviously, the actual effect of this situation is that Växjö has a major advantage to other cities when moving to their own target of complete decarbonization of the municipal building sector by 2030.

The table makes it clear that most cities face major challenges in the coming decade, when moving towards contributing their share to the Paris agreement.

2.2.3. Critical Success Factors. From the survey, internal and external factors are derived which have significant influence on a city's success in moving towards decarbonization. External factors, particularly the geographical location and the available natural environment have a major influence on the energy demand and on available local energy sources (e.g. availability of power generation from wind and water, availability of biomass). Also, changes in the grid energy mix cannot be easily influenced but have a major impact on the carbon emissions associated with the building sector.

In contrast to those external factors, a set of internal factors are identified as critical to success in achieving significant emission reductions. These critical success factors are

- Commitment,
- Collaboration,
- Funding,
- Capabilities.

Commitment refers to establishing a consistent thinking across all departments of a municipal administration base on developing and sharing a long-term vision. A common understanding towards decarbonization across political parties has repeatedly been reported to be essential for long-term success beyond single legislative periods. Also, higher political support for administrative actions is essential for successful execution of climate change mitigation measures.

Collaboration across departments inside the municipal administration is essential and requires efficient structures. Complex structures with a diversity of ownership and management / operational responsibility for municipal buildings, in contrast, are a significant challenge. Also, effective collaboration with non-municipal stakeholders of a city is critical for success. Available instruments need to be exercised and trained, e.g. Public-Private-Partnerships (PPP) with Energy-Service-Companies (ESCOs).

Funding refers to typically high initial investments for carbon-saving measures. Particularly if long-term financial savings from taking actions are neglected – as is typically the case – funding with available sources may be a challenge. While some funding resources from national and European programs may be available, climate change mitigation measures require sufficient initial financial resources.

Capabilities refers to the need for skilled and educated staff within the municipal administration to support changes in technologies and approaches. But it also refers to the need for (not only financial) resources, e.g. with enough skilled workers at construction companies to effectively execute measures.

3. Case Study: The City of Växjö, Sweden

One of the forerunners of urban climate actions surely is the city of Växjö in Småland, Sweden. The case of the city of Växjö is elaborated with reference to the above-named critical success factors. Växjö is a city with a population of 92.000 and an economic growth of more than 30% (GDP) from 1993 to 2015.

Commitment: The city's initial focus on environmental issues dates back to the 1960s, when the city started to take action against pollution of their surrounding lakes. In the following decades, the city continued to not only remediate polluted areas but also to step into biomass based district heating, increasing use of local renewable energy and to respond to the United Nation's program for sustainable development, the Agenda 21 [8]. The city of Växjö decided to take a leading role in sustainable development in Sweden and adopted their environmental policy in 1993 and started to monitor per-capita-CO_2-emissions.

As early as in 1996, Växjö announced for the first time the ambition to become a fossil-fuel-free city, which is now targeted for 2030, including homes, industry, and transportation – including planes taking off from the local airport.

Collaboration: Along the long-term chain of activities in Växjö, the municipal administration continuously engaged with all stakeholders in the city. This includes initiatives to influence the behavior of citizens, as well as providing support to act appropriately. Apart from providing cheap district heating (see below) from local biomass-sources, Växjö also secured attractive public transport to encourage citizens to stay away from fossil fuel powered cars, as an example.

Funding: One of the effects of Växjö's early uptake of environmental awareness and actions was that both, national Swedish and European funding was repeatedly available for new projects. Also, because of Växjö's early shift to biomass-based district heating, the city was able to offer cheap renewable energy to their citizens, when Sweden introduced a CO_2-tax in 1991.

Overall, the focus on sustainable development allowed the city of Växjö to reduce CO_2-emissions by 58% from 1993 to 2016, while securing a GDP-growth of 32% from 1993 to 2015.

Capabilities: From the municipality's feedback, it became clear that a general entrepreneurial culture and openness to try new ideas among the citizens was a very helpful basis to engage in sustainable development. Also, a general desire for independence from outside energy suppliers, fueled by the oil crises of the 1970s and 1980s, greatly supported the city's move towards local, fossil-fuel-free energy supply.

Overall, the case of Växjö nicely demonstrates how all of the named critical success factors need to be integrated in a positive way for a city to be successful in integrating sustainable development and mitigating climate change.

4. Framework model to support cities act towards the 2-degrees target

Both, the cities-survey, as well as a study from C40 Cities[2] and ARUP [9] clearly indicate that cities generally need to increase engagement towards climate change mitigation. Also, it is clear that many cities require active support to do so. Overall, required technologies to change to low carbon activities are available, yet the uptake of these technologies and the execution of climate actions is the problem.

---

[2] C40 Cities is a network of almost 100 of the world's largest cities, aiming at increasing climate actions and promoting sustainable development. www.c40.org

For this means, a management plan is presented, called “Navigating the Path”. It utilizes the identified critical success factors and provides a concrete framework for bringing cities into action.

4.1. Navigating the Path
Core of this management plan is designing climate action plans. Such a climate action plan reflects a comprehensive approach to urban concepts, accounting for all aspects that matter, both directly for climate change mitigation, as well as for integrating climate actions into the municipality’s and city’s traditional activities.

Basis of the management plan is the calculation of the relative contribution of a city to limiting global warming, by using the Science Based Target approach (particularly the Sectoral Decarbonization Approach). With the derived emission reduction targets, a solid, manageable target is defined.

The actual management objectives are developed from interpreting the above-named critical success factors for the respective city. In that sense, it must be noted that a general understanding of the elements of a management plan may be generic, while the concrete management plan must be specifically tailored to a city’s situation. Any “one-fits-all” management advice were too arbitrary to provide meaningful guidance.

4.2. Critical success factor “Commitment”
As a basis, accurate and current data is required for any action on climate change. With a solid data foundation, a Science Based Target calculation can be executed. It is important to also integrate the city’s future economic development and to differentiate between sectors, in order to provide a clear picture on goals and their economic value. This will form the basis to develop a common understanding, avoiding confusion or uncertainty on the relevance of the information and the targets, bringing faith in the decisions to be taken.

One useful guidance document for setting targets for reducing carbon emissions is a set of four action areas with 12 opportunities that have been identified in a study “Focused acceleration” from C40 and McKinsey [10]. These four action areas are:

- Decarbonizing the electricity grid,
- Optimizing energy use in buildings,
- Enabling next-generation mobility,
- Improving waste management.

The study “Focused acceleration” also estimates the share of 2030 emission targets that a single opportunity may deliver. Using these action areas and the dedicated opportunities in combination with the calculated SBT-based reduction targets, a city can obtain very specific, operational targets to work against.

4.3. Critical success factor “Collaboration”
The imperative of active collaboration should not be considered to be different for climate change mitigation actions. Moreover, a general understanding of the obstacles and barriers for collaboration need to be adopted to the matter.

Important elements to operate with may be transparency on the different and potentially competing objectives of stakeholders, engaging in aligning these objectives, as well as moderating lack of understanding and the different perspectives towards a situation. Quite frequently, the involvement of external experts on the subject as moderators and solution developers is a very feasible means of improving collaboration.

4.4. Critical success factor “Funding”
With about 70% of the surveyed cities lacking the appropriate financial resources, external experts may cooperate with a municipality’s budgetary department to identify the required funding. This requires to consider all available funding sources and to develop reliable business cases for urban climate projects.

This may also include the identification and development of alternative financing instruments as well as the development of public-private partnerships.

4.5. Critical success factor "Capabilities"

For the critical success factor *Capabilities*, a direct focus on the above-named action areas helps to understand the need for the right skills. Once the specific opportunities to engage in climate actions are identified, internal and external experts can start with developing project roadmaps.

For the action area *Decarbonizing the electricity grid*, both, a thorough understanding of conventional and innovative electricity generation and storage technologies is required, as well as a solid approach to grid management and organization.

For the action area *Optimizing energy use in buildings*, often a broader perspective than the traditional view on a building, omitting user-induced energy consumption is needed. The required capabilities range from innovative processes and methods (Building Information Modeling – BIM to Lean Construction Management – LCM) to understanding the inter-dependencies of energy consumption with other aspects of buildings, typically integrated by green building certification schemes.

In the action area *Enabling next-generation mobility*, the focus will avert from the car-centric transportation planning to ease transportation without cars and to integrate novel transportation technologies.

In the action area *Improving waste management*, the focus will move from recycling or disposing of waste to real circularity in all material streams. This will increasingly include the cities' buildings and construction works to be understood as valuable resource repositories. Also, focus will grow on aligning supplier, distributor and consumer networks regionally to optimize material streams.

In addition to these action areas, the field of *Digitization* will play a vital role in changing cities' approach to new objectives such as climate change mitigation. Here, this is even more the case as climate actions intensely rely on various stakeholders and large groups of citizens to align on specific actions which are based on solid data. Hence, ICT technologies and solutions are required for a wide range of objectives, typically integrating large sets of data and providing meaningful interpretation of the data to support decision making.

5. Summary and conclusions

The empirical study done with 15 European cities on their current situation in the field of mitigating climate change shows a diverse picture. The cities' engagement ranges from essentially being compliant with current laws to thorough strategies for becoming fossil-fuel free within a decade. Only a small portion of cities have set carbon reduction targets that comply with the 2-degrees target that has been defined in the Paris agreement of 2015.

The Science Based Targets method provides a very useful framework to derive carbon emission reduction targets from the 2015 Paris agreement to the level of an individual city and dedicated sectors of the city. The Science Based Targets method is also used to estimate the cities' current position on the way to comply with the 2-degrees target and the required reduction targets.

One impressive example of how a city has developed into a forerunner of climate action is the city of Växjö, Sweden. This city has managed to achieve significant economic growth while decarbonizing the city to quite an extend already. Moreover, it has a clear plan to become fossil-fuel free (including planes staring from the local airport) by 2030.

From the survey, four critical success factors, commitment, collaboration, funding and capabilities are derived. These critical success factors must be positively addressed to enable successful climate actions.

From these insights, a management plan "Navigating the Path" has been developed, covering the critical success factors on a framework level. This management plan gives guidance on how to tackle the points raised and on how to engage in climate action to reach carbon emission reduction targets, which have been defined before.

Overall, the study clearly shows the need for cities to actively assume responsibility for their contribution to meeting the 2-degrees target. It shows that some cities did become active quite some time ago and it provides an instrument for other cities to effectively follow. With the developed management plan, cities have been enabled to break down the hard to digest objective of acting to meet the 2-degrees target into operational tasks to reduce carbon emissions.

A more elaborate report on that matter [11] is available with the authors.

Acknowledgments
The authors wish to thank Ms. Sarah Benarey-Meisel for her contributions, particularly to the empirical analysis, which were part of her study program at Chalmers University and ESB Business School Reutlingen University. The authors also wish to thank Mr. Gregor Grassl from Drees & Sommer for supporting the study.

On net zero GHG emission targets for climate protection in cities: More questions than answers?

Lützkendorf T[1], **Balouktsi M**[1]

[1]Karlsruhe Institute of Technology, Centre for Real Estate, Karlsruhe, Germany

thomas.luetzkendorf@kit.edu

Abstract. Two separate, but interacting, global agendas are now leading to new, additional requirements for the future development of cities: The UN Agenda 2030, putting cities at the heart of sustainable urban development with its Sustainable Development Goal (SDG) 11, and the Paris Agreement COP21 adopting the 1.5 °C target as a basis for global emissions reductions. Regulators and researchers have widely recognized the necessity to put cities, as an important object of assessment, and city authorities, as an important actor group, at the core of climate mitigation efforts. For cities themselves this topic becomes a factor of competition among peers. In their pursuit of a low carbon future, however, they are confronted with a number of theoretical and practical questions regarding target setting and subsequent planning for mitigation. As a contribution to the current discussion, the paper initially clarifies on which principles the allocation and accounting of city-related greenhouse gas (GHG) emissions are typically based. A good understanding of the GHG sources and reduction potentials is essential for defining feasible targets and designing efficacious reduction strategies. Built on this, the paper then presents how climate targets are defined at city level and analyses the methodological considerations that arise in the case of target-setting approaches involving bringing the emissions balance to zero. Although first definitions of "net zero emission" concepts on an urban scale can be found in literature, their precise meaning and applicability still remain vague, with unclear system boundaries, calculation and assessment rules. This paper provides a definition framework for clarifying such concepts.

1. Introduction

2015 marks a historic turning point for the future development of cities: The UN Agenda 2030 with its Sustainable Development Goals (SDGs) and the Paris Agreement have put in place new framework conditions for a sustainable transition to a greenhouse gas (GHG) neutral and climate-resilient future. The two agendas cannot be achieved if tackled individually. Climate protection is an important partial aspect of sustainable development and contributes to the preservation of the natural basis for life. Conversely, long-term climate goals can and must only be achieved by sustainable means, and thus, if placed in the wider context of sustainable development. SDGs make this abundantly clear with SDG 7 "Affordable and clean energy", SDG 12 "Responsible consumption and production" and SDG 13 "Climate Action". At the same time, SDG 11 aiming to "make cities and human settlements inclusive, safe, resilient and sustainable" recognises cities as an important level of action encompassing active climate protection as a sub-goal among others.

In this sense, putting cities at the core of climate mitigation efforts is a practical imperative to achieving several SDGs. But it is also a strategic one: although cities occupy only a tiny proportion of the total global surface area (around 3%), over 70% of global CO2 emissions from final energy use can be attributed to them [1] (accounting for where emissions are caused, the respective proportion would be about 30% lower). In the absence of action, this proportion will be further raised due to the projected rise of the global population in cities to 2.5 billion plus by 2050 [2]. Today, the potential for cities to limit the magnitude of climate change through effective mitigation actions to reduce their environmental impact is widely recognized [3]. This has led to a continuously growing number of international initiatives and organisations which assist city governments in proceeding towards decarbonisation [4]. This assistance takes a variety of forms, such as international guidelines or reporting platforms (e.g. the carbonn® Climate Registry), broad catalogue of measures (e.g. C40 Cities Climate Leadership Group), or collective agreements (e.g. the Global Covenant of Mayors for Energy and Climate).

However, tapping the full potential of cities in the area of climate protection necessitates the discussion of some basic challenges: first of all, the “city” as an object of assessment and level to act is difficult to define and model due to its dynamic, complex and constantly evolving character. Cities involve not only tangible assets (e.g. buildings and infrastructures), but also intangible values (e.g. cultural heritage, social relationships, etc.) often being important determinants of, or barriers to, progress. In this regard, experts ask for more interdisciplinary collaboration between hard and soft disciplines [5]. The “city” is also a network of actors and agents of change – with the city government as the main one. Secondly, the local climate action plans that are developed and implemented need to be built on long-term ambitious targets, aligned with the global goals. Setting net zero emission targets facilitates city officials to work towards ambitious strategies that are consistent with the required greenhouse gas neutrality by the second half of the century. Nevertheless, the precise meaning and applicability of concepts related to zero emissions remain unclear. The heterogeneity of the different accounting schemes [4, 6] creates problems for target setting, action planning and monitoring of success.

The paper deals with the aforementioned challenges by answering the following questions: a) What is the definition of “city” and its role in reducing GHG emissions as part of a sustainable urban development? b) How the target of net zero GHG emissions increasingly adopted by cities can be more precisely defined? To answer these questions, the city authority’s level of influence and control in each sector and field is taken into account as a necessary ingredient for making change happen.

2. City: “actor”, “level of action” and/or “object of assessment”

A clear definition and system boundary setting of “city” is essential for identifying the different sources of greenhouse gas emissions tied to it. There is no universally applicable definition of what constitutes a “city” yet [7,8]. City is a system of interdependent subsystems that can take on a variety of forms and functions. Depending on the research discipline (i.e. urbanism, geography, economy, sociology, etc.), a city can be seen as an administrative unit, an assemblage of buildings and infrastructures, a system with energy- and mass flows, a place to live and work, a place of history and cultural heritage, a value-creating system, or a network of actors amongst others. All these definitions represent different perspectives with regard to city and exist equally side by side.

It is important to select appropriate urban-specific system boundaries based on the specific targets and research questions [9]. In the context of the present paper, where the aim is to analyse the establishment of aspiring targets for GHG-emission reductions, three of the possible perspectives are considered: (1) the city as a “system” with energy and mass flows entering and leaving its boundary (and therefore a system associated with emissions embodied in the inputs and output of its processes); (2) the city as a “place to live and work” with a corresponding demand for goods and services (demand side) that can be assigned to individual needs (e.g. housing, food and mobility), as well as with a corresponding supply of goods and services (supply side) both in and outside its boundary (i.e. a “place” associated with emissions generated from the production and transportation of products and services to satisfy the “consumers” in the city and emissions directly caused from producers in the city); (3) the city as a “network of actors” whose actions influence directly and indirectly the level of emissions.

The perspectives (1) and (2) have an influence on the way emissions sources are determined and the system boundaries are demarcated. It is not “cities” themselves that cause GHGs [7] but rather particular production and consumption activities by households, businesses, industry and institutions. GHGs are therefore allocated to cities on the basis of either a) being produced within city geographical boundaries (production-based approach (PBA) – accounting at source point) or b) being generated as a result of city actors' use or consumption of goods and services and waste generation (consumption-based approach (CBA) – accounting at end user point) [10, 11]. These two different views of how city GHGs may be accounted for are linked to the capacity and responsibility of different groups of actors (city authority, consumers) to act on limiting the sources and activities that cause the greatest impact [12]. In case a), responsibility is assigned to the producers of emissions, and therefore the actors in charge of the actual sites of the emitting processes (e.g. production facilities). In case b), responsibility is assigned to the final consumers of goods and services irrespective of where they are produced (emissions are associated with their manufacture and transport), and therefore to the actors representing the demand side.

Typically, the choice is made between an accounting procedure as per a) or b) on a macroeconomic level, with the first one being much more developed and widely adopted than the latter one [13, 14]. An exact description of the selected approach is necessary for ensuring comparability when the aim is the assessment or benchmarking of performances and practices – here double counting has to be avoided (a possible risk as illustrated in Figure 1). This was also the intention of the GPC reporting standard which outlines three scopes for the inventorying of GHG emissions [15]: Scope 1 covers the direct emissions from sources located within the city boundary, and therefore the territory-based emissions; Scope 2 includes the indirect emissions that occur as a result of the use of grid-supplied electricity, heat, steam, and/or cooling within the city boundary; Scope 3 includes all other indirect consumption-based emissions.

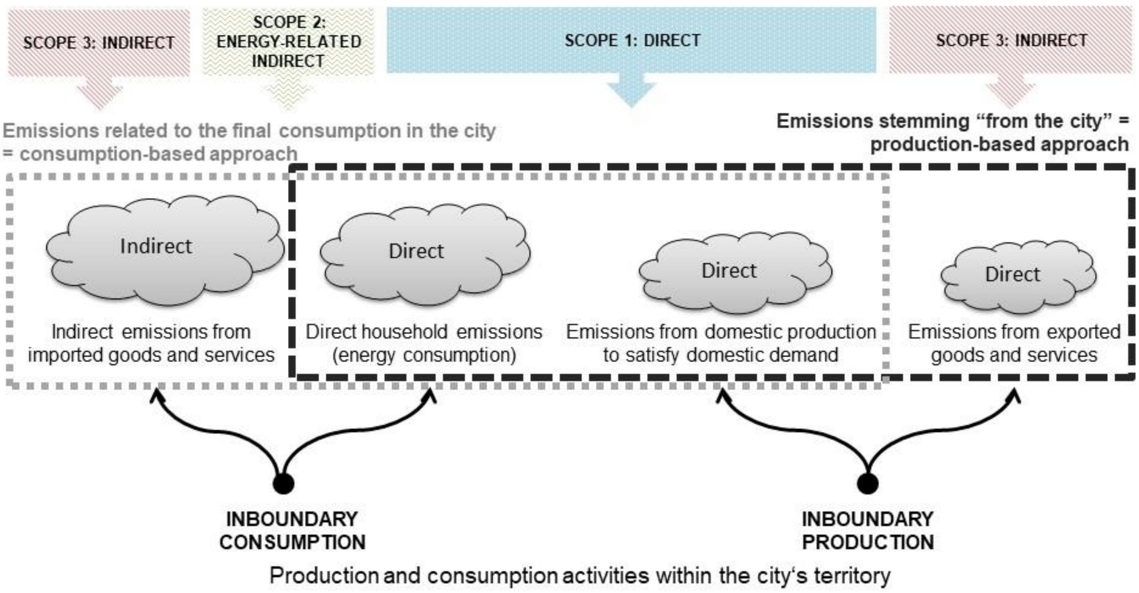

Figure 1. Illustration of the overlapping boundaries between PBA and CBA (adapted from [17]), and their correspondence with the GPC's three-scope framework [15].

For the development of mitigation strategies, the situation is different; the avoidance of double-counting is not a relevant consideration. Perspective (3) leads to the realization that actor-specific strategies are indispensable. Cities should be primarily concerned with the exploitation of all possibilities for action both on the production and demand side rather than the benchmarking of their performances. A narrow focus on PBAs – especially in the case of developed countries (and their cities) as primarily net importers of GHG emissions due to their high-consumption urban lifestyles – leads to substantial proportions of cities' GHG emissions being absent from their local emissions inventories and reduction targets [14]. This proportion can be twice or thrice as high as a city's direct emissions [16]. It is now widely recognized that effective policy-making needs to consider both approaches in a complementary fashion [12]. Only by looking at both sides efficiency, sufficiency and consistency strategies can be combined.

Once the system boundaries of the city are defined and sources and/or causes of emissions identified, the latter need to be attributed to, and therefore structured according to, key sectors (and subsectors) – when the supply side is investigated – or consumer needs (e.g. food, housing, commuting, etc.) – when the focus is on the demand side. This allows for an effective and comprehensive accounting of its GHG emissions. Already here the first difficulties arise. So far there is no uniform and generally accepted typology of sources or “polluters”. General structuring possibilities for both approaches should be worked out in standardization and harmonization efforts. However, for sector-based structures, GPC [15] can now be considered as a form of “international protocol”, since it is the one recommended by the Global Covenant of Mayors for Climate and Energy which counts more than 8000 members. For the consumer-based structures there is no “international” standard for cities, only national ones, e.g. [29].

3. The issue of target setting

The most important concept around which cities share somewhat different views and terms is the GHG (or carbon/CO2) emissions reduction target [18] as a contribution to global climate protection. Both relative and absolute targets can be used in order to assess urban-related GHG emissions and drive the design of policies and measures. Relative means to achieve a certain percentage reduction in emissions against a defined baseline, also known as “base-year target” [19], while absolute means to achieve a certain amount of GHG emissions by a target year (no need to specify a reference/baseline year in this case), also known as “fixed-level target” [19].

A global analysis by the German Federal organizations BBSR and BBR [4], which looked at 21 cities from different regions around the world, showed that many of them intent to achieve relative but not absolute reduction goals by 2030 or 2050. Some cities, however, are already shifting from relative targets to absolute global targets to guide their efforts. This category also involves conceptual targets, such as “carbon neutrality”, “climate neutrality”, “fossil-free”, “energy independence”, or “100% renewable”. Figure 2 provides an overview of some actual examples of cities with this form of target-setting. This movement towards such targets is also reflected in the emergence of a global network of cities (among other city networks operating at different scales and targeting GHG reductions in cities), the Carbon Neutral Cities Alliance (CNCA), coalesced around a shared commitment to carbon neutrality. The majority of the cities shown in Figure 2 are founding members of CNCA.

Although such absolute long-term targets provide a clear signal to all stakeholders and businesses about the city authority’s commitment to a low carbon transition, it is difficult to find clear definitions for these concepts. Focusing on the target of “climate neutrality”, according to United Nations [20], being “climate neutral” means (in general terms) to achieve net zero emissions of GHG by reducing such emissions as much as possible, while developing trade-off mechanisms to offset the remaining unavoidable emissions. Climate neutrality can therefore be used as a synonym for the scientific term “net zero GHG emissions” [21]: any remaining ton of CO_2 and non-CO_2 emissions (expressed in units of CO_2 equivalence) is balanced by the so-called negative emissions of CO_2 (i.e. CO_2 removals from biomass regrowth and/or CO_2 capture and permanent geological storage) or through offset credits.

However, although climate neutrality, as defined above, is “the goal to which all urban areas should aspire” (again according to the United Nations [20]), allowing the “balancing out” of the continued combustion of fossil fuels, without specifying minimally acceptable conditions or limits for it makes it less aspiring as “100 percent renewable”. Recognizing the dangers of leaving an unspecified room for offsets, efforts are lately focused on a more science-based perspective on the concept of climate neutrality. The negative effects of climate change can be limited if global warming remains below 1.5 °C. This possibly results in a budget of CO_2 or GHG per city or per capita. This is an ongoing discussion and the first contributions can be found at [22].

A budget-like approach has been embraced already by some cities in Germany (and Germany as a whole striving for 1 tonne CO_2 per capita and year by 2050 [23]). For example, the policy document of the City of Berlin [24] considers the ceiling per-capita budget of GHG emissions for the projected population of earth in 2050 (i.e. 9 billion people) that would keep global warming below the threshold of 2°C [25]. According to this, every person on Earth is endowed with 2 metric tonnes of CO_2eq. (life cycle-based), which means that Berlin's target should be to reduce its CO_2 emissions by 85% compared to 1990 levels (Figure 2). Another example is Munich, which, also starting from a science-based approach, sets a seemingly more ambitious neutrality target for 2050, that of 0.3 tonnes CO_2eq. per capita and year, in an effort to align as much as feasible (given the level of political enforceability) with the threshold of 1.5°C (with 66% probability) [26].

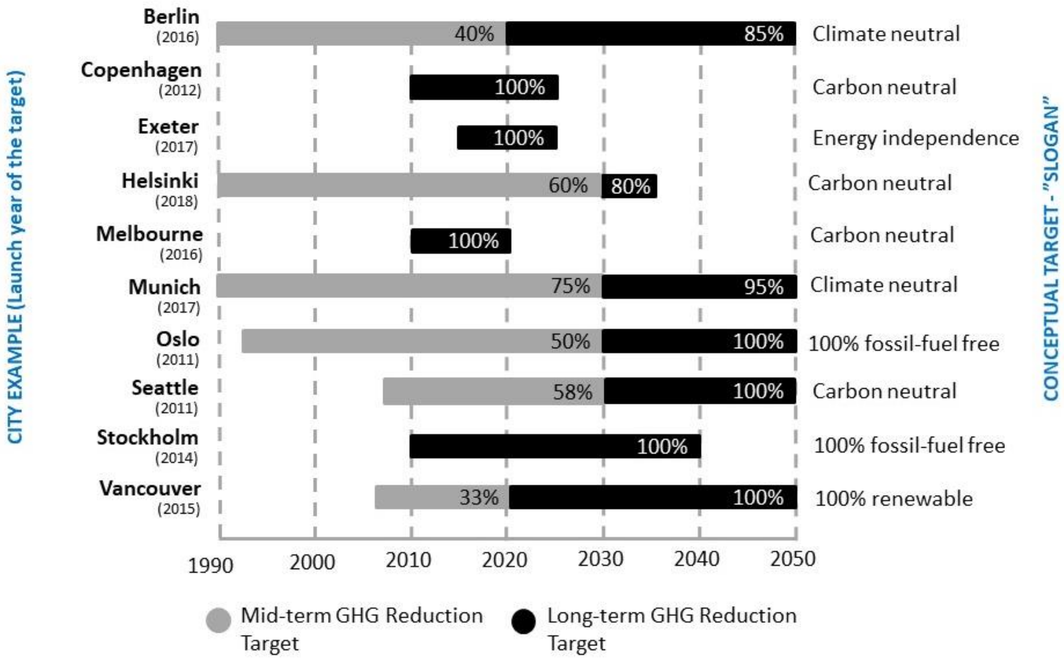

Figure 2. Examples of cities' conceptual long-term targets (adapted from [18] with new additions: Exeter, Munich and Helsinki).

At the same time, the usage of the word "climate" might be misinterpreted; it might be easily assumed that it also refers to air pollutants other than GHGs. Some have thus started replacing it with the term "GHG neutrality" [23]. Additionally, it is often used interchangeably with the term carbon neutrality; however, the last one is unclear as to whether "carbon" refers exclusively to carbon dioxide or other greenhouses gases as well.

Despite the existence of some definitions in literature, "net zero emission" or "neutrality" concepts still remain vague, with unclear system boundaries, as well as calculation and assessment rules; Variations in ways of thinking about these concepts can influence urban development. In this regard, operationalization is required, if they are to be adopted as a goal for the future development of cities [27]. The clarification points presented in Figure 3 are based on the present authors' observations and ideas and can be used as a first step towards improving transparency.

3.1. Type and scope of emissions

Type of emissions: Many neutrality targets merely relate to CO_2 and neglect other non-CO_2 gases [4]. The reason for this can often be attributed to the lack of reliable information on these GHGs. However, these cause up to 40 percent of global GHG effect and should therefore not be omitted from inventarisation, target-setting and mitigation strategies [4]. Indeed, most of existing GHG accounting and reporting standards cover the GHG gases specified by the Kyoto Protocol [15]. However, some cities adopt a middle-road approach, accounting only for carbon dioxide (CO_2), nitrous oxide (N_2O), and methane (CH_4) [13].

Scope of emissions: Cities typically estimate Scope 1 and Scope 2 emissions. However, some cities have begun to experiment with consumption-based inventories that extend into Scope 3, e.g. City of Seattle. Although Seattle does not include these emissions in its carbon neutral scenario analysis, it has included a consumption-based inventory in its plan, as well as related actions [28]. This is a good example of a double strategy for exploiting all possibilities for action. Hence the inclusion of a complementary target-setting package according to the "consumer-based" approach is recommended by the authors to obtain a real picture of energy consumption and GHG emission balance. This is also useful for bringing citizens and local stakeholders "on board" as end-users and encouraging them to assume responsibility, since in many cases the share of emissions caused directly by municipality is rather small. It is no coincidence that C40 Cities recently released a new study establishing consumption-based GHG inventories for its 79 member cities on the basis of PAS 2070 methodology [29] with the aim "to better understand the ability of cities to contribute to GHG emissions reduction activities beyond their city boundaries" [30]. This study specifically reveals that cities have a 60% increase on their carbon footprint, compared to the previous estimations for the same cities using the GPC's sector-based approach [30]. Without doubt, this undertaking implies that the time is ripe for utilizing additional accounting approaches in city-level target-setting as well as that the window of opportunity to influence consumption patterns is huge.

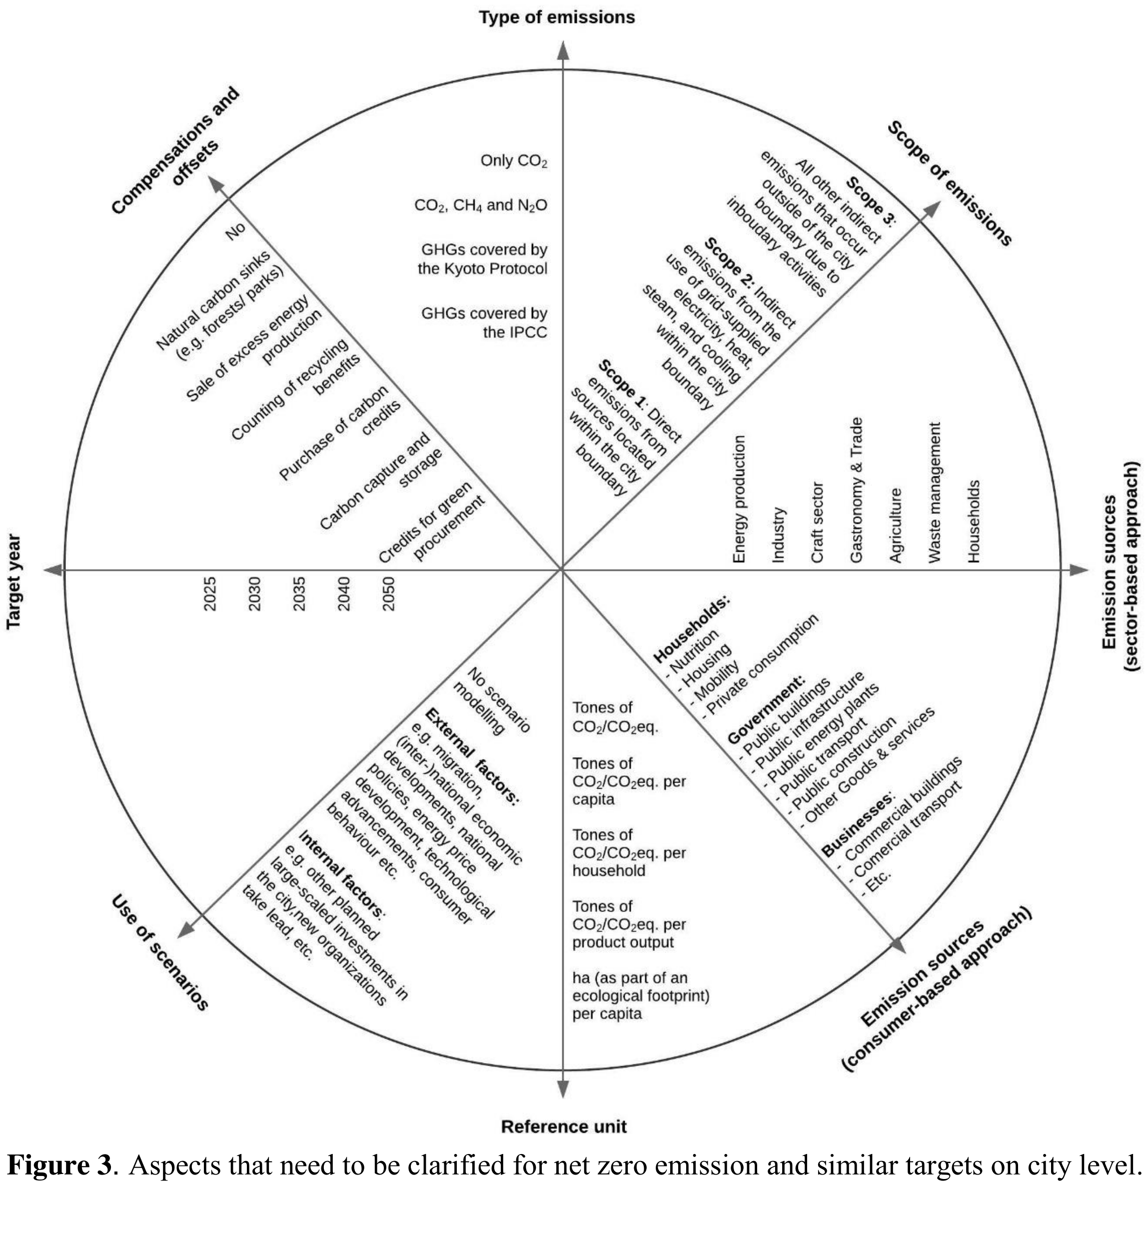

Figure 3. Aspects that need to be clarified for net zero emission and similar targets on city level.

3.2. Emissions sources

Emission targets can be set either for the entire suite of emission sources (activities in a city) represented and accounted in the GHG inventory or only for the ones over which the city governments have the greatest direct influence. While setting goals over all (or nearly all) emissions makes sense at national level (e.g. as part of the Intended Nationally Determined Contributions (INDCs) submitted under the Paris Agreement), this may be counter-productive for city-scale GHG inventories [31]. For example, some cities are dominated by emissions from large point sources, such as power plants and industrial facilities (usually serving demands far beyond the city boundary), over which they have little influence. It is recommended that cities initially exclude such emissions (only from the balance, not from the list of necessary actions – influencing industry is also essential for reducing impacts to local environment, in addition to GHGs) and instead follow a step-by-step approach, starting from the target of establishing a "GHG neutral" city administration. In addition to the decision of which sources to include in an inventory, the breakdown itself can also have an influence on the results. Figure 3 presents a breakdown both for sector-based and consumer-based approaches. The first breakdown follows the structure of macroeconomic sectors. The logic behind the second breakdown is to clearly distinguish between the different types of consumers (households, government and businesses) and the most common fields of need assigned to households, as well as end-uses assigned to other consumers, according to the currently available end-use classification frameworks. The latter is also largely compatible with [29].

3.3. Reference unit

The emission quantities can be expressed using different units and/or methods of normalization (e.g. per capita, per gross city product, etc.). For example, setting targets for per-capita emissions, in addition to overall emissions, ensures that expected population growth is being accounted for. In general, the indicator GHG emissions per capita and year is becoming central in the global debate and has already been adopted several cities as earlier described.

3.4. Temporal aspects

Use of scenarios: When planning is built in a long-term goal, understanding the baseline emissions scenario(s), also referred to as business-as-usual (BAU) emissions scenarios, is essential for better dealing with the uncertainties of the future. BAU represents the future emissions with the highest probability of occurrence in the absence of a mitigation target. Developing a baseline scenario typically requires a wide variety of inputs, such as data on critical GHG emission drivers, assumptions about how these drivers are expected to change, and information on policies that may cause these changes. On the other hand, a target scenario represents the cities' future GHG emissions based on the likely reduced emission levels caused by the planned actions (depending on whether action planning precedes or follows target-setting), and thus it shows the reduction pathway. The "distance" between a city's BAU and target scenario equals the emissions savings. There are many methods of scenario modelling that can be used [32] and various cities have extensive experience in using them, but this is not part of this paper. It is important though to distinguish "external" factors – i.e. factors capturing the uncertainties emerging from the outside world and not in the sphere of influence of the city authority, such demographic, economic and technological developments – from "internal" factors – i.e. factors that include future developments shaped by the decisions of city authority [33]. The development of scenarios as a process can also be used for another purpose: to support and stimulate larger scale discussions with non-experts and enlarge the circle of decision-making through workshops [27, 33].

Target year: Another question is how to decide upon the horizon over which the end target needs to take place. The time frame chosen influences the need for including interim targets. Setting intermittent targets as near-future milestones to compliment the longer time frames necessary for achieving overarching targets could bring several benefits [34]. This increases the particularity and practicality of the climate plan, as well as the sense of urgency, responsibility and political commitment, leading to the enhancement of the overall credibility of the "reduction path". Indeed, Figure 2 shows that most of the cities with targets beyond 2025 have also interim targets in place.

3.5. Compensations and Offsets

Several cities have adopted compensation and offsetting measures as an option for fulfilling their total carbon reduction targets. It is important to place restrictions on offsetting the unavoidable emissions in order to ensure that the focus is not shifted from overall emission reductions. This means that before anything else cities have to work on their own mitigation strategies, so as to reach the optimum level of emission reductions that can be achieved, and then take the offset possibilities as a way to balance the remaining emissions. Additionally, detailed guidance is required around the types of offset allowed, for example, in terms of whether offset actions occur onsite (e.g. production of a surplus of green energy, as in the case of Copenhagen planned to offset part of its CO_2 emissions through the provision of excess wind power to the electricity grid [35]) or offset credits are purchased from a third party (e.g. Melbourne included the purchase of carbon offsets in its 2020 plan [36]), and in the latter case, how credible the offset provider is [37]. Figure 3 shows different options for addressing a city's remaining emissions. The pros and cons of each option are explored in [28].

4. Conclusions and Recommendations

Despite the lack of a shared understanding of net zero concepts, several cities and developments around the world claim to be on the path to net zero GHG emissions, mostly focusing on a combination of efficiency and consistency strategies (improvement of energy efficiency and increased use of renewable energies). If the demand side is included, the addition of sufficiency strategies is indispensable. However, even under the condition that common understanding will be reached in the future, comparing the climate efforts of different cities around the world in terms of their "distance" to net zero emissions target would not be reasonable. It is an indisputable fact, that the starting position of each city with respect to mitigation and the way in which each one of them intends to achieve its claimed status often differ considerably [27]. The issues earlier described are not the only ones requiring attention. They bring out the need for further work in other related areas. The present authors identify implications and consequences in the following fields:

Data collection: Strong and comprehensive data that enable the tracking of changes over time is a prerequisite for any systematic work on monitoring, assessing and reducing GHG emissions. Most cities lack sources of such data. Especially in the context of the deregulation of energy markets, there is hardly any institution/body collecting all the energy consumption-related data. An additional problem is that this type of data is usually subject to data protection laws. This forces the city authorities and the experts commissioned by them to be dependent on the analysis of (partial) data from different sources. Under these conditions, besides their necessary involvement in the development and implementation phase of the action plan, industries and citizens should be also actively involved in the provision of the necessary data to ensure a more comprehensive accounting and assessment.

Reporting instruments: Cities can benefit from borrowing ideas and practices from big companies; one example is the instrument of sustainability reporting that can also be used by city authorities for the formulation of goals and the monitoring of the compliance with them.

Standardization: Currently, it is unlikely that there will be an international agreement on harmonized methods and procedures for the net zero GHG emissions approach in cities in the form of one international standard. It is rather likely that an even greater number of approaches will continue to be pursued in parallel. It is, however, important to first attempt to reach a more global consensus on a set of minimum information (including the system boundaries, the offsetting methods and limitations, etc.) to be reported in the future when municipal climate protection concepts are published. In the medium term, the development of a standard leaving adequate leeway for adaptation to the local situation, while supporting a transparent declaration of used methods and system boundaries and providing a basic typology of cities is possible. The profiles indicators according to ISO 37120 [38] already provide a good basis for the latter; the definition of cities' profiles for the purpose of fairer cross-city comparisons.

In this sense, this topic cannot yet be considered as completed and further investigation and discussion is needed.

Abstract. This paper addresses the role of virtual reality in addressing the specific challenge of the increasing complexity and decreasing usability when dealing with the level of detail required to model a zero emission neighbourhood (ZEN).[1] In such neighbourhoods, there is a need to handle both 'top down' neighbourhood level data with 'bottom up' building and material level data. This can quickly become overwhelming particularly when dealing with non expert users such as planners, architects, researchers and citizens who play a key part in the design process of future ZENs. Visualisation is an invaluable means to communicate complex data in an interactive way that makes it easier for diverse stakeholders to engage in decision making early and throughout the design process. The main purpose of this work has been to make ZEN key performance indicators (KPIs) more easily comprehensible to a diverse set of stakeholders who need to be involved in the early design phase. The paper investigates how existing extended reality (XR) technologies, such as virtual reality, can be integrated with an existing dynamic LCA method in order to provide visualise feedback on KPIs in early phase design of sustainable neighbourhoods. This existing method provides a dynamic link between the REVIT Bim and the ZEB Tool using a Dynamo plugin.[2] The results presented in this paper demonstrate how virtual reality can help to improve stakeholder participation in the early design phase and more easily integrate science-based knowledge on GHG emissions and other KPIs into the further development of the user-centered architectural and urban ZEN toolbox for the design and planning, operation and monitoring of ZENs. [3]

1. Introduction

In the future, municipalities must handle a completely different level of complexity in society. In order to have well-functioning cities, cities must improve how they utilise their resources and how they engage with technologies in different ways. A smart city will use digital technologies to enhance performance and wellbeing, to reduce costs and resource consumption and to engage more effectively and actively with its citizens. In this context, the objective of this work is to investigate how visualisation methods, such as, Virtual reality (VR), can support the evaluation of zero emission neighborhood (ZEN) and zero emission building (ZEB) design concepts with respect to key performance indicators, such as, greenhouse gas emissions and other potential environmental impacts. [4, 5] The aim is to evaluate how virtual reality can help communicate, involve and improve participation from diverse stakeholders involved in the ZEN design process including politicians, municipality planners, design/planning practitioners, and citizens.

Current methods for visualizing semantic information are mostly limited to coloured map overlays, 2d and 3d-graphs or values spread across maps. The potential of using Immersive technologies, such as VR to enable users to explore and interact with real design projects is investigated in this paper, as well as, the extent to which it can be used for the planning of complex infrastructures and the visualisation of multiple key performance indicators (ZEN KPIs). This VR approach is particularly of interest to diverse experts and decision-makers in order to provides them with the means to explore results early in the design phase and on-site. Full details related to the research presented in this paper can be found in Løvhaug and Mathiesen. [6]

1.1. ZEN Definition, KPIs and pilot project

1.1.1. ZEN Definition and ZEN KPIs

The vision of the ZEN Research Centre, together with its industrial partners, is to create zero emission neighbourhood in smart cities (ZEN). [1] In the ZEN Research Centre, a neighbourhood is defined as a group of interconnected buildings with associated infrastructure, located within a confined geographical area. A ZEN aims to reduce its direct and indirect greenhouse gas (GHG) emissions towards zero over an analysis period typically of 60 years, in line with a chosen ZEN ambition level with respect to which life cycle modules, buildings, and infrastructure elements to include. The ZEN assessment criteria and key performance indicators are divided into seven categories (GHG emissions, energy, power/load, mobility, economy, and spatial qualities), and each of these categories is divided into several assessment criteria. [4] The assessment criteria are then divided into several key performance indicators (KPIs) which are listed in Appendix A.

1.1.2. ZEN Pilot projects

In the context of the ZEN Research Centre, pilot projects are geographically limited (primarily urban) areas in Norway and serve as innovation hubs where researchers, building professionals, property developers, municipalities, energy companies, building owners and users, test new solutions for the construction, operation, and use of neighbourhoods in order to reduce the greenhouse gas emissions to zero on a neighbourhood scale [4]. Various stakeholders will have different influences on a ZEN pilot area at different times during the development of the area. In this case, key stakeholders include Trondheim municipality and the project owner NTNU, as well as, other stakeholders. The pilot site at Nidavoll Skole [7] in Sluppen is located in the larger ZEN pilot project called The Knowledge Axis [8] and culminates in Sluppen, a mainly commercial area that is planned to be developed into a multi-functional neighbourhood.[9]

1.2. Virtual Reality

There exists a variety of techniques, tools and technologies for displaying data using diverse media. Examples includes 2D-based screens like traditional desktop applications, tablets or interactive multitouch solutions. On the other hand, there are more immersive tools which are covered by the term Extended Reality (XR), which is an umbrella term to refer to all real-to-virtual combined environments such as Augmented Reality (AR) and Virtual Reality (VR). While more traditional user interfaces like desktop applications which are more advantageous when displaying and navigating through large quantities of text-based data, whereas XR is more suited to creating an experience for the user. Solutions span from showing information on a tablet, to strapping the user into a haptic suit with a head mounted display. Due to the immersive effect of head-mounted displays, the user can interact with the data in a way that is limited in desktop-applications. For this project, it was decided to further explore the possibilities of visualizing data using VR. In recent years, the main focus for VR has been centred around the entertainment industry. This focus has driven the innovation in the field where different manufacturers are promising better and cheaper solutions, and has also made the technology available for consumers. There has been a large increase in technologies allowing for users to interact and alter a virtual environment, and technologies suited for immersive experiences.

Virtual Reality is a computer-generated experience which takes place in an virtual environment. Normally the user wears a head mounted display (HDM) with two individual images for both eyes, creating a depth perception. The HMD is tracked by either itself (inside-out) or sensors in the room (outside-in). This allows the application to mirror the position of the user in the real world, in the virtual world. The user can interact with the environment by using speech, hand-tracking, eye-tracking or input devices, where the most common is a form of controller which is tracked in all directions, mimicking the user's movements. VR technologies are potentially groundbreaking for visualising data and creating an experience for the user. It is now possible to not only showcase the data and environment on a 2D screen, but also put the user in the actual environment itself. Combined with different techniques of data visualisation, the overall aim is to leave an impression on the user, as found in a study from University of Maryland where their results showed that participants remembered on average 8.8% more of information presented in VR.[10] By using existing floor plans one has the ability to create a digital twin of the buildings. With this 3D-model one have the ability to re-create a realistic replication of the environment with connected information displayed on and around the 3D-model. In addition to the data visualisation, it is also possible to display the building in a realistic way before the building is even constructed. This use case can make it easier to communicate data and engage diverse stakeholders early in the design process. There are several VR products available, all in different price-ranges which can be defined in two sub-categories; low- and high-end.

The focus of this paper is on the results using high-end VR involving the development of the HTC Vive [11] for use in our application using the Unity 3D software[12] which works well with all known VR headsets and controllers supporting OpenVR. The reason for choosing the HTC Vive was also because of its availability and ease of use. As opposed to the low-end sub category, this kind of equipment is in general more expensive. While the application relying on the low-end equipment can be tried at home, the high-end solutions often needs to be made available for user at for example stands or promotional events. The technology needed to fulfill the requirements in the high-end sub category varies depending on the application. For less intensive tasks, it can suffice to use with a mid-range desktop computer, but for applications which demand more processing power, it is recommended to use a top of the line GPUs. VR head mounted devices (HMDs) have seen rapid development, which initially was mostly driven by the fast hardware iterations of the smartphone industry. The current wave of VR devices began with the Oculus Rift Kickstarter campaign in 2013 accumulating close to 2.5 US dollars in pledges.

Table 1 Development of of VR devices based on popular HMDs

Date	Description	Resolution per Eye	Horizontal View	Features
3.2013	Oculus Rift DK1	640x800	90	only 3 DoF tracking
7.2014	Oculus Rift DK2	960x1080	90	
4.2016	Oculus Rift CV1, HTC Vive	1080x1200	90	
10.2017	WMR Lineup	1440x1440	90	inside-out tracking
4.2018	HTC Vive Pro	1440x1600	90	
2.2019	Pimax 8k	3840x2160	170	

2. Method

2.1. Research Method

The Design Science Research [13] has been used in this research and focuses on three different cycles, as explained by Hevner [14]. This includes the *relevance* cycle, *rigor* cycle and *design* cycle. In short, the *relevance* cycle ensures that the result of the research fits into the intended usage area. The *rigor* cycle aims to ensure that the research is representative of the 'state-of-the-art' in the application domain. Finally, the *design* cycle facilitates a development process which consists of several iterations with rapid evaluation.

The prototype used in this research is the ZEN pilot project at Nidarvoll Skole [7] as the main design project, and gives the user the ability to view the pilot project from both a building- and neighbourhood perspective. The embodied carbon data is gathered from an Excel based tool called The ZEB Tool [15]. The pilot project is in a very early stage of design and since there is limited available data, the data used in the prototype is based on another school named Østensjø School in Oslo. There are also limitations regarding to the availability of a 3D model, however, by using existing building plans, an initial Revit model of the main building has been created. New models will be added to the system in the coming months. By using this project for the ZEN VR application, the results from retrofitting and new buildings with data from early phase design can be compared to data from different stages of design to visualise how different design or materials changes impacts the different KPIs in a design project.

2.2. Data Source and LCA Method

This works builds upon the work already developed by Houlihan Wiberg together with students to develop a visual LCA method, using a user interface in the form of a dashboard, connected to an integrated dynamic Revit 3D and the ZEB Tool [16, 17]. In this initial version of the developed VR software, the focus is on visualizing the KPIs related to carbon embodied in the production, transport, and replacements of building materials. The embodied carbon data from the ZEBTool [15] is stored together with data from other sources in a MySQL database which is specifically developed for the purpose of structuring and storing building LCA studies in a comparable and accessible format [18], so that the data can be used in applications such as the one presented in this paper. This solution allows easy online access and ensures that the user is always presented the most up to date information and that it is easy to add new information relevant for the application. Furthermore, the database has a set of additional building LCAs which are used to set reference values when benchmarking the results of the case study. In order to be able to run the application offline, the application has a local copy of the database which it used when there is no database connection.

2.3. User study and questionnaire

The VR application and its potential was evaluated through the use of semi-structured expert interviews and its usability, through a questionnaire. The participants of these two methods of data collection tes the application on the same terms, with a set of predefined tasks. These were conducted in order to answer the research questions. The strategy for obtaining informants used was primarily the snowball technique. To evaluate the user interface and ascertain the degree of usability when using the system, a questionnaire was designed. The questionnaire was designed after the principles of a Likert scale. The general methodology used when conducting the user study has been semi-structured expert interviews which allows one to get the chance to ask the informant specific questions, but it also allows for unexpected turns. There were three participants in each of the interviews including the informant and two of the authors of this paper which allowed for one to lead the interview and the other to take notes on essential parts of the interview. However, the main collection of data were audio recordings that were later were transcribed. A detailed description of the user study and questionnaire methodology may be found in Løvhaug and Mathiesen [6].

2.4. 3D Model – Unity Software - VR

For the visualisations to be as realistic as possible, the buildings are exported from the BIM software Revit [19]. The models are then converted Autodesk Maya [20] before importing them into the Unity 3D, because when Revit exports 3D modes, it does not use a naming convention resulting in some building elements end up being unnecessarily detailed, making the app run slow. The choice of using BIM models in the application ensures that the building models are directly linked to the work of the architects, and visualisations can therefore be part of an iterative design process.

3. **Results**

The preliminary results in this paper describe the application prototype, and the informal and rapid feedback from user testing in order to visualise ZEN KPIs and improve stakeholder participation early and throughout the design process. The results provide a way to visualise a selection of KPIs from the an actual ZEN pilot projects at different levels of detail. Non-expert users of the application can see how this neighbourhood is performing compared to other projects in the vicinity. It is also possible to walk around the neighbourhood, inspect individual buildings and identify which building components and materials are the highest driver of emissions. The application also has the flexibility to add new KPIs when more data becomes available for each pilot.

3.1. VR Application Overview

The Research Centre on Zero Emission Neighbourhoods in Smart Cities have defined a set of assessment criterias and key performance indicators which are used to track, evaluate and validate the progress of ZEN pilot areas. The developed prototype builds upon existing work conducted at the Fraunhofer Research Centre in Singapore, where several different VR and AR-applications have been developed, one of which is used to assist the Housing and Development Board in Singapore. [21] This application utilizes VR in a way that correlates with the vision of the end product of our research. The application aims to visualize data for the Nidarvoll site in light of a selection of these predefined criterias. In order to achieve different levels of detail, a three layered model with the following views which were developed in the VR application as shown in table below:

1. *Full view*
   This view displays all available projects in the Sluppen area. The map of the neighbourhood and surrounding area are are put on a table-surface and the user have the ability to get an overview of the whole area. Relevant KPIs for this view would be aggregated values from all buildings and other high level high level KPIs such as mobility, economy and energy efficiency.

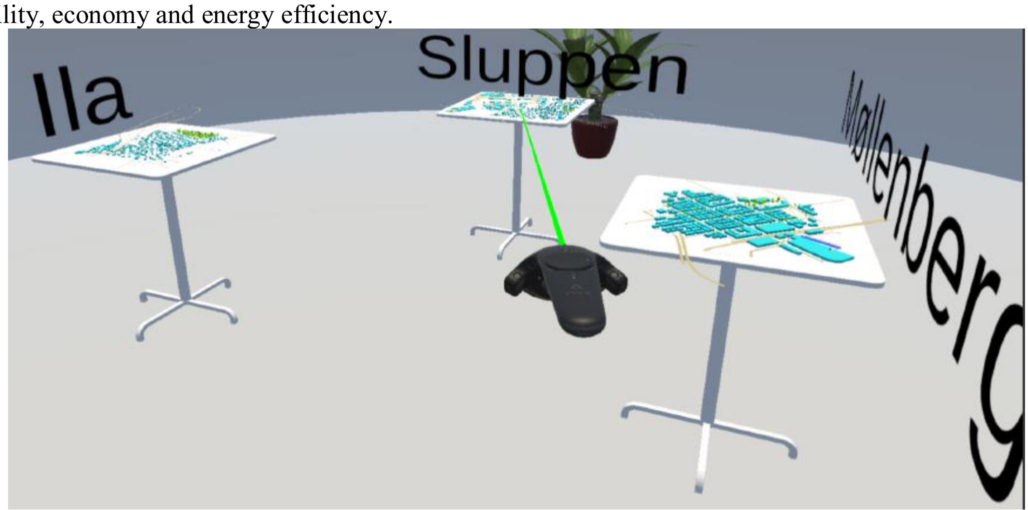

Figure 1. Full View of the Sluppen area Using VR

2. *ZEN-view*
   When selecting a specific pilot project in the full view the user gets transported down one layer, and is presented with the ZEN view. In this view the user stands in a small scale model of the environment and have a ability to teleport around and inspect each part of the neighbourhood. The user can, to begin with toggling between two different KPIs i.e. GHG emissions and energy consumption/generation. Emission values are presented as either a colorisation of the buildings or a column visualisation, both of which have a possibility to be further developed in the future. For comparing the score of the buildings in the neighbourhood, the user has two options: 1) evaluate the buildings total CO_2eq/m^2 compared to the total CO_2eq/m^2 for all buildings present in the pilot area. 2) Evaluate the buildings total CO_2eq/m^2 compared to the total CO_2eq/m^2 for all buildings that are present in the database. To put these numbers into context and to engage the user, it is possible to visualise the weight of the CO_2eq emissions in terms of vehicles most users are familiar with using images of airplanes and cars. In addition, it is possible to get an explanation as to what the emission equals in kilometers driven in cars and round world trips in airplanes. This is shown on the left in Figure 2. Energy is visualized as a bar which displays energy consumption versus energy production for each building. The user will also be able to see the sum of consumption and generation. In the next stage of development, when the energy KPI has actual data, the user would be able to get examples of feedback for energy usage.

Figure 2. Snapshot in ZEN View of the Sluppen area using VR to visualise emissions of buildings

3. *ZEB-view*
   If the user selects one specific building in the ZEN view, they teleport down to the ZEB-level (Building level). This view focuses on one particular building, and serves the purpose of communicating the KPI GHG-emissions for both each building part and every material in said building part. This view has two models; one 1:1 model where the user can teleport inside and experience/inspect the building. The other is a "dollhouse"-model where the user can inspect and interact with the building by clicking on building parts. The user is also presented with a menu for toggling between different building parts. The KPI score is visualised using colorisation similar to the ZEN-view. The user can choose two different approaches; the first compares the performance of each building part to the total emission of the building. The second approach weights the building mass as part of the equation and returns a score based on both the emission and building part mass compared to total building mass. If the user selects one specific part, they get presented with material information in tabular form for the selected element. In addition to the tabular form, the materials used will be visualised in actual size and weight so the user can put the quantity of materials into context. The intensity of the emission is visualized by using the same columns from ZEN-View. The purpose again is to give the user a more immersive experience and to put the numbers into context.

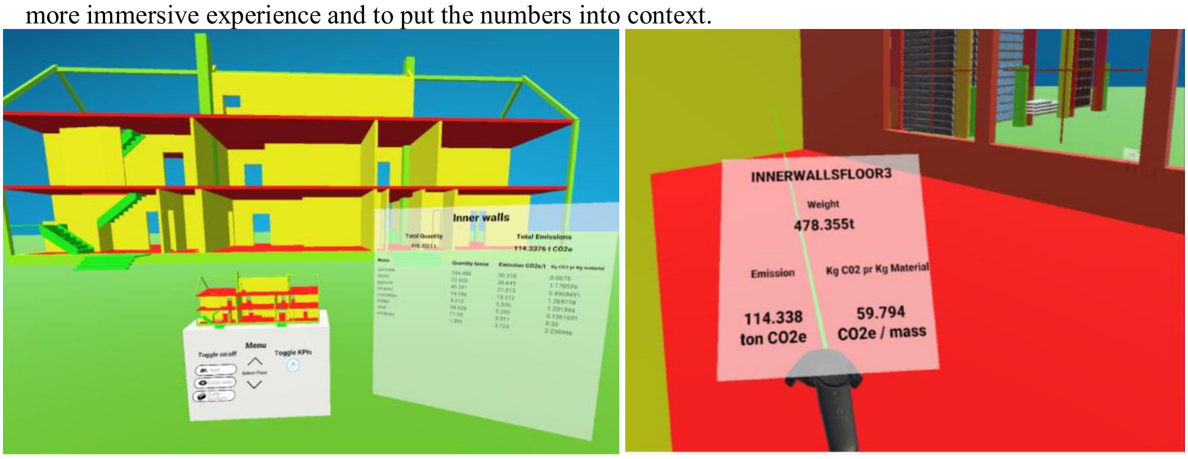

Figure 3. ZEB View of a building using VR to visualise emissions and by listing materials in tabular form

3.2. Results of user tests and questionnaires

After conducting some informal user-tests on subjects without prior knowledge regarding sustainable neighbourhood design, the results show that average citizens and other stakeholders do not find it easy to understand what the emission data means in relation to the neighbourhood context, and designers find it difficult to understand how to integrate this data into the design process. As a result, a design has been developed which focuses more on the immersive experience and visual display of data as a means to communicate complex KPI data. An example of this, is the visualisation of the amount of timber used in construction not only as a number, but also as as number of virtual logs stacked. Another example is, that the contribution of transport related emissions is indicated as a number of different vehicles and GHG emissions for travel distance and intensity of pollution is indicated in size and colour.

It was found that when working on the application, that by using high-end VR equipment, a more immersive experience is achieved which results in more engagement from the user and facilitates easier interaction and feedback with the ZEN KPIs. The results also show that users enjoy exploring the novelty of a virtual environment and because of this, it was decided to only implement a small portion of the pilot area, so the user would not get lost in the experience, but rather focus on interacting with the relevant information and specific KPIs for the area. It was also found that the *Unity 3D* software allows for quick prototyping and development for multiple platforms at once in addition to making a high quality result.

Another finding was that size matters. Some of the visualisation methods, first deemed unnecessary, ended up being the most important in making an impression on the user. By using only colour visualisation of the emission data, the user does not fully understand the significance of the emission results. However, it was found if different sizes of columns are used instead to communicate the significance of the level of resulting emissions from the building, it was found that the users more easily understood this data in this more visual context. One of the test-subjects stated when looking at a large, red column that she *"I would not like to live in that house"* due to the associated high emissions.

4. Conclusion and Discussion

The results of this paper show that this ZEN VR approach provides for a new and intuitive way of interacting with and viewing multiple KPIs simultaneously. This approach presents a new way of combining KPI data with BIM models early in the design process. By utilising visualisation methods which inspire and engage diverse stakeholders to explore the environment and learning by putting numbers into context, the ZEN vision of a sustainable neighbourhoods can more easily be communicated by diverse stakeholders. VR is a valuable tool to engage users with no prior knowledge of ZEN or KPIs, to put data into context and to more easily understand the meaning and size of the numbers presented. This VR approach improves communication with and between stakeholders and provides a means to overcome traditional interdisciplinary barriers. It was also found that high end equipment offers a better immersive experience by having better image quality, performance and input possibilities. This makes it easier to engage the user and keep their attention in the application while learning useful information, but with an increased cost and more cumbersome setup.

The research explored the utilization of virtual reality as a tool for engaging and interacting with emission data in new and immersive ways. A VR application, called ZENVR, was developed through several iterations by connecting an existing MYSQL database, containing life cycle assessments of 11 projects in Unity 3D. Furthermore, the application and its potential was evaluated through the use of semi-structured expert interviews and its usability through a survey. The participants of these two methods of data collection all tested the application on the same terms, with a set of predefined tasks. These were conducted in order to answer the objectives of this work which was to investigate how visualisation methods, such as, Virtual reality (VR), can support the evaluation of zero emission neighborhood (ZEN) design concepts with respect to key performance indicators, such as, greenhouse gas emissions and other potential environmental impacts.

The results of this study found that virtual reality is a good platform for communicating and visualising complex data including the KPIs in sustainable neighbourhoods, for not only researchers but also for the general public. ZENVR can be used as a data visualisation tool for presenting data in a understandable format by creating a presence inducing environment which subsequently may result in an emotional experience when interacting with the application. In ZENVR we have shown that these principles can be used to visualize the KPIs from ZEN. These visualisation methods are exemplified through greenhouse gas emissions related to the transport and use of materials, but the principles are transferable to numerical data in general.

In terms of which form of data visualisation are most beneficial for comprehending the KPIs for different user group, it was found that ZENVR allows for selecting between several forms of data visualisations. Expert interviews revealed that professionals preferred traditional visualisation approach i.e. columns, colors and numbers when looking at KPIs. It was further discovered that in order to make a lasting impression, which ultimately is the goal of ZENVR, one have to use visualisation methods which appeal to the human emotions. This can be achieved by anchoring the visualisations to human factors by using the principles mentioned earlier, for instance using sizes to make the user feel small or movement of objects for dramatic effects. The visualisation type which made the biggest impact on all users was when numbers were put into context by using relatable objects from everyday life.

In relation to how can VR be used to improve stakeholder participation in sustainable neighbourhood projects, the results show potential areas where ZENVR can be used to improve stakeholder participation include citizen engagement, promotion and the advertisement of ZENs, tool for interdisciplinary communication and collaboration between professionals. With its natural immersive properties, VR has proven to be a suitable platform to spark engagement among its users. Through a well designed VR environment, highlighting the beneficial parts of an environmental friendly neighbourhood, all subjects agreed that this has a huge potential to promote sustainable neighbourhoods. In addition, VR allows for displaying data in new perspectives making it understandable for different stakeholders, reducing the barriers of interdisciplinary communication and collaboration.

5. Further work

The application in its current state is experimental and should be viewed more as providing a foundation for further development. Further work should investigate how more KPIs can be included in the application and the associated effect on stakeholders. In addition, when the application is more complete and thorough, user-testing might reveal if the usability improvement suggestions from the latest iteration are indeed useful. From a technical point of view, some alterations and features which might benefit the application arose from conducting user tests and interviews. These mostly centred around the user interface and how it might be changed to better suit the user's needs and understanding. It would be advantageous to test the application with other virtual reality systems to test its compatibility and possible adaptations that may be necessary.

Acknowledgements
This research has received funding from the Research Centre on Zero Emission Neighbourhoods in Smart Cities (FME ZEN). The authors are thankful for the support from the ZEN partners and the Norwegian Research Council. The authors gratefully acknowledge the support of The Fraunhofer Singapore Centre at Nanyang Technological University in Singapore for hosting the Masters students during their research stay.

Crafting local climate action plans: An action prioritisation framework using multi-criteria decision analysis

Balouktsi M[1]

[1] Centre for Real Estate, Karlsruhe Institute of Technology, Karlsruhe, Germany

maria.balouktsi@kit.edu

Abstract. The COP21 target to keep global warming to well below 2 (or 1.5) degrees Celsius cannot be met without massive transformation in cities. A major challenge on the road to nearly greenhouse gas (GHG) emissions-neutral cities is the successful development of a climate action plan (CAP) by the local authority, sometimes within the framework of its participation to different initiatives (e.g. the Global Covenant of Mayors). While the identification of the best actions for reaching their long-term GHG emission reduction target constitutes a common decision-making problem for local authorities, it is also an intricate one: conflicting and incommensurable aspects such as environmental, economic, social and technical issues, as well as conflicting stakeholder interests should be dealt with simultaneously when actions have to be programmed. Multi-Criteria Decision Analysis (MCDA) methods are well-known to cope with these complexities and have already been used for decades in several fields. However, they have not been systematically used within the context of local CAPs. The methodologies which are normally implemented to support the prioritisation of actions wholly or to a great extent rely on economic analyses and do not capture the potential co-impacts. In this context, this paper proposes a general participatory framework for guiding collaborative prioritisation of actions as a methodology to help local authorities with the development of more sustainable CAPs, while using MCDA. Finally, advantages, limitations and further steps in research regarding the proposed framework are discussed.

1. Introduction

Climate change is undoubtedly the global environmental risk currently receiving the most attention, and is, according to the Intergovernmental Panel on Climate Change (IPCC) [1] one of the most serious contemporary challenges to achieving a sustainable society. A collective response of nations to the urgency of tackling climate change is marked by the COP21 target to keep global warming to well below 2 (or 1.5) degrees Celsius compared to preindustrial levels. However, it is nowadays well-acknowledged that such ambitious global goals are predestined to fail if climate action is limited to national or regional levels [2]. Massive transformation in cities and the engagement of non-state actors in mitigation action are indispensable, since cities' residents are responsible for more than two-thirds of the global energy consumption and up to 70 percent of GHG emissions [3]. Certainly, the recognition of the vast potential of cities to mitigate climate change by both researchers [4] and policy makers [5], has led to an increasing number of local governments committing to climate and energy pledges and developing local climate action plans (CAPs), sometimes within the framework of their participation to different city networks. Examples of such networks are the EU Covenant of Mayors (CoM) and the Compact of Mayors, which were recently merged together to form the largest global coalition of cities and local governments of all sizes, the Global Covenant for Mayors for Climate and Energy (GCoM) [6]. Particularly in Europe, already more than 60 percent of its cities have some sort of local climate plan in place [7]. In France, Slovakia and the UK, the adoption of such local CAPs is even compulsory for municipalities [7].

Although these numbers are encouraging, not any type of climate plan is sufficient. Cities should not only eventually strive to limit their emissions as close to zero as possible (i.e. become climate neutral), but also do so in the most sustainable way possible. Climate action is not an issue to be considered in isolation; it is one of the sustainable development goals (SDGs) of UN Agenda 2030 (i.e. SDG13) and is significantly linked – positively or negatively – with achieving many of the other SDGs [8]. In this sense, for local authorities on the road to developing a successful CAP the decision-making problem of identifying and choosing the best actions for practical implementation among the plethora of the possible ones is a multi-criteria and intricate one: conflicting and incommensurable aspects such as environmental, economic, social and technical issues, as well as conflicting stakeholder interests should be addressed simultaneously. It is no coincidence that a 2017 survey by the EU CoM Office on their community's capacity-building needs and knowledge gaps for the design and implementation of Sustainable Energy and Climate Action Plans (SECAPs), revealed that the second strongest methodological need of EU cities is "defining and prioritising actions based on certain criteria" [9]. In other words, local authorities lack understanding for prioritizing mitigation (and adaptation) actions.

Multi-Criteria Decision Analysis (MCDA) methods are well-known to cope with the complexities inherent in participatory and transdisciplinary decision-making and have already been used for decades in several fields. However, the methodologies which normally support the prioritisation and eventual selection of actions as part of developing local CAPs are limited to analyses wholly or partly relying on economic metrics. Most CAPs do not suggest the systematic use of MCDA. Indeed, there is still a limited number of case studies where MCDA methods have been applied to address this specific problem. In this context, this paper proposes a general participatory framework for guiding collaborative prioritisation of actions as a methodology to help local authorities with the development of more sustainable CAPs, while using MCDA. The framework is primarily built on a scan of recent literature and developments and it has not yet been systematically tested on real projects.

2. MCDA: An alternative approach to traditional methods for prioritizing interventions

In general, in addition to traditional financial analysis, the most employed and widely accepted forms of analysis amongst governments to inform decision of whether a particular project or policy is worthwhile are cost effectiveness analysis (CEA) and cost benefit analysis (CBA) [10]. CEA is limited to identifying the most "cost-effective" action for achieving a single objective – in this case GHG emission reduction – and is therefore inappropriate for evaluating alternatives with co-impacts [11]. On the other hand, CBA can incorporate potential co-impacts by first assigning a monetary value to non-monetary aspects that need to be considered, such as environmental quality and health effects (in order to make all aspects comparable) and then comparing the aggregated costs and benefits of different alternatives expected to accrue along a specified duration [12]. However, for several social, environmental and technical aspects, monetization becomes controversial as limited examples of valuation techniques are available, or if available, significant uncertainties remain [13]. Several authors warn about converting all values into single metrics like monetary units [14].

In those cases, the use of alternative evaluation techniques, such as MCDA is advisable. MCDA enables the evaluation of the performance of an action or policy on multiple objectives/criteria and offers an alternative to the monetary valuation of environmental and social aspects when faced with the selection of actions. As pointed out by Ürge-Vorsatz et al. [13] MCDA has at least three strengths that go beyond what social CBA can offer and make it particularly suitable for climate-related decision-making. First, it provides a framework to handle together quantitative and qualitative information, therefore it can deal with incommensurability and it does not necessitate the use of any valuation technique to monetise non-monetary aspects [13, 15]. The fact that MCDA can include criteria which CBA cannot immediately makes it more suitable for strategic decision-making [16]. Second, it allows the inclusion of stakeholders' preferences into the decision-making process through the definition of weights for the criteria. Third, it frames decision-making within a structured process of social deliberation and dialogue between stakeholders, analysts and scientists [13, 17, 18]. In other words, MCDA allows the use of qualitative information, the incorporation of stakeholder perspectives through weighting, and promotes a more democratic decision-making in the search of a compromised solution.

However, MCDA is not as standardised as CBA, despite its wide application in academic research – also in fields related to climate action – and the publication of government guidelines for some countries to support public authorities in its effective conduction (e.g. see [10]). The lack of official guidelines leads to most officials being less familiar with MCDA techniques [10]. However, when informed, they view MCDA as a useful decision-support tool for complex decisions. A study where 21 Dutch transport officials (and therefore real decision makers (DMs)) were interviewed showed that: (1) they find the composite result of CBAs pretentious and therefore they use CBA in a non-decisive manner, and (2) they are interested in appraisal tools which clearly show the important tradeoffs of different policies [19]. Therefore, it is recommended to use MCDA as a tool to support the early stages of climate action planning for first narrowing down the wide number alternatives to the most promising ones from a multi-stakeholder perspective. Then, one can switch to CBA for more detailed analysis.

3. The framework

The systematic undertaking of MCDA to support the prioritisation of actions requires specific procedures, methods and tools to be available. This section provides a standardised and transparent decision procedure that integrates MCDA as a tool to help decision makers to the specific problem of climate action prioritisation and eventual selection (Figure 1). Roy [20] distinguished between four major stages of the decision procedure with regard to multi-criteria decision problems: definition of alternatives, definition of criteria (i.e. parameters characterising the decision problem), synthesis and modelling of the DMs' preferences, and solving the problem. The structure of the standardised procedure proposed in this paper expands Roy's major stages and was partly inspired by previous work in this field [21, 22]. The proposed procedure consists of three phases, namely: (a) problem structuring, which establishes the context within which the prioritisation takes place; (b) development of the MCDA model, which defines all the inputs required to run a multi-criteria evaluation according to the selected method; (c) the MCDA application including a sensitivity analysis. These steps are further subdivided into eleven further methodological steps requiring different methods/tools. Due to the limited space here, the paper focuses on steps V, VI, VIII, while Phase I is only briefly described (since it forms the basis).

3.1. Problem structuring

It is generally well-acknowledged that the participation of local stakeholders in energy and climate planning could improve not only the quality of the local CAPs due to the integration of local knowledge, but also their acceptance and effectiveness [23]. To identify stakeholders and assess them based on their power, interests, motives and attitude in relation to climate planning (as part of Step I, Figure 1) the instrument of stakeholder analysis has to be utilized. Such an analysis facilitates authorities to eventually bring the most salient stakeholders into the decision-making process. The literature proposes various methods for facilitating the process of stakeholder analysis [24]. Most papers argued that no method is better than the others and that a combination of existing methods likely produces the most useful results. The same applies to the engagement methods, where again a variety of possibilities are available [23], and the decision will depend on whether the purpose of participation is to inform, consult, cooperate, collaborate and/or empower. Regardless of the methods selected for the stakeholder analysis and their subsequent engagement, special attention should be paid to the two following aspects not enough highlighted in literature: (1) in addition to inviting powerful stakeholder groups as DMs in the process, representatives of vulnerable populations that will be most impacted by the plan must also be involved. This will help avoid situations of environmental, social and economic injustice; (2) in the creation of communication messages not only complex concepts should be simplified but also should be tailored to the mental model of each targeted stakeholder. Useful advice on how to more effectively communicate the controversial topic of climate change to non-technical public is available by Shome et al. [25].

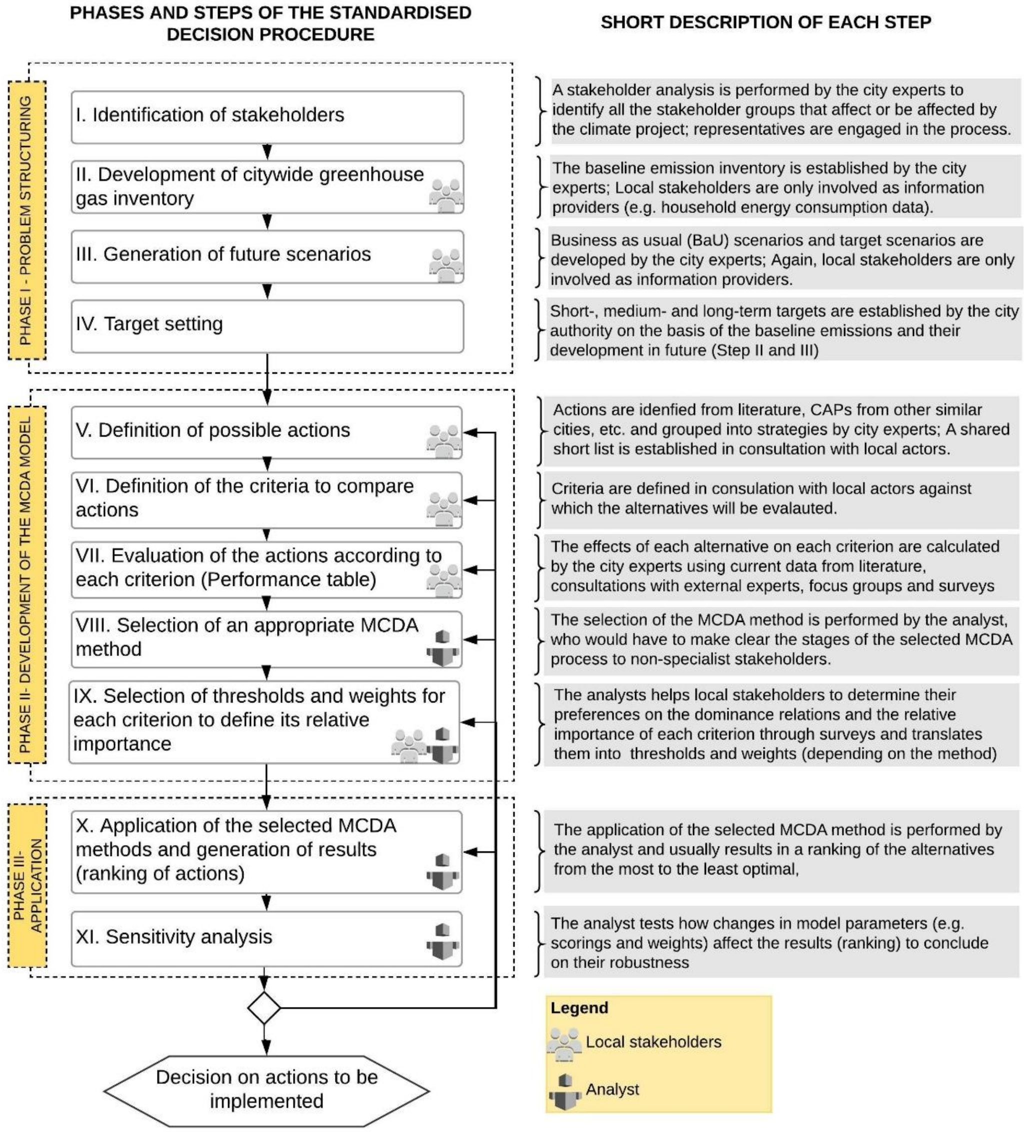

Figure 1. An action prioritisation framework for CAPs on the basis of typical MCDA procedures

The creation of a citywide GHG inventory (Step II, Figure 1) is mainly a technical task usually assigned to the related technical departments of municipality. A GHG inventory helps in determining the baseline emissions and identifying key emission sources and reduction opportunities [26]. In this step local stakeholders are involved as information providers and not as DMs. There are several inventorying methodologies in place that cities can apply [27]. The current trend is though towards the use of common reporting standards, such as the Global Protocol for Community-Scale Greenhouse Gas Emission Inventories (GPC) to allow the comparability of climate progress. Regardless of the inventorying standard used, it is noteworthy that although the city authorities are responsible for the generation of the inventory, they are not exclusively responsible for all of the emissions reported; some sources can only be influenced on a national level (e.g. industry). After selecting the strategic areas of action, cities have to conduct scenario analysis (Step III) to identify possible future emission trends on the basis of different socio-economic growth and climate mitigation assumptions [26]. This serves the basis for setting short-, medium-, and long-term citywide emission reduction targets (Step IV). The local knowledge, the baseline emissions, and the different targets form the ground of all the steps that follow.

3.2. Definition of possible actions

Actions are the fundamental building block of CAPs [26]. In addition to the categorisation and examples of climate actions provided by the EU CoM [28], there is nowadays an abundance of sources (either in the form of reports, tools or databases) that provide similar generic listings and categorisations (e.g. see [27, 29, 30, 31]) and can form a basis for this step. Many of them only incorporate actions in critical sectors where cities have the greatest control (i.e. buildings, transportation and waste management). Of course, actions can also be cross-sectoral. In addition to these typical lists, cities can also learn from implementation experiences in other cities. However, each city has its own geographic and socio-economic context and an action proved to be effective in one city may not be in another. Although the usefulness of learning from already realized good practice initiatives has been acknowledged by the EU CoM through the provision of a related database [32], the only context specific factors provided to filter the provided real examples of (more than 6000) measures are the population and country.

A need for more contextualized comparisons (with the purpose of learning) among cities is better expressed in CURB tool – the recommended tool to use by the Compact of Mayors for the development CAPs [30]. This tool, through its "benchmarking module" allows comparison of cities with similar characteristics on the basis of three filters: (1) region; (2) socioeconomic development (measured on the basis of the Human Development Index (HDI) rating); (3) climate. The latter parameter is an especially strong driver of energy consumption and associated GHG emissions in buildings, since heating and cooling demand may vary widely across cities with different climates, even in the same region. Although this "module" primarily aims at comparison, cities in the process of developing a CAP can use it to identify similar cities with already some experience and learn from their successes or failures.

Another critical point for cities to consider in this step is that achieving ambitious targets means that cities should also consider the inclusion of testing of more innovative actions in their climate plans. They should therefore grasp the opportunity to move from an above typical (or good) practice to becoming a leading paradigm for cities of a similar type. In this sense, for populating the list of possible actions cities can also seek inspiration from initiatives, such as C40 and Carbon Neutral Cities Alliance (CNCA), which actively encourage the recognition of the boldest and most ambitious climate actions in cities not only though climate leadership awards [33] and innovation funds [34], but also through reporting on best practice (e.g. in the Cities100 report [35] or the CNCA game changers report [36]).

Finally, for this step, it is not only important to identify possible actions per stakeholder (with the main one being the local authority), but also to develop a typology of actions and group them under certain strategies. A good practice example of such a typology is the distinction between "major actions" (i.e. actions for which the direct GHG emissions reduction can be quantified) and "enabling actions" (i.e. indirect actions that enable, accelerate, or multiply the effect of the major actions – e.g. campaigns about climate change and better training for the workforce) employed by New York City [37].

3.3. Review of criteria used in MCDA models

Using multiple criteria to evaluate, prioritise and select actions to be included in local CAPs is not yet a common (or transparent) practice. In most action plans, although an impressive list of actions is included, no clear-cut reference to the use of some kind of criteria to help in the choice of actions can be found [38, 39]. Indeed, out of the seventeen CAPs of CNCA cities only two of them, the City of Toronto and New York City, present a distinct prioritization approach (see [40] and [37]). To identify a set of generic criteria against which DMs can evaluate the feasibility and impact of actions as part of an MCDA framework, the present author investigated selected literature sources, including the two above-mentioned local CAPs. Specifically, the survey included: (1) studies and guidance frameworks developed by major national, regional and international organisations, i.e. the German Federal Institutes BBSR and BBR [27], the United Nations [41] and the C40 cities [42]; (2) Three open access decision support tools for city-level climate action planning, i.e. the CLIMACT Prio Tool [43], the BEST Cities Tool [29] and the most recent CURB tool [30]; (3) individual researches [22].

The results of the literature survey are presented in Table 1. In the case of the EU CoM signatories one can argue that the proposed indicators by the CoM already used by local authorities to describe key actions as “Benchmarks of Excellence” can also be applied as criteria to solve the MCDA problem of action prioritisation [44]. In this regard, this has also been included as a source in Table 1 (see [28]). One can easily observe that, in addition to effectiveness (GHG emissions saving potential) the most common type of criteria found in the different sources are the ones of primarily economic nature (initial investment cost, annual running cost and generation of jobs). The ones that follow in popularity are the technical feasibility and the speed of implementation. When combined with “effectiveness” the first most recommended/used criteria (except for job generation) help in finding the most cost-effective actions, while the second ones help in identifying the key easy to implement short-term opportunities (i.e. “quick wins”). With the inclusion of quick wins in an action plan, municipalities can effectively demonstrate the added value produced by the plan and more easily engage people in contributing to the reductions until the longer-term benefits of the plan become apparent [16].

Table1. Parameters identified in selected literature sources that can act as criteria in an MCDA model.

	Criterion group	Criterion	[41]	[28]	[27]	[42]	[43]	[30]	[29]	[40]	[37]	[10]

		Noise pollution	-	-	-	-	o	-	-	✓	✓	-
		Aesthetic quality	-	-	-	-	o	-	-	-	✓	o
		Social mobilisation potential	✓	-	-	-	o	-	✓	-	✓	✓

Note 1: “✓” indicates that the parameter is explicitly mentioned; “o” indicates that it may form part of a broader category
Note 2: In some sources the cost(s) and revenue(s) (financial feasibility) are examined as part of marginal abatement curves (cost-effectiveness), e.g. [40]

However, for achieving ambitious 2030 and 2050 targets cities will need to ensure that they move beyond low cost and quick win opportunities and also pursue more investment intensive ones that take longer to play out but will be critical in achieving the required decarbonisation (such as urban densification and land-use planning) [45]. The business case for including such actions can be made by looking at their co-benefits. Actions delivering multiple benefits at once not only can be considered as cost-efficient, but they also increase the likelihood of their success by engaging more diverse communities of interest (also as investors) and demonstrating compelling added value for them [46]. These are the so-called “win-win” actions. Table 1 shows that although an increasing interest in the inclusion of co-benefits is observed, the inclusion of a larger list of sustainability indicators to account for positive side effects of actions as criteria in a MCDA model is still not the norm. In addition to that, an action may also be associated with unintended adverse consequences (co-harms). Most guides, however, solely use expressions such as “co-benefits” or “multiple benefits” introducing a positivity bias towards the impacts. For actions to be “no-regret”, they should not only be cost-effective and involve co-benefits but also be free of hard negative side effects with other objectives. For these and many other reasons, municipalities must seek comprehensive coverage of potential co-benefits and co-harms in their prioritization process to avoid counterintuitive results [46].

A problem that can arise in the case of including the numerous sustainability aspects as individual criteria in the MCDA model is that its complexity increases and therefore the interpretability of its results decreases. Some researchers agree that an average person can handle a maximum of nine criteria because of the general limitations of abstract thinking [47, 48]. When the number of the criteria is more than nine, the aggregation of criteria into groups is generally recommended. Several attempts to develop an ordinal scoring method for quantifying the qualitative mapping the positive and negative interactions between SDGs and their targets have been observed in the literature (e.g. see Nilsson et al. [49] for a sophisticated seven-point scoring method). This way of thinking can be easily transferred to the analysis of synergies and trade-offs between specific climate actions and other objectives. This is evident in the New York City’s plan where a five-scale qualitative system is employed, ranging from “major risk” (score 1) to “major benefit” (score 5) [37].

In regard to other underrepresented criteria in the various sources, it becomes clear that only a few MCDA models include social feasibility criteria. In general, social feasibility is concerned with gaining people’s acceptance regarding the actions to be programmed. In participatory frameworks where anyway representatives of stakeholders are included in the overall process, measuring their “acceptance” and include it as a criterion in the MCDA becomes easy. However, for a broader public acceptance the process of asking a considerable sample of local residents of the willingness to accept certain solutions may be impractical and time consuming. The present author suggest that the criterion of social compatibility is applied in any case, which can indirectly provide information on public acceptability [16]. Social compatibility captures the extent to which a solution is compatible with people’s current frame of mind and does not challenge their values and habits. Solutions with low social compatibility are usually met with a low degree of acceptability. For example, car sharing requires a significant shift in people’s mindset and travel habits. This was also revealed in an EU-wide survey [50], which found that only a minority of the respondents were interested in a car-sharing service, and even fewer considered this service as an actual alternative to car ownership. Information on social compatibility can be fairly easily retrieved from a discussion with the main stakeholder groups, literature sources and common sense.

Finally, it is also significant that cities take into account their “level of power” (i.e. control). Again, this criterion is not as highlighted as expected in the different guides. This factor can be included in a local CAP either as a criterion in the overall action prioritization exercise or it can form the starting point for a first shortlisting of actions, which are later evaluated and prioritized against all the rest criteria. To assist the first case, C40 provides a scoring framework broken down into four main categories, each with a score from 0-3 [42]: (1) Own/operate; (2) Set/Enforce Policies and Regulation; (3) Control Budget; (4) Set Vision. A similar framework is also employed by the BEST Cities Tool [29].

All these considerations are taken into account in the generic criteria tree presented in [16]. This tree may be used by city leaders as a starting point in order to facilitate the implementation of this step and/or may form the heart of a potential future standardization of the prioritization procedure in the context of climate action planning. Whatever the criteria tree used from literature (or a future standard) is, it should only be seen as a foundation to start this step; its acceptance by all involved DMs is crucial and criteria might be added and/or dropped depending on the specific objectives of the different DMs and the CAP.

3.4. Selection of an appropriate MCDA method

Selecting a suitable MCDA method (Step VIII) is a multi-criteria problem in itself. Each method has its weaknesses and strengths (e.g. for a comparison see [17]) and there is no consensus about which methods are more appropriate in a particular context. A comprehensive review of studies comparing the application of selected MCDA models in the same case study to investigate whether the resulting rankings and the derived recommendations vary depending on the method shows that no definitive answer can be given [51]. In some cases, different methods led to the same best alternatives and in others the rankings changed significantly. Under these circumstances, to increase the robustness of the results, several authors recommend to use different methods in parallel [52, 53]. Usually the analyst decides which method(s) to use based on discussions with the DMs and his own competencies. The proposed framework does not aim to recommend a specific method. What can only be advised is to consider the use of methods that do not allow a high degree of compensation, and therefore support the strong sustainability concept [54]. Although it is argued that many of the compensatory MCDA techniques, such as the weighted sum model, use simpler algorithms, are easier to communicate, and potentially have less problems in gaining acceptance from stakeholders [17], any mathematical complexity can be handled if user friendly softwares are available. Several researchers [16, 17, 55] point out that the availability of software support to implement an MCDA method, manage the information and visualise the results in a clear, dynamic manner can provide considerable additional value for the user, and therefore can also be an important reason for choosing one method over the other. Indeed, the availability of such tools is growing – even the ones allowing the parallel use of different methods (e.g. Diviz [56]).

4. Conclusions and next steps

Whereas the technologies and expertise are in place for cities to reach climate neutrality, the challenge to change their emissions trajectory while meeting multiple competing priorities is still tremendous. It has become evident by surveys that local authorities lack understanding and methodological bases with respect to the definition and prioritisation of actions based on certain criteria. The present paper attempted to translate the decision process with respect to action prioritisation into a standardised or formal procedure which integrates MCDA technique to enhance the bindingness of the overall exchange between stakeholders. Due to limitations, the paper focused on particular steps in the process and attempt to shed light on the latest sources and developments that could support them. It is recognised that quantifying stakeholder's preferences and a great number of criteria may be a laborious and time-consuming process. For this reason, city governments, when faced with limited resources, should make effective use of all ready-at-hand existing tools to support this task. Next steps in research that could help improving and accelerating the implementation of such a framework in the context of next generation local CAPs are: (1) the creation of a common database of best practice of climate actions in cities allowing the application of "filters" – so that to enable local authorities to focus on cities with similar geographic and socioeconomic context – to facilitate and accelerate the definition of actions. It is recommended that this becomes part of the future activities of GCoM to promote shared learning; (2) the development of "co-impacts" tools assisting their integration into the prioritization of actions; (3) Group decision-making software tools especially designed for the task of action planning that guide the municipalities throughout the entire action prioritization process, from the stakeholder analysis (Step I) to the sensitivity analysis (Step XI) and streamlines the communication process between stakeholders.

Abstract. Planning and managing the rapidly growing cities in a manner that delivers a balanced solution for their environmental, social and economic long-term development constitutes one of the grand challenges of societies. In the urban planning field, several sustainability assessment systems emerged to guide the planning process towards these goals. After two decades of existence, there is a need to further analyze the lessons learned from the application of these systems and discuss the pathways towards more sustainable societies. This paper provides a literature review of the most widely used urban sustainability assessment systems: BREEAM Communities, LEED Neighborhoods, CASBEE Urban Development, Green Star Communities, and DGNB Urban Districts. Here, we analyzed 124 publications on the topic published between 2015-2018, using the selected assessment systems as keywords. This study revealed that there is a need for context customization of global targets into local actionable measures; involvement of regulatory bodies to ensure the successful application of such systems; and, consideration of socioeconomic factors as the assessment is still very focused on the environmental impact. This study provides insights for practitioners and researchers on the existing systems to assess urban sustainability and pathways for future research.

1 Introduction

The share of the global population that lives in cities has been growing and is projected to rise to 68% by 2050 [1]. While cities are hubs of development, they also pose increased stress in the demand for scarce resources and environmental concerns, which affects the economic and social balance of urban areas. These concerns rise the need for systems that can enable sustainable planning for managing the rapid growth of cities in a long-term perspective [2], [3].

As a response to these concerns, the construction industry has been making efforts to integrate sustainability principles into projects planning and practices by developing sustainability assessment systems like BREEAM (UK, 1990), LEED (USA, 1998), CASBEE (Japan, 2001), GREEN STAR (Australia, 2002) or DGNB (Germany, 2008), used and recognized internationally [4], [5]. These systems provide a set of indicators to evaluate the sustainability performance of a building, which can help the project owner to manage the impacts of their construction project [6]. Although the number of indicators and metrics may differ, they all define a set of criteria to assess a construction project based on their environmental, social and economic dimensions [6][7][8][9]. In the last decade, these systems have also new versions for neighborhood sustainability assessment (NSA), such as BREEAM Communities, LEED Neighborhoods, CASBEE Urban Development, DGNB Urban Districts. At the neighborhood scale, buildings become a component of an urban system, interrelated with the other components, such as public transport, and services. At this scale, it is also possible to explore to its fullest the synergies among buildings and its surroundings, for instance, by making use of district energy solutions and taking advantage of economies of scale. However, it also introduces complexity in the evaluation process, with a higher number of stakeholders involved, and the increased number of indicators [4], [5], [10], [11]. Moreover, there are still few certified neighborhood projects compared to the building scale. For instance, sustainable assessment systems, such as BREEAM passed already the 400.000 building certificates [12], but only summed 50 neighborhood projects by 2018 [13], followed by LEED system with over 100.000 certified buildings and only 188 neighborhood projects [14].

Previous research has largely discussed the metrics for evaluating sustainability at the building scale, for which more mature assessment systems exist for a longer time, but relatively few studies have focused on the urban scale [15]. Happio [16] was one of the first studies to provide a critical review of the main categories used by three of the most well-known NSA systems (BREEAM-Communities, LEED-Neighborhood development, and CASBEE-urban development) and highlighted the potential problems of using these systems outside its region of the origin. In this line, Sharifi & Murayama [8], [17] conducted an in-depth analysis of seven NSA systems, introducing a framework for the examination of NSA systems, and discussing some of their common limitations. Regarding the categories used to measure sustainability, Komeily & Srinivasan [18] criticized the systems for underperforming in the social, economic, and institutional aspects of sustainability. Tam et al. [19] contributed with an extended review of the NSA systems, evaluating 20 international systems and comparing their different approaches on urban sustainability, similarities, and limitations. While previous review studies contain implicit or explicit knowledge of the NSA limitations and research gaps, no prior study, to the best of our knowledge, has applied a systematic review approach to identify the main shortcoming of the existing systems for assessing urban areas.

In this study, we selected five of the most widely spread NSA systems for an in-deep analysis: LEED Neighborhood Development, BREEAM Communities, DGNB Urban Districts, CASBEE Urban Development, GREENSTAR Communities [20] [19]. These five systems were chosen because they are well developed and known internationally, have the highest number of certified projects, have publicly available manuals, and include scoring as part of their process. Here, we browsed the existing publications on the topic based on the name of each system as a keyword. The analysis is limited to the publications between 2015-2018 in-peered review articles in the urban planning field, which resulted in the identification of 124 publications. Afterward, we made an in deep-analysis of the gaps and limitations of these systems for future improvement. This framework can be a starting point for researchers to formulate new assessment systems or improving the existing ones.

This paper is structured as follows. Section 2 describes the analytical framework used for identifying the gaps in the literature. Section 3 presents and discusses the results of the gap analysis. Finally, Section 4 summarizes the main conclusions of this analysis and identifies future research avenues.

2 Methodology

This study started with a comparison of each system based on the statistics and content analysis from their technical manuals. This process focused on the analysis of their similarities and differences in terms of timeline, spatial spread, categories, and certification. Even though each NSA system aims at measuring and attaining sustainability in urban areas by providing a set of criteria and weights, the organization of these criteria tends to be different, making it difficult to compare the systems. To overcome this challenge, we rearranged the issues and indicators of the NSA systems in a common framework, grouping the criteria under the three main sustainability dimensions: environmental, social and economic. We proceeded with the review of the published scientific literature concerning the NSA systems to identify the gaps most frequently mentioned. This review followed the Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [21] [22] [23]. We started with a search in Web of Science and Scopus of the following by keywords: “Neighborhood Sustainability Assessment”; “LEED neighborhoods” or “LEED-ND”; “BREEAM communities” or “BREEAM-CM”; “CASBEE urban development” or “CASBEE-UD”; “DGNB urban districts” or “DGNB-UD”, and “Green Star Communities” or “Green Star-CM”. With this approach, we identified 821 records, of which 275 duplicated were removed. Then, we restricted the data to peer-reviewed articles written in English and published between 2015-2018, and to literature that focused on the urban scale rather than buildings. This resulted in the selection of relevant 124 articles for further systematic review and identification of the most frequent gaps of the NSA tools.

3 Results and discussion

3.1 Comparison of the NSA systems.

This section presents the comparison of the analyzed NSA systems regarding their timeline, spatial spread, categories and scoring (summarized in Figure 1, Figure 2, Table 1).

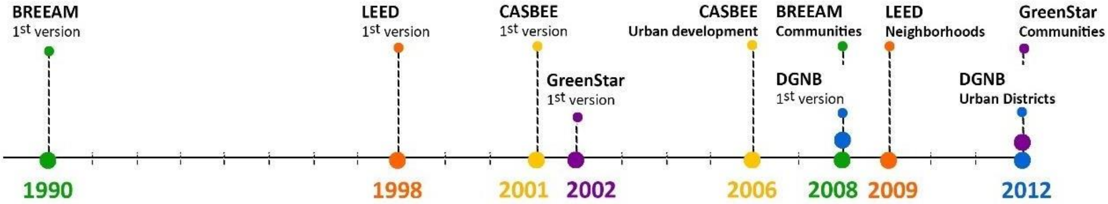

Figure 1 - NSA systems timeline

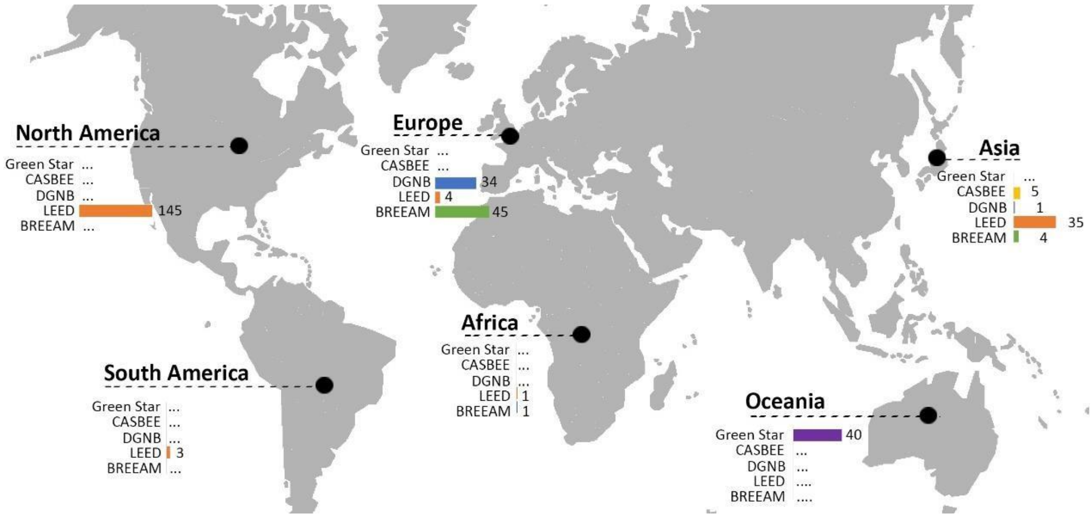

Figure 2 - NSA systems around the world (number of certified projects by the system in 2018)

BREEAM was the first developed system. Its first version for the building scale was launched by the UK Building Research Establishment in 1990, and BREEAM Communities (BREEAM-CM) version for urban planning was released in 2012 [24]. BREEAM-CM provides a set of criteria to evaluate sustainability distributed within five main categories: governance, social & economic wellbeing, resources, land use and ecology, and transport and movement. It also provides bonus credits for innovative features. Distributed under these categories, there are 40 criteria, subjects to scoring, of which 12 are mandatory. By fulfilling the criteria, projects earn points that determine its certification level: Pass (30 points), Good (45 points), Very Good (55 points), Excellent (70 points) and Outstanding (80 points) [24]. In 2018, there were 50 BREEAM-CM certified projects, 45 in Europe and 5 in Asia [25].

LEED was launched by the U.S. Green Building Council in 1987, and LEED Neighborhoods (LEED-ND) version was released in 2014 [26]. LEED-ND evaluates sustainability performance at the urban scale by addressing three main categories: smart location and linkage, neighborhood pattern and design, and green infrastructure and buildings. It also accounts for two extra categories: innovation; and regional priority. Distributed under these categories, there are 40 credits subjects to scoring and 12 prerequisites that must be respected but do not count for scoring. By fulfilling credits, projects earn points that determine its certification level: Certified (40 points), Silver (50 points), Gold (60 points) and Platinum (80 points) [26]. In 2018, there were 188 certified LEED-ND projects, 145 are in North America, 35 in Asia, 4 in Europe, 3 in South America, and 1 in Africa [27].

CASBEE was launched by the Japan Sustainable Building Consortium (JSBC) in 2001, and CASBEE Urban Districts (CASBEE-UD) was released in 2006 [28]. It considers the improvement of three main urban dimensions: environment, society, and economy. The evaluation attributes a score to each of these dimensions based on two factors: built environment quality (Q) and built environmental load (LR), the assessment scale for Q and LR ranges from 1 to 5. Then, these two factors are used to calculate the final score for Built Environment Efficiency (BEE). For CASBEE-UD there are no mandatory requirements. The calculated score projects determine its certification level: Poor (BEE 0.5), Fairly Poor (BEE 0.5-1), Good (BEE 1-1.5), Very good (BEE 1.5-3), and Excellent (BEE 3) [28]. In 2018, there were 5 CASBEE-UD projects, all of them in Asia [29].

DGNB was first developed for the building scale in 2008, and DGNB Urban Districts (DGNB-UD) was released in 2012 [30]. DGNB-UD includes the five main categories of assessment: environmental quality, economic quality, sociocultural and functional quality, technical quality, and process quality. Distributed under these categories, there are 30 criteria subjects to scoring. By fulfilling credits, projects earn points that determine its certification level: Silver (55 points), Gold (65 points), Platinum (80 points) [30]. In 2018, there were 34 certified DGNB-UD projects, all in Germany [31].

Green Star was launched by the Green Building Council of Australia (GBCA) in 2002, and Green Star -Communities (Green Star-CM) was released in 2012 [32]. The evaluation process comprises the collection of credits for four main categories: governance, livability, economic prosperity, and environment. It also provides bonus credits for innovative features. Distributed under these categories, there are 32 credits subjects to scoring. By fulfilling credits, projects earn points that determine its certification level: 4Star (45 points), 5Star (60 points), the 6Star (75 points). In 2018, there were 40 certified Green Star-CM projects, all in Australia [33].

Overall, although the number of indicators and metrics may differ between systems they all define a set of criteria to assess a construction project based on their environmental, social and economic dimension, as summarily presented in Table 1. This analysis shows that BREEAM-CM, LEED-ND, and DGNB-UD present a higher number of criteria and weight related to access to services, but attribute a much lower number of criteria and weights to cultural heritage and life cycle costs. In fact, BREEAM-CM, LEED-ND systems address only indirectly life cycle costs by incorporating it in the energy's evaluation measures and reuse of materials. In CASBEE-UD the weights are more evenly distributed, attributing slyly higher importance to waste, land use, participation, and governance, but there is no specific category for life cycle costs. Finally, GREEN STAR-CM also attributes higher importance to participation and governance, but less importance to cultural heritage. Overall, the NSA tools have more criteria and attribute more weight to the environmental and social dimensions of the evaluation, rather than the economic factors.

Table 1 - NSA tools: criteria and weight comparison

		BREEAM-CM	LEED-ND	DGNB-UD	CASBEE-UD	G.STAR-CM
Environmental criteria	Energy	energy strategy*; transport carbon emissions (Wst: 7%)	minimum building energy performance*; solar orientation; optimize building energy; renewable energy; district heating and cooling; infrastructure energy efficiency (Wst: 9%)	energy infrastructure; LCA -emissions (Wst: 9%)	possibility demand/supply …; adaptability and expandability (Wst: 6%)	greenhouse gas strategy; peak electricity demand (Wst: 8%)
	Water	water strategy*; water pollution; rainwater harvesting (Wst: 5%)	indoor water use reduction*; outdoor water use reduction; wastewater management (Wst: 5%)	water cycle (Wst: 3%)	water resource – waterworks; sewerage (Wst: 6%)	integrated water cycle (Wst: 7%)
	Waste	low impact materials; resource efficiency; existing buildings*; sustainable buildings (Wst: 12%)	construction activity pollution prev.*; solid waste management; building reuse; certified green building*; recycled and reused infrastructure (Wst: 8%)	lca-resource cons; resilience and adaptability; resource management (Wst: 10%)	resources recycling-construction; operation; environmentally considerate buildings (Wst: 17%)	materials; waste management; sustainable buildings (Wst: 11%)
	Land use	ecology strategy*; enhancement of ecological value; green infrastructure; land use*; landscape (Wst: 12%)	smart location*; imperiled species*; wetland & water body conservation*; agricultural land conservation*; site design for habitat or wetland*; restoration of habitat or wetlands; long-term conservation management; minimized site disturbance (Wst: 4%)	biodiversity; land use; smart infrastructure; land use efficiency (Wst: 15%)	greenery - ground greening; building top greening; biodiversity – preservation; regeneration & creation; consistency with upper level; planning; land use (Wst: 17%)	sustainable sites*; ecological value (Wst: 4%)
	Well-being	noise pollution*; light pollution (Wst: 3%)	light pollution reduction (Wst: 1%)	thermal comfort open spaces; open space; noise, exhaust and light emissions (Wst: 10%)	View; inhabitant population; staying population (Wst: 8%)	healthy and active living*; light pollution (Wst: 6%)
	Climate adapt	adapting to climate change; flood risk assessment*; flood risk management; microclimate (Wst: 8%)	rainwater management; floodplain avoidance*; steep slope protection; brownfield remediation; heat island red (Wst: 8%)	urban climate; environmental risks; groundwater and soil protection (Wst: 7%)	basic disaster prevention; disaster response ability; traffic safety; crime prevent (Wst: 11%)	adaptation and resilience; safe places*; heat island effect (Wst: 7%)

Social criteria	Access to services	access to public transport; public transport facilities; transport assessment*; cycling network; cycling facilities; local parking; demographic needs*; delivery of services, facilities; public realm; utilities; inclusive design; safe and appealing streets (Wst: 26%)	preferred locations; access to quality transit; transit facilities; transportation demand management; bicycle facilities; reduced parking footprint; compact development*; connected and open community*; mixed-use neighbor.; access to civic & public space; access to recreation facilities; neighbor. schools; walkable streets; local food production; visibility and universal design; tree-lined & shaded streets (Wst: 51%)	motorized transportation; pedestrian and cyclists; robust social and functional mix; social & commercial industry; barrier-free design (Wst: 21%)	convenience; health and welfare, education; development of traffic facilities; traffic - logistics management (Wst: 11%)	sustainable transport & movement; walkable access to amenities; access to fresh food; digital infrastructure (Wst: 9%)
	Heritage	local vernacular (Wst: 1%)	historic resource preservation (Wst: 2%)	urban design (Wst: 3%)	history and culture (Wst: 3%)	culture, heritage and identity (Wst: 3%)
	Participation	consultation plan*; consul. & engagement*; design review; training and skills; community management of facilities (Wst: 15%)	community outreach and involvement (Wst: 2%)	integrated design; consultation; project management); governance; monitoring (Wst: 10%)	compliance; area management; information service performance; information system - block management (Wst: 17%)	green star accredited professional; design review; engagement; corporate responsibility; sustainability awareness; community participation & governance; environmental management; community development* (Wst: 28%)
Economic	Economic prosperity	Economic impact*; Housing provision (Wst: 12%)	Housing and jobs proximity; Housing types and affordability (Wst: 10%)	Local economic impact; Value stability (Wst: 6%)	Economic development - revitalization activity (Wst: 6%)	Community investment; Affordability; Employment& economic resilience; Education & skills (Wst: 13%)
	Life cycle	Not found any exclusively dedicated criteria, although costs calculation is included in the energy-related criteria (Wst: 0%)	Not found any exclusively dedicated criteria, although costs calculation is included in building reuse and energy criteria (Wst: 0%)	Life cycle cost; partially included in resilience and adaptability (Wst: 6%)	(Wst: 0%)	Return on investment; Incentive programs (Wst: 4%)

* = includes mandatory requirements, wst = weight subtotal

3.2 *Identified shortcomings*

This section presents the most frequently identified limitations of NSA systems (in Table 2) that can be used to discuss the possible pathways for improvement of these systems.

Table 2 - NSA systems: results from the gap analysis

Gaps identified	% of Papers
G1 Lack of consensus on sustainability definition and concepts	10%
G2 Overlapping and incoherent distribution of criteria and weighting	18%
G3 Need for widening the scope by including evaluation criteria on socioeconomic conditions, mobility and walkability, disaster resilience and climate change, cultural factors	26%
G4 Little flexibility for local adaptation, particularly for developing countries	28%
G5 Need to adapt the assessment systems for urban regeneration projects	11%
G6 Regulatory bodies involvement and participation	18%
G7 Need for widening the scale of assessment	9%
G8 Integration of the NSA with computer-based models	6%

*total number of papers analyzed: 124

G1 - Lack of consensus on sustainability definition and concepts. Results from the literature review show that sustainability is not a fixed term yet [34], [19]. One of the first definitions of sustainable development was set by the Brundtland Commission 1997 [35], that emphasized that sustainable development is only achievable through the integration and acknowledgment of economic, environmental, and social concerns throughout the decision-making process. These concerns became the main pillars for most of the NSA systems, which investigate practical ways of measuring and achieving the sustainable development of urban areas [19], [34], [36] [37] [38]. As argued by Boyle [7], although NSA systems address the concept of urban sustainability by providing a practical pathway to measure it based on a set of indicators, they often group and use different metrics and weights to each sustainability issue. In this sense, further consensus on the concepts and definition is necessary to make them globally applicable and understood.

G2 - Overlapping and incoherent distribution of criteria and weighting. Because of the lack of consensus on the definition of sustainability, these systems often face the problem of completeness, and overlapping criteria [39]. Reith [39] further highlights that the lack of a consensual definition and clear metrics makes it difficult to measure the sustainable performance of a project and makes the comparison of the different rating systems ambiguous, as it is not possible to make a direct correlation between categories or translation between their oversell scores. For instance, a high score achieved by a project in the BREEAM-CM does not immediately translate into LEED-ND high performance, which raises the question about what exactly do they measure ("Do green neighborhood ratings cover sustainability?"). Wallhagen [40] argues that the use of interchangeable criteria can create a bias in the analysis because if the sustainability aspects are exchangeable, a project can become certified without being sustainable. Also, Komeily [18] and Kaur [22] argue that there is a need for a more coherent distribution of the criteria and categories. Ali-Toudert [15] argues that these systems have often overlapping criteria, and often ignore interactions between the criteria, which may lead to the overestimation or underestimation of sustainability compliance.

G3 - Need for widening the scope. Although the efforts of NSA systems to provide a holistic approach towards sustainability, the literature review revealed that most of these systems lack completeness in terms of content and criteria. Authors such as Wu [41], [42] notice that these systems emphases on the ecological and environmental aspects, ignoring the economic and social aspects of sustainability. Gouda [43] and Riggs [44] discuss the criteria used to evaluate the mobility modes and point out the need for a more expansive view of walkability based on both quantitative and qualitative factors. Sally Naij [45] and Diaz-Sarachaga [46] notice the need to include evaluation criteria for climate change adaptation and disaster resilience. Kaur [22] highlights that the evaluation often attributes more importance to certain aspects like infrastructure and resource management rather than cultural, business and innovation.

G4 - Little flexibility for local adaptation. Most of the NSA systems are developed within a certain country but are often used in contexts other than their origin. This opens the debate on the viability of using global standards and the pertinence of their use in actual local conditions [47] [48]. In this context, Gouda [49] further highlights that NSA systems are often related to standards, codes, guidelines highly dependent on the country of origin, which is contradictory to their characterization as independent or international. Kaur [22] argues the need to assure local requirements and site-specific aspects which may differ within cities and regions. Authors such as Dawodu [50] Diaz-Sarachaga [51] also point out that most of the existing NSA systems come from developed countries, particularly North America and Europe. Yet the developing countries such as African cities, are the ones expected to have the highest expansion rates over the next years. Therefore, the expansion of the existing systems or development of new ones for developing countries is a major challenge to be addressed.

G5 - The need to adapt the assessment systems for urban regeneration projects. The NSA systems are mostly designed to evaluate and guide the development of new urban areas, however, authors such as Zheng [52] and Boyle [7] highlight the need to adapt and use these systems to the context of previously build urban environments and their role in achieving global sustainability. Further, on this topic, Cappai [53] explores the reuse of brownfields to meet urban densification and sustainable development requirements. Appendino [54] stresses the need to develop a set of indicators to assess the role that heritage could play in urban sustainable development.

G6 - Regulatory bodies involvement and participation. The results from the literature review show that a key factor for the successful adoption of green communities is government involvement and social participation. To this point, Boyle [7] argues sustainable urban regeneration must be grounded in principles of urban governance, participatory action and an understanding of market dynamics. Therefore, it is necessary for a new iteration of the NSA systems centered on institutional mechanisms to engage citizens and support local action. In fact, Morris [55] conducted a survey on Green Star-CM and concluded that the main factor frequently appointed in the interviews for implementing this system was the requirement for government involvement and funding. Göçmen [56] and Oliver [57] discusses how planning at the local government level play a fundamental role to play in advancing local and regional sustainability. Encinas [58] argues that the improvement of the obligatory minimum standards may push forward the current voluntary standards by establishing a more demanding baseline that incentivizes competitiveness in the market.

Gap 7 - Need for widening the scale of assessment. While the first sustainability assessment systems and studies focused on the evaluation of single buildings, a growing number of studies are shifting towards larger scales by widening the evaluation to the neighborhoods and cities. To this point, Verovsek [59] stresses that at the neighborhood scale buildings become modules of a system that also considers spaces in-between buildings, public spaces, and infrastructures, the holistic and the community aspect. Addressing sustainability at larger scales opens new opportunities for improved efficiency and better management of local resources, but also opens new challenges because of the increased complexity and interconnectivity. Skaar [60], Aghamolaei [61] and Koutra [62] discuss the importance and difficulties of passing from Zero Emission Buildings to Zero Emission Neighborhoods. Wu [42] discusses how the traditional focus on the green building can transit to green communities by comparing LEED versions for buildings and neighborhoods. Additionally, Pedro [63] addresses the opportunities and challenges of scaling up LEED-ND from the neighborhood towards the city scale. Koutra [62] reviews existing systems and how they address the challenges of sustainability at the building, neighborhood and city level.

G 8 - integration of the NSA with computer-based models. NSA systems are typically expert-based rather than computer-based models, although a few recent studies suggest the integration of both. In this sense, Kuster [64] proposes a near real-time environmental assessment approach for the district level, that combines the expert consultation with ICTs and artificial intelligence to ensure an improved temporal and local adaptability of actual neighborhood sustainability assessments. Oregi [65] further discusses the use of ICT systems in sustainable urban planning projects and the advantages of integrating them in the early stage phase, providing a way of visualizing the sustainability performance scores and means to communicate with stakeholders about the sustainable performance, right from the start of the project. Cheshmehzangi [66] suggests integrating environmental performance analysis for urban design with Computational Fluid Dynamics (CFD) to achieve urban sustainability. Pedro [63] argues that combining sustainability assessment with a computer-based model such as geographic information system (GIS) enables assessing large datasets in reduced processing time. Chen [67] proposes incorporating sustainability assessment into architectural design software such as REVIT to facilitate the integration of sustainability concepts in the normal workflow of architectural professionals.

4 Conclusion

This paper provides a systematic literature review on five of the most widely used urban sustainability assessment systems (BREEAM Communities, LEED Neighborhoods, CASBEE Urban Development, Green Star Communities, and DGNB Urban Districts). Therefore, we analyzed 124 publications on the topic published between 2015-2018 and identified the following eight shortcomings: 1) lack of consensus on sustainability definition and concepts; 2) overlapping and incoherent distribution of criteria and weighting; 3) need to widen the scope by considering, for instance, more socio-economic factors; 4) little flexibility to local adaptation; 5) need to adapt assessment systems for urban regeneration projects; 6) call for regulatory bodies participation and involvement; 7) need to widen the assessment scale; 8) quest for integration with computer-based models. Despite providing a systematic review of recent literature, this study is limited to journal articles found by the selected databases between 2015-2018, within the urban planning field. Therefore, future work can consider expanding the time range and a more detailed analysis of each of these gaps considering hypothesis for improvement. Overall, these findings can be a starting point for researchers and practitioners to formulate new assessment systems or adapt the existing ones, thereby promoting the continued development of this field.

Optimization-based planning of local energy systems - bridging the research-practice gap

Andrew Bollinger L, Marquant J, Sulzer M

Empa – Swiss Federal Laboratories for Materials Science and Technology, Urban Energy Systems Laboratory, Überlandstrasse 129, 8600 Dübendorf, Switzerland

andrew.bollinger@empa.ch

Abstract. Optimization-based planning of local energy systems – though increasingly mature from a methodological perspective – is not commonly applied in practice. This paper synthesizes learnings from 4 case studies – focused on 4 different sites – in which optimization-based methodologies have been applied to the planning of local energy systems. The aim is to generate insights to facilitate the more effective application of optimization-based methodologies to local energy systems planning in practice. The results indicate that an intensively iterative methodology is critical not only as a basis for adapting the analysis based on stakeholder input, but also to facilitate learning on the part of stakeholders with regard to the value and limitations of the approach and the results. With regard to optimization methodologies, in particular temporal decomposition methodologies are identified as critical to preserving computational tractability in the optimization of complex technical systems, especially those featuring networks and those with many energy carriers or technology options. It is suggested that the methodological tailoring of an optimization model to a specific case and the calculation/visualization of key indicators can be largely automated, which could significantly accelerate future studies and reduce the knowledge required for their execution.

1. Introduction

Optimization-based planning of local energy systems refers to the use of computational optimization methodologies to facilitate the planning of decentralized energy systems for neighborhoods, campuses, urban quarters/districts and municipalities. In particular over the past decade, significant research has been dedicated to the development of optimization-based methodologies to facilitate local energy system planning. The added value of these methodologies is their ability to enable a more comprehensive and holistic perspective in the design of local energy systems. This research domain is generally characterized by the application of linear or mixed-integer linear programming approaches, sometimes in combination of genetic algorithms or other meta-heuristic approaches, and a focus on energy systems featuring multiple energy carriers and multiple conversion/storage technologies.

Optimization-based planning of local energy systems – though increasingly mature from a methodological perspective – is not commonly applied in practice. While numerous examples of the application of this approach to practical cases can be found in literature [1-7], the focus is generally on methodological demonstration/validation. Systematic integration of this approach into local energy systems planning processes is lacking. If the potential of optimization-based local energy systems planning is to be realized, it is critical to understand the reasons for this lacking, and how the research-practice gap can be more effectively bridged.

This paper synthesizes learnings from 4 case studies – focused on 4 different sites – in which optimization-based methodologies have been applied to the planning of local energy systems. Each of the case studies was carried out in close collaboration with one or more industry partners with a strong interest in using the results of the study for the planning of the respective site's energy system. The aim of this paper is to generate insights to facilitate the more effective application of optimization-based methodologies to local energy systems planning in practice.

In the next section, the approach of optimization-based local energy systems planning is clarified, and important methodological developments explained. Each of the 4 case studies is then briefly described, after which key learnings are extracted and elaborated.

2. Optimization-based planning of local energy systems

Optimization-based planning of local energy systems encompasses a range of methodologies, which may be combined or adapted depending on nature of the problem. Most commonly, the problem is formulated as one of cost minimization [2,4,8-10], with costs most often (though not always) expressed as the system's life-cycle costs (investment costs + maintenance costs + energy/fuel costs + decommissioning costs). Most often, the problem is formulated as a linear or mixed-integer linear programme. Variables commonly include the input and output energies of conversion and storage technologies per timestep and the capacities of these technologies. Mixed-integer formulations are necessary for cases in which binary variables are required to represent the installation of the specific components or their operation within a given timeframe. Less commonly programming approaches are combined with meta-heuristic approaches – in particular genetic algorithms – in the context of a bi-level approach as a basis for enabling the solution of more complex problems [11,12]. Multi-objective optimization – the simultaneous optimization with respect to multiple objectives – is most often enabled through the use of an epsilon (ϵ)-constraint method [13], in which a pareto front of optimal solutions is built up by optimizing with respect to costs and constraining a second variable to sequentially higher or lower values.

This basic optimization problem may be augmented or adapted in different ways depending on the requirements of the study and the complexity of the problem to be solved. Research in recent years has led to the development of various methodologies which may be applied in combination with the basic approach described above. This includes, for instance:

- **Thermal and electrical network optimization methodologies**, which extend the basic approach from a single-node to a linked multi-node problem. This enables the identification, e.g. of optimal structures and capacities of thermal networks between buildings [9, 14,15]
- **Spatial clustering methodologies**, which reduce the complexity of multi-node problem formulations by clustering nodes so as to decrease the number of problem variables. Different algorithmic clustering methodologies have been developed, including density-based clustering (most common), load-based clustering and combined clustering [16,17]
- **Temporal decomposition methodologies**, which reduce the complexity of the basic optimization problem by reducing the number of timesteps and thus the number of problem variables. Whereas the basic optimization problem is characterized by a set of sequential timesteps – most commonly hourly over the time horizon of one year – temporal decomposition methodologies either select a subset of "representative" timesteps for capturing the most critical features over the entire year (e.g. typical days methodology), or divide the optimization problem into smaller chunks (e.g. rolling horizon methodology) [18,19]
- **Multi-stage optimization methodologies**, which entail optimizing not just a "snapshot" system design, but rather the sequence of technology investments to be made over a defined period of time. This is essential for cases in which multiple planning phases are foreseen, or in which the composition (e.g. number/type of buildings) of a site is expected to change over time [20,21].
- **Stochastic and robust optimization methodologies**, which enable the explicit representation of parameter uncertainties into the optimization problem, either with associated probabilities (stochastic optimization) or windows of feasible values (robust optimization) [22-24].

Each of these methodologies may essentially be viewed as modular add-ons to the basic optimization problem outlined above. It is possible, and sometimes even necessary, to apply multiple of these methodologies in combination in order to arrive at a formulation of the optimization problem which both sufficiently accurately represents the real-world problem and is capable of being solved within a reasonable amount of time. A particular challenge, however, is that each methodology requires a (to some degree) fundamentally different formulation of the optimization problem (i.e. different sets, parameters, variables and constraints). Insofar as the application of optimization-based approaches to local energy systems planning in practice requires identifying solutions on a short timeframe, the manual development of a tailored problem formulation based on the specific needs of a given case is prohibitive. Within this context, an important motivation for the research team behind the case studies described below was to understand which specific methodologies are necessary for addressing different types of real-world cases and if/how the associated formulation of the optimization problem could be automated to enable rapid but tailored assessment of each case.

3. Case studies

In this section, the 4 case studies are introduced and briefly described. Each case study was carried out in close collaboration with an industry partner, and focused on a specific physical site (see Table 1). However, to a greater or lesser degree, each case study was a broader collaborative initiative involving multiple stakeholders including for instance the building-/land-owners, general planners, local utilities and municipalities. The case studies addressed sites of different sizes. The first two dealt with building agglomerations of 10-15 buildings. The second two case studies dealt with building agglomerations on the scale of hundreds of buildings. All case studies dealt with sites located in Switzerland. The second case study dealt with a greenfield site, whereas the others were focused on sites with an existing and, importantly, evolving building stock. The different scales and characteristics of each case study, as well as the different categories of stakeholders involved, meant that each case came with a specific set of questions and methodological requirements. The case study descriptions below are presented in anonymized form at the request of the involved partners.

Case study	Main industry partner	Size of site (buildings)	Type of site
1	Municipal authority	10-20	Existing
2	Local utility	10-20	Greenfield
3	Local utility	600	Existing
4	Engineering consultancy	1000+	Existing

Table 1: Key features of the case studies.

The analysis for each case study was carried out using a common software tool – the *Ehub Tool* – developed by the researchers prior to the start of the case studies. In the course of carrying out the case studies, the tool was further developed to accommodate the specific requirements of each case and the specific knowledge needs of the respective industry partners. In addition to contributing to the development of an energy plan for each site, a goal of the researchers was to adapt and extend the software base of the Ehub Tool to meet the requirements of real-world problems such that the Tool could be more efficiently applied to similar cases in the future. A third goal of the researchers was to develop a replicable methodology for applying the Tool to local energy systems planning in practice. Prior to the start of the case studies, the research team defined a preliminary version of such a methodology. This methodology provided a common overarching sequence of steps to be carried out – or at least considered – in each of the projects, although it was understood that this methodology would inevitably vary to some degree across the case studies. Indeed, better understanding the necessary deviations from this methodology was a central goal of the research team. The following basic steps defined the methodology:

1. **Requirements definition & problem specification**: Define the scope and objectives of the study, the assumptions to be made and the key performance criteria.
2. **Data collection & processing:** Compile and prepare the necessary input data for the study, including e.g.: estimated building energy demands (hourly profiles for heat, electricity, cooling, steam, etc.), technical & cost specifications of supply technologies (e.g. efficiencies, lifetimes, installation costs, operation costs), on-site renewable energy potentials (e.g. solar, groundwater)
3. **Adaptation Ehub Tool:** As necessary, adapt or extend the Ehub Tool based on the specifications of the problem, by adding custom constraints, objectives or evaluation criteria.
4. **Case implementation & execution:** Implement the problem specification in the input files of the Ehub Tool. Run the tool.
5. **Results analysis & interpretation:** Assess the results to identify the optimal technical configurations under different conditions and the performance of each in terms of the specified evaluation criteria. Key outputs of the tool include the optimal sizing and locations of conversion, storage and thermal network components to be installed, the respective optimal operational schedules of each, and the resulting life-cycle costs and CO_2 emissions of the system.
6. **Iteration:** Iterate to evaluate alternative scenarios or test sensitivities to boundary conditions.

3.1. Case study 1 - Strategic energy planning for a mixed-use urban neighborhood

The first case study focused on the development of a strategic energy plan for an existing mixed-use urban neighborhood. The primary energy users on the site are currently industrial operations with large demand for high-temperature process heat (85-170 degrees C). Significant uncertainty exists regarding the long-term development of the site and thus the future quantity and type of energy demands, in particular after 2030. After 2030, it is possible that industrial operations may cease at the site, being replaced for instance by greater intensity of residential or commercial use. A set of 15 scenarios for the future development of the site in terms of floor area and building tenants were defined. The site is furthermore characterized by the existence of several historically protected buildings, which limits possibilities for energy-focused building retrofitting. It is also characterized by an existing groundwater well which may serve as a low-temperature thermal source for heating and cooling. In the short-term, it will be necessary to replace or renovate parts of the site's current energy system. The industry partner would prefer to make these short-term decisions in line with a longer-term strategy for the future development of the site's energy system. The task of the research partner was – given the inherent uncertainties in the future development of the site – to facilitate the identification of an energy strategy in line with the stakeholders' priorities.

3.2. Case study 2 - Early-stage energy planning for a greenfield commercial campus

The second case study focused on the development of an early-stage energy plan for a greenfield commercial campus. The future tenants of the site and precise configuration of buildings was uncertain, though it was possible to bound this uncertainty in the form of a handful of scenarios for the future tenants and energy demands of the site. Unlike the first case study in which a high-level, long-term energy plan was sought, here the stakeholders sought to identify a specific technological energy system configuration for the site. Key criteria for evaluating potential configurations were life-cycle costs, carbon dioxide emissions and energy autonomy. Of particular interest were technology configurations based around a thermal network. The optimal topology and temperature levels for this network, as well as the optimal set of buildings to be connected to the network, was an open question to be addressed by the analysis. Additionally to be addressed by the analysis was the optimal mix of production and storage technologies to install at each parcel within the site, and the optimal location of an energy center. Next to more conventional technologies, the potential roles of rooftop and facade PV technologies and seasonal ground heat storage were of particular interest.

3.3. Case study 3 - Strategic energy planning for an urban district

The third case study dealt with the development of a strategic energy plan for an urban district of ca. 600 buildings. The site in question is a mixed-use site with significant industry presence. Already now and even more so in the future, the site is undergoing a transition towards greater intensity of commercial and residential use. This shift is expected to result not only in changing energy demand patterns – in particular, increased future cooling demand by commercial buildings is foreseen – but also greater demand for sustainably produced energy. The goal of the industry partner was to determine which technological energy supply options may be best suited to meet these demands, and to what degree it is technically and economically feasible to achieve an energy supply based largely on renewable resources. The site already features a thermal network which provides heating to a fraction of the buildings in the district. An important question was the degree to which, and in which areas, it might be desirable to extend this network, and potentially complement it with a groundwater-fed cooling network.

3.4. Case study 4 - Energy master planning for an Alpine municipality

In 2008, the first energy master plan for the municipality in question was developed. Ten years later, the municipality requested an update of its energy master plan, which was to review the last 10 years while also giving an updated outlook for 2035 and 2050. The 2018 master plan sets new targets for the municipality based on the Swiss Energy Strategy 2050. The goal of the study was to understand how different combinations of energy technologies could best contribute to meeting the new targets. Of particular interest in this case was the potential of an energy system based around the provision of groundwater-based heating and cooling distributed via an anergy (low-temperature, <20°C) thermal network. In addition to groundwater, the potential contributions of various hourly-/seasonally-varying renewable energy resources such as local hydroelectricity and solar energy were a particular focus of the study. A critical question was how to bridge the winter shortfall in renewable energy availability.

4. Synthesized learnings

In this section, key learnings from the four case studies are synthesized. The actual results of the case studies are not presented – rather we focus here on methodological learnings which may inform future studies applying optimization-based approaches to the planning of local energy systems in practice. Three categories of learnings are presented here:

1. Learnings with regard to *project methodology*, i.e. the overarching procedure followed to achieve the stated goals of the study.
2. Learnings with regard to *optimization methodologies*, i.e. which optimization methodologies were of relevance.
3. Learnings with regard to *key indicators and results presentation*, i.e. which indicators were relevant to the involved stakeholders and to which forms of presentation did they best respond.

4.1. Project methodology

In section 3 above, the basic sequence of steps foreseen to be used in each of the case studies was presented. This basic methodology proved to be relatively robust across the case studies, with the major differences across cases seen in the duration and manner of execution of the individual steps rather than the structure of the methodology itself. Two specific patterns are worth noting.

Firstly, the data collection and processing phase was generally found to take considerably longer than foreseen, and was itself subject to multiple iterations. Two categories of data were most effort intensive: building energy demand data and technology cost data. For each of the case studies, building- or parcel-scale energy demands at hourly resolution were required. In all cases a combination of building simulation, standards-based assumptions, public building databases and monitored data was used to obtain suitable demand profiles. A particular challenge – the scale of which was not foreseen in advance – was the presence of missing and erroneous values in building databases and monitored data. This challenge was particularly onerous in case studies 3 and 4 due to the large number of buildings and the inconsistency of the databases used. In both cases, considerable manual effort was required to identify anomalous data points and replace them with justifiable estimates. A second challenge was the estimation of time resolved demands for industrial buildings. The energy intensity and temporal distribution of industrial energy demands are very specific to the processes involved, which are often not precisely known in such studies. Monitored data was therefore especially critical to estimating the energy demands of industrial buildings – sometimes workarounds using available data were necessary. For instance, in case study 1, highly resolved electricity demand data could be used as a basis for estimating the refrigeration demand of the industrial buildings. A specific challenge with regard to technology data was to estimate the capital costs of technologies in a comparable manner. These costs may be highly local, and reliable databases covering the full range of possible technologies do not exist. Moreover, different data sources may rely on different assumptions, meaning that the costs of two technologies may not be comparable if the data is drawn from two different sources. Most of the case studies here included several dozen different conversion and storage technologies, more than was anticipated. For each technology, multiple data sources had to be compared and necessary assumptions had to be verified with the involved stakeholders.

Secondly, for most case studies, the overarching methodology was more iterative than anticipated. Each iteration turned up unexpected results which had to be verified, and adjustments made. For instance, in case study 2, it was observed after one iteration that an external district heating network connection – the costs of which had been roughly approximated – was being used exclusively to cover heat demand peaks rather than provide for the heat base load. This was deemed an unrealistic modelling artifact and adjustments were made to the technology definitions in the subsequent iteration. It was also observed that multiple iterations are necessary not only as a basis for refining the results, but also as a basis for helping stakeholders to grasp the approach, the inherent assumptions underlying it, and the value and limitations of the results. These iterations therefore served the secondary purpose of a learning process for the stakeholders. In most of the case studies, 4 to 6 iterations were eventually necessary to arrive at a set of results acceptable and understandable to the stakeholders. In most of the cases, the possibility and benefit for further iterations beyond the conclusion of the original project was foreseen, in particular focused on the development of detailed concepts for specific subsystems, such as district heating networks or seasonal storage, which could be addressed at only a relatively high level in the holistic analysis.

4.2. Optimization methodologies

As evident in the descriptions above, the requirements of each case study differed, due to the varying knowledge needs of the involved stakeholders. This resulted in different sets of demands on the optimization methodologies used. As illustrated in Table 2, two of the case studies required multi-node problem formulations due to the need for optimizing the topology and dimensioning of a thermal network. In both cases, a temporal decomposition approach was required to preserve computational tractability of the optimization problem. Due to the large size of the site, case study 3 also required clustering in the spatial dimension to reduce the problem size. In case study 2, temporal decomposition was complicated by the need to represent seasonal storage technologies, requiring a solution tailored specifically to that case. Case study 1 – uniquely amongst the case studies – required a multi-stage problem formulation in order to accommodate phased changes in the spatial development of the site. Although a single node problem, the need for a multi-stage formulation in case study 1 and the large number of technologies being represented (due to many different energy carriers), significantly increased the complexity of the optimization problem, again requiring the use of temporal decomposition. None of the case studies used stochastic or robust optimization methodologies. Rather it was generally preferred by the stakeholders to address uncertainties through the use of scenarios and sensitivity analyses, as this provided a transparent basis for assessing the effects of different sources of uncertainty.

Methodology	Case study			
	1	2	3	4
Network optimization		thermal	thermal	
Spatial clustering			density-based	
Temporal decomposition	typical days	typical days	typical days	
Multi-stage optimization	3-stage			
Uncertainty handling	scenarios	scenarios		scenarios

Table 2: Overview of the methodological extensions used in each of the case studies.

Although the different case studies were subject to different methodological requirements, it was possible to carry them out using a common code base. In particular, it was possible to implement each of the methodologies into the Ehub Tool such that they could be active or inactive depending on the requirements of the problem at hand. This allowed for the formulation of the optimization problem to be automatically structured based on the problem definition as expressed in the Tool's input files, which are prepared individually for each case. However, it was noticed that each case came with certain characteristics that required the implementation of a limited set of parameters and constraints tailored specifically to that case. Based on the authors' experiences in these case studies, this is unavoidable, and suggests that there are limits to the development of a standardized "one-size-fits-all" software code base for optimization-based local energy systems planning.

4.3. Key indicators and results presentation

Based on the preferences and feedback of the stakeholders, a specific set of key performance indicators was calculated based on the results of each case. Five categories of indicators were relevant in one or more of the case studies: economic, sustainability, resource use, system design, system operation and energy autonomy. As indicated in Table 3, certain indicators were requested by the stakeholders in all case studies, including life-cycle costs, CO2 emissions and the optimal supply system configuration. Groundwater energy use and electricity grid interaction patterns were also required in 3 of the 4 case studies. In 2 of the 4 case studies, the stakeholders requested that all indicator values be compared with those of a "reference" scenario – a scenario based around the use of a conventional (in both cases natural gas-based) system configuration for the site. Comparison to the reference scenario served as an indication to the stakeholders of the potential benefits of developing a "non-conventional" energy supply system for the site. This was critical to enabling the industry partners to justify the results to other stakeholders and decision makers not directly involved in the project.

A challenge for the research team, especially in case studies 1 and 2, was the large number scenarios calculated. In all cases, multiple pareto fronts composed of 4-8 "optimal" solutions – a cost-minimizing solution, as CO2-minimizing solution and several in-between solutions – were calculated. In case study 2, such a pareto front was calculated for each of 45 different scenarios. This produced 180 "optimal" solutions for which each indicator was calculated. Identifying and communicating key patterns within this large body of results data were key challenges in this case. This was accomplished through the use of color-coded comparison matrices, which condensed a large amount of information into a single visualization, facilitating the identification and communication of important patterns. Detailed results for selected solutions were additionally provided to enable greater depth of understanding.

Category	Indicator	Case study			
		1	2	3	4
Economic	Life-cycle costs (per kWh or per m2)	■	■	■	■
	Cost breakdown (CAPEX, OPEX)		■	■	
	Overnight costs (per technology)		■		
Sustainability	CO2 emissions (per m2)	■	■	■	■
	CO2 avoidance costs	■			
Resource use	Primary energy use		■	■	
	Groundwater use patterns	■		■	■
System design	Optimal supply system configuration (optimal set & dimensioning of technologies)	■	■	■	■
	Optimal thermal network structure		■	■	
System operation	Storage utilization patterns		■	■	
	Renewables-based production			■	■
	Electricity grid interaction pattnerns		■	■	■
Energy autonomy	Hours of autonomous operation		■		

Table 3: Overview of the key indicators calculated for each case study.

5. Conclusions

The aim of this paper has been to generate insights to facilitate the effective application of optimization-based methodologies to local energy systems planning in practice. Key learnings from 4 different case studies were presented, each carried out in close collaboration with industry partners and focused on a specific physical site. The following learnings have been emphasized:

- It is possible to apply a *common overarching methodology* to case studies with different requirements and in the presence of different knowledge needs.
- An *intensively iterative methodology* for optimization-based local energy systems planning projects is critical not only as a basis for adapting the analysis based on stakeholder input and developing detailed concepts for specific subsystems, but also to facilitate learning on the part of stakeholders with regard to the value and limitations of the approach and the results.
- The presence of *anomalous, inconsistent and incomplete data resources* – especially with regard to building energy demands and technology costs – requires significant manual effort.
- *Temporal decomposition methodologies* are a critical enabler to preserving computational tractability in the optimization of complex technical systems, especially those featuring networks and those with many energy carriers or technology options.
- Both the methodological tailoring of a model to a specific case – i.e. the selection and adaptation of methodological extensions suited to solving the problem at hand – and the calculation of key indicators (see Table 3) can be *largely automated* using basic object-oriented software approaches.

In general, it was observed that at least 4 categories of knowledge are necessary for carrying out case studies similar to those presented in this paper: (1) on-the-ground knowledge and data concerning the site in question, (2) engineering knowledge regarding feasible technological solutions, (3) knowledge of optimization methodologies, and (4) software development knowledge. In the experience of the authors based on the case studies described in this paper, the 3rd and 4th categories of knowledge can be effectively solidified in a generally applicable – within certain limitations – software tool. To a certain degree, the 2nd category of knowledge can be solidified within a consistent and complete technology database linked with such a tool.

Taken together, the findings of this paper suggest that a combination of software tools and consistent/complete technology and building databases could significantly accelerate future studies and reduce the knowledge required for their execution. Effectively implemented, such a resource has the potential to facilitate the uptake of optimization-based local energy systems planning approaches in practice.

Acknowledgements

This research project is supported by the Swiss Innovation Agency lnnosuisse and is part of the Swiss Competence Center for Energy Research SCCER FEEB&D. The authors would furthermore like to thank the industry and research partners who participated in the case studies described in this paper, including Hochschule Luzern, Lauber Iwisa, Migros Ostschweiz, Regionalwerke Baden, St. Galler Stadtwerke, Stadtwerke Gossau and Stadt Zurich.

Abstract. Nature Based Solutions contribute both to mitigate and to adapt the cities to the impacts caused by climate change at urban level. Several methods and tools exist for assessing each strategy. However, none of them allow to cover the whole steps included from analyzing climate trends that could affect the cities, to NBS effectiveness. This paper reviews and classifies existing methods according to the relevant steps of climate resilience and NBS effectiveness, and a combination of various of those methods is presented in a practical case study. Bottom-up city energy, economic and environmental modelling have been performed to understand mitigation effects of NBS implementation at building and neighborhood level. Urban hydrodynamics and fluid dynamics have been modelled too, allowing the estimation of the adaptation effectiveness of the NBS scenarios in flooding and temperatures reduction respectively. Moreover, city vulnerability and urban risks, considering IPCC scenarios regarding climate trends, have been assessed to understand the areas of the city more vulnerable to the impact of climate change. Results show that strategies and climate hazards has been worked in a split way and there is a need to connect better mitigation and adaptation information to facilitate the municipalities taking robust decisions regarding the NBS implementation.

1. Introduction

Urbanization is widely acknowledged to be on an upward trend with 66% of the global population expected to be living in cities by 2050 [1]. Projections of climate change show increasing frequency and severity of extreme weather events, such as heatwaves. Such events, coupled with the UHI are likely to amplify the challenges facing this urban growth [2].

In this context, the European Union considers between their four main goals in this topic, the need of developing climate change adaptation and mitigation strategies. In order to promote this goal, for the current budget period 2014-2020, the European Commission has proposed that at least 20% of the budget (Multiannual Financial Framework) should contribute to climate change objectives, helping to ensure substantial support for adaptation and mitigation action in the Member States [3].

Following this, in March 2014, the European Commission launched the Mayors Adapt initiative on urban adaptation. It merged in 2015 with the Covenant of Mayors, combining urban adaptation and mitigation into an integrated approach. Today, the EU Covenant of Mayors for Climate & Energy brings together thousands of local governments voluntarily committed to implementing EU climate and energy objectives [3]. The trend driven by the Covenant of Mayors for Climate and Energy (CoM) is to include both climate and mitigation aspects [4]. This is also aligned with IPCC approach which considers that Adaptation and mitigation are complementary strategies for reducing and managing the risks of climate change [2].

In this global context of mounting challenges (e.g., climate change) and human activities (e.g., rapid urbanization), this Special Issue of Environmental Research attemps to lay the theoretical and applicative foundations of the Nature based solutions (NBS) concept by focusing on the most recent innovative strategies and scientific advances for building resilient landscapes and cities [5]. NBS are living solutions inspired, continuously supported by and using nature, designed to address various societal challenges in a resource-efficient and adaptable manner and to provide simultaneously economic, social and environmental benefits [6]. Having recognized NBS as one of the most comprehensive approaches for developing resilient landscapes and cities, governments and scientific communities are currently faced with the challenge of moving from general pronouncements to practical applications [5].

This paper presents the analysis of the existing methods and tools for assessing NBS effectiveness to mitigate and/or adapt the urban environments to climate change. Considering the trends driven by the most relevant entities about considering both mitigation and adaptation contributions, special focus has been put to identify methods that allow considering both strategies with the idea of providing an integrated approach.

2. Procedure followed

The procedure followed to understand the potentialities of the methods and tools to provide robust information regarding NBS effectiveness to climate change mitigation and adaptation has been done in 4 main steps:

- Step 1: Climate resilience methodology. Definition of all the features that a climate resilient methodology must cover.
- Step 2: Methods selection and characterization. Identification of all the methods and tools that can cover at least one part of the previously defined features.
- Step 3: Methods classification. Classification of the methods according to the relevant steps of climate resilience and NBS effectiveness that they cover.
- Step 4: Case study. Analyze in a practical case study a combination of various of those methods

2.1. Step 1: Climate resilience methodology.

The ambition of the climate resilience methodology as is understand in this paper, was the identification and organization of all the potential issues of interest in the context of climate change and NBS fields. Following objectives were defined for the methodology:

- It must allow understanding how the climate trends can affect the cities.
- It must consider how to assess the climate hazards that could affect the cities.
- It must allow assessing mitigation and/or adaptation strategies.
- It must include how to assess the effectiveness of the NBS to improve city resilience.

These objectives guided a completed state of the art revision which was supported in the identification and analysis of more than 80 references [7]. These references include more than 60 scientific articles identified thanks to key words such as climate resilience, mitigation, adaptation, Nature based solutions, urban climate trends, urban heat island effect, etc. Related projects and networks were identified and analyzed too, providing a detailed view of the of the state of the art.

From the literature review, information was extract in order to stablish the basis the methodology development. This information attends to the climate issues, scale (region, city, district, object), target of the measures (adaptation, mitigation, resilience), type of NBS considered, indicators used, actuation areas, etc.

The literature review had as a result the collection of all the features of interest that a methodology that allows assessing from climate trends to NBS effectiveness must cover:

1) Climate trends: air temperature, Rainfall/precipitation, air quality
2) Climate threats/impacts/hazards: Colder winters and warmer summers, Urban heat Island effect (UHI), runoff, air pollution, water quality, wind field.
3) Strategies: Mitigation and adaptation
4) Indicators to assess urban vulnerability and risks: Building cooling and/or heating energy demand reduction, global warming potential reduction, primary energy demand reduction, runoff reduction, carbon sequestration, external air temperature reduction.
5) Nature based solutions: parks and gardens, structures associated to urban networks, structures characterized by food and resources production, natural and semi-natural water bodies and hydrographic networks, constructed wetlands and built structures for water management, green roofs, urban planning strategies, works on soil, vertical structures (green walls and façades), direct human interventions.

2.2. Step 2: Methods selection and characterization.

This step consisted on the identification of all the methods and tools that can cover at least one part of the previously defined features of the methodology. After the identification, the methods have been characterized according to the mentioned features.

2.3. Step 3: Methods classification.

The classification of identified methods and tools according to their suitability for the urban climate resilience and NBS methodology application has been done by using the RACER method. RACER is an evaluation framework design by the European Commission to assess the value of scientific tools for use in policy making [8, 9, 10]. RACER stands for Relevant, Accepted, Credible, Easy and Robust:

- Relevant – e.g. closely linked to the objectives to be reached.
- Accepted – e.g. by staff and stakeholders.
- Credible for non-experts, unambiguous and easy to interpret.
- Easy to monitor – e.g. data collection should be possible at low cost.
- Robust – e.g. against manipulation.

This generic approach has been adapted to the objectives of the method classification:

- **Assessing urban climate issues**: methods that take into account issues related to climate, (such as temperatures, rainfall, air quality) are considered relevant for the purpose of the methodology.
- **Consideration of different scales**: methods that cover object, neighbourhood and city scales

are needed in order to fully characterize the NBS effectiveness over the climate resilience of the city.

- **Analysing all the stages**: from identification of threats to the analysis of NBS effectiveness. Methods that allow assessing the whole process are presented as suitable for the purpose of the methodology. However, according to the specific characteristics that this methodology wants to fulfil, it was considered challenging finding a method that could assess the whole process.
- **Assessing NBS**: as Nature Based Solutions are the focus of the project, methods that consider several NBS are included as relevant.
- **Feasibility to apply the method**: data, tools and information availability for the application of the methods by the municipalities, it was considered interesting too.

These dimensions have been considered as the main criteria to appraise the climate resilience of the cities and NBS.

2.4. Step 4: Case study. Donosti/San Sebastian city (north of Spain)

A real case study has been defined and the most promising methods according to the RACER, to the classification and to the issues of interest for the municipality, have been selected to understand the integration options of them.

It is important to note that after identifying all the potential interesting methods regarding the climate change and NBS fields, several expectations have been defined to be answered by the method (or methods in plural):

- understanding current situation (climate threats currently affecting the municipality),
- identifying potential future impacts due to the climate change if there is no intervention (BAU),
- building NBS scenarios to try to minimize the potential impacts,
- assessing the scenarios and
- selecting the most suitable NBS solutions according to their effectiveness

Following this approach, the case study of has been defined and performed and integration options have been studied:

- Envi-met has been used to understand the effectiveness of the NBS to adapt the neighbourhood to the expected temperatures increase.
- CityCAT, on the other hand, has been used to understand the NBS effectiveness to run-off reduction.
- ENERKAD has been used to understand the mitigation effects of the NBS in the energy demand of the buildings.
- NEST has been used to understand the NBS effectiveness to reduce the climate impacts at the neighbourhood scale.

3. Results

3.1. Methods characterization: Climate resilient features covered by analysed methods.

Full list of considered methods is given in chapter 3.2. In total, 21 methods have been studied and characterized. Results from the methods characterization is given in table 1.

Table 1. Climate resilient features covered by analyzed methods

Climate resilient feature	Climate resilient (sub)feature	Number of methods
Strategy	Mitigation	8
	Adaptation	14
	Mitigation & Adaptation	5
Climate trends	Air temperature	11
	Rainfall / precipitation	11
	Air quality	9
Climate threats/impacts	Colder winters, warmer summers	12
	Urban Heat Island	12
	Runoff	12
	Air pollution	13
	Water quality	8
	Wind field	10
Indicators	Building cooling and heating energy demand reduction	9
	Global warming potential reduction	6
	Primary energy demand reduction	7
	Runoff reduction	11
	Carbon sequestration	5
	External air temperature reduction	10
Scale	Object	15
	District	17
	City	17
	Up to the city	15
Nature Based Solutions	Parks and gardens	15
	Structures associated to urban networks	15
	Structures characterized by food and resources production	13
	Natural and semi-natural water bodies and hydrographic networks	13
	Constructed wetlands and built structures for water management	14
	Green roofs	17
	Urban planning strategies	12
	Works on soil	13
	Vertical structures (Green walls and facades)	15
	Direct human interventions	12

3.2. Methods classification according to their suitability to assess from climate trends to NBS effectiveness.

Table 2 summarizes the results obtained from the RACER assessment applied to selected methods together with the number of features of the methodology that they consider.

Table 2. Methods classification according to their suitability to assess from climate trends to NBS effectiveness

Method	RACER position	Methodology features covered (tot 32)
Envi-MET	1	21
Library of Adaptation Option	2	25
Design Builder	3	9
EPA Storm Water Management Model (SWMM)	4	18
Enerkad	5	13
Green Pass	6	23
HAVURI	7	26
NEST	8	14
CITY-CAT	9	18
Soil and Water Assessment Tool (SWAT)	10	19
Climate-ADAPT web platform	11	7
Rayman	12	8
Fault tree analysis (FTA)	13	21
SIRVA	14	26
Simile	15	22
URB-CLIM	16	19
EPESUS	17	22
Enviro-HIRLAM	18	9
PLINIVS models	19	6
IVAVIA	20	27
IPCC projections	#NA	7

TEB, i-tree eko and Solweig methods have been identified as potential methods of interest and will be included in next steps of the work done in this field.

3.3. CityCAT, ENVI-met, ENERKAD and NEST methods applied to a real case study.

CityCAT method allows to calculate quantitatively the effectiveness of any type of Nature Based Solution regarding runoff reduction, at any scale. CityCAT allows the visualization of the results given as a reduction of a high of the sheet of water and as runoff reduction in centimetres. Although, the model requires a very time consuming cartography pre-processing, once this work is done, the simulation of different scenarios with different NBS configurations or different meteorological conditions, is very easy to perform. Moreover, ENVI-met model, needs very similar inputs to the ones required for CityCAT. Therefore, the information can be shared for both models.

ENVI-met method allows to calculate quantitatively the effectiveness of any type of Nature Based Solution regarding temperature reduction, at neighbourhood scale. Meteorological information representative of the study site matches with the information demanded by CityCAT. According to ENVI-met results, the effectiveness of NBS temperature reduction varies depending on the selected moment of the day and according to the solar radiation. Unfortunately, there is a lack of consensus on how is the better way of measuring the thermal effectiveness of adaptation measures. The scientific community is working on standardising thermal effectiveness related process that is, the way of measure the thermal variable and the metrics to express the effectiveness.

Enerkad allows studying the NBS effectiveness to reduce the energy demand of the buildings. In this sense, the implementation of NBS it is considered a mitigation strategy. This is because the aim is to reduce the consumption of energy and, as a consequence, to minimize the environmental impacts due to energy consumption. Enerkad can be also linked with ENVI-met, but strong efforts are needed to obtain the whole hourly temperatures of a year with this approach, other urban climate tools like UWG would be more adapted1 as it directly provides local climate temperature in a district in function of a temperature from close rural meteo station, depending on the district land use. It also can be use with weather projection to add the local NBS effect. Regarding the NBS, it must be note that Enerkad is focused on buildings and, as a consequence, only NBS that can be implemented in buildings, such as green roofs and green façades, are going to have remarkable effects on the results.

NEST tool has been selected for the case study in order to understand the NBS effectiveness to reduce the climate impacts at the neighbourhood scale. In this sense, the implementation of NBS it is considered a mitigation and adaptation strategies because it allows the assessment of the impacts of:
(1) Vegetation on GWP and runoff reduction
(2) Permeable pavements and green roofs on runoff reduction

Runoff reduction is given in NEST in terms of absorbed water (green spaces and mineralised areas with low permeability) and unabsorbed water in m3/year. This kind of results differs from the ones provided by CityCAT (runoff reduction in cm). Therefore, depending on the objective of the study, one or the other could be more suitable.

Enerkad results can also be translated to GWP reduction due to NBS implementation. Nevertheless, the scale at which Enerkad and NEST work is different. A bottom up approach can be applied to compare the results of both methods but and, again, depending on the aim of the study could be more suitable selecting one of them.

4. Conclusions

Nature Based Solutions contribute both to mitigate and to adapt the cities to the impacts caused by climate change at urban level. Several methods and tools exist for assessing each strategy. However, none of them allow to cover the whole steps included from analysing climate trends that could affect the cities, to understand the NBS effectiveness to mitigate and/or to adapt the cities.

Results show that strategies and climate hazards has been worked in a split way. Some methods are focused in a specific climate feature, and do not provide information about other potential benefits of implementing NBS. Analysing the same NBS scenarios with different methodologies, reflects other advantages associated to NBS implementation. Data needed for the methods and the treatment of it was similar in some cases. Nevertheless, is not possible to put together the results obtained with each method and the different approaches do not allow the comparison between results. Therefore, there is a need to connect better mitigation and adaptation information to facilitate the municipalities taking robust decisions regarding the NBS implementation. This conclusion can be also transfer to the specific field of adaptation.

[1] http://urbanmicroclimate.scripts.mit.edu/uwg.php

This paper presents just the starting point of the work to be done in this field. Conducting a full study, from understanding climate trends, to identify urban vulnerabilities and risks, to analyse nature based solutions effectiveness to minimize the effects of climate, is something that the municipalities are already demanding. Scientific community must answer to this demand in a robust way and must help the municipalities in the decision making processes regarding the most suitable NBS to be implemented. As a result, the introduction of NBS in the cities will be supported too and the climate change effects will be minimized.

Abstract. For dealing with participatory aspects in urban planning, the method of Living Labs (LL) currently turns out to be a most popular and promising approach. In our project LiLa4Green we apply such a Living Lab in the City of Vienna for implementing green solutions in densely built settlement areas characterised by heterogenous ownership and building structures, few public open space and green areas and the dominance of car traffic. In the first year, the potential analysis of the status-quo situation was completed, and the Living Lab had been established. First lessons from the now successfully running LL process can be drawn. The analysis and the initiated process revealed deficits, but also clear potentials for the implementation of green measures which could significantly improve the current situation. So far, the Living Lab process made clear that the people are generally affected and therefore interested in the topic of heat stress and greening the city, but it does not seem to have top priority for them. Although many people could be addressed and involved in discussions, only a small group of people were willing to take part in the first workshop. Confronted with such challenges the strategy for the next stage was to bring the LL process closer to the people's everyday life context and to extend the participatory methods. Innovative ICT-solutions which help to intuitively visualize and understand green solutions and their effects were tested, as well as a co-decision process for the realization of a first intervention was offered. The higher participation rate in the second green lab indicates that this is a promising approach which will be continued in the further LL process.

1. Introduction

In order to sustain the livability of a historically grown city such as Vienna, adaptation measures to climate change must already be considered and implemented today to proactively counteract negative developments in the future. Climate models predict a clear upward trend of heat waves and tropical nights [1] which will affect an increasing number of people in future decades, not only in Vienna, but worldwide as urbanization as well as climate change is expected to continue through the 21st century [2] [3].

Consequently, many cities start to strategically plan and adapt the urban environment to the changing framework conditions. The building structure (height, orientation, density, facades/roof color, texture, etc.) plays an essential role for the urban microclimate. Equally decisive are type, shape and extent of the greening as well as a corresponding rainwater management [4] [5] [6].

The Urban Heat Island (UHI) effects in cities are intensified by solar radiation which is absorbed by buildings during the day and emitted during the night in form of sensible heat as well as by anthropogenic heat emissions, which are among others produced by traffic, households and industry and increasingly through air conditioning systems [7]. Due to this, the air temperature in the city and in the countryside can differ by 1 to 3 degrees in annual average during the day and up to 12 degrees during the night [8]. Buildings and green influence each other via light reflection, shadow, radiation, etc. A comprehensive implementation of green-blue infrastructure measures represents a possibility to significantly reduce the extent of UHI [9] [10]. Although strategies for counteracting the UHI in the city of Vienna already exist (e.g. UHI STRAT [9]), the realization of green-blue infrastructure measures is challenging as it addresses various urban issues (green&open space, traffic&pipeline infrastructure, water&sewage infrastructure, etc.) and stakeholders.

The Smart Cities demonstration project "LiLa4Green"[1] presented in this paper aims to support the realization of green-blue infrastructure projects (urban green and urban water areas) in densely built areas of the City of Vienna. It is carried out by an interdisciplinary project consortium consisting of the Austrian Institute of Technology, Technical University of Vienna, Weatherpark, PlanSinn, the green innovation laboratory GRÜNSTATTGRAU and GREX IT. In order to realize measures that not only consider climate-resilient aspects, but also social aspects such as quality of life, health, safety and usability, a Living Lab is set up that involves citizens, stakeholders and decision makers in the implementation process (co-creation). The Living Lab aims to raise the awareness for the positive effects of green-blue infrastructure measures as well as strives for increasing the acceptance and willingness to implement and invest. LiLa4Green started in March 2018 and has now run for one year. First findings on the potentials for greening densely built urban areas and the added value of applying a Living Lab approach are presented in the following.

2. Need for greening the City of Vienna?

Vienna is, like many other European cities, particularly affected by the impacts of climate change. Analysis of climate data clearly demonstrates the already pressing need for action as regional impacts of the global climate change for the city of Vienna are already apparent. Increasing temperature during the summer months is the most significant impact in terms of visibility in meteorological data and negative consequences for the inhabitants.

2.1. Heat waves and tropical nights in Vienna on the rise

For the climate analysis conducted within LiLa4Green hourly data of air temperature for the time period from 1984 to 2017 were purchased from the national weather service ZAMG (Zentralanstalt für Meteorologie und Geodynamik) for the climate station "Wien Innere Stadt" and "Wien Hohe Warte". The climatic analysis focused on two parameters that clearly show how quickly the character of summers in Vienna has changed during the last 30 years: the frequency of so called “Kysely-days” (i.e. heat wave days) and of hot nights with minimum temperatures above 20°C (“tropical nights”). A day is defined as a heat wave day, if there are three or more consecutive days with 30°C maximum temperature or more. The mean number of heat wave days per year in the city center of Vienna was 8.4 in 1984 and increased to 18.9 in 2017. The temperature data show a clear upward trend over the whole period, with maximum values reaching more than 30 days per year in the second half of the period (after the year 2000). The number of hot nights also rose significantly over the last 30 years. In 2018 there were 41 “tropical

---

[1] LiLa4Green is funded by the Climate and Energy Fund and implemented under the "SMART CITIES - FIT for SET" program.

nights”, which is the highest number ever recorded in the city center. The mean value over the whole period was 13,8 tropical nights per year.

Especially the longer lasting heat waves and tropical nights pose an additional stress to the body and lessen the quality of life. Respiratory and cardiovascular diseases, impacts on mental health and, as a consequence, reduced work performance and productivity are just some of the proven implications of heat waves [11]. Particularly affected are elderly and sick people as well as children.

The temporal development of these and other parameters clearly show that the intensity and duration of hot periods during the summer months are rising dramatically. As a consequence, the city and its inhabitants have to adapt to new characteristics of summer, including extreme events becoming more frequent. Facing such changes, greening and proper rainwater management can have an essentially positive influence on the microclimate in densely built city structures. Green within the city not only creates a valuable recreational space while reducing CO_2, it also reduces the noise and pollutant exposure, decreases the radiation temperature through shadowing and cools down the adjacent air due to the evaporation of plants. Thus, vegetation should not only be limited to parks and dedicated green areas but integrated into the entire urban fabric for realizing its full micro climatically positive potential.

2.2. Microclimatic situation in the test area “Quellenstraße Ost”

The LiLa4Green test area “Quellenstraße Ost” illustrates the dilemma that is fairly common in densely built urban areas: the amount of green, unsealed areas is quite high with 33 %. However, the densest area - the Wilhelminian style block development area “Kreta” existing of 6 blocks crossed by 3 streets - shows no greening at all and is characterized by sealed surface and stationary traffic. Predominantly in such areas, green infrastructure measures are of utmost importance for the city´s climate and social cohesion.

The microclimatic analyses reflect the dense urban structure. During hot summer days the air temperature and the human comfort measure “PET” (Physiological Equivalent Temperature) rise in the mainly north-south and east-west orientated street canyons. While the distribution of the air temperature is quite even, the PET values vary strongly. Around noon the maximum values in the north-south-street canyons rise up to 50 degrees, which means that people experience strong heat stress in these areas. Minimum values are around 26 degrees, which is felt as slightly warm by humans. Areas with these moderate values are shady spots along north- or east-facades or under trees. The high values can be explained by a lack of vegetation and shade and the corresponding high radiation input, both short wave radiation from the sun and long wave radiation (i.e. sensible heat) from the blacktop and the building facades. During heat waves air temperature stays high also in the night.

Putting this characterization in context with the climate of the whole city, the test area “Quellenstraße Ost” can be described as a residential area with high bioclimatic stress. The area is vulnerable with respect to densification. Common recommendations for such areas are ameliorating the fresh air supply, increasing the green infrastructure and unsealing the ground.

3. Greening Potentials

In addition to the (micro-)climatic analysis, the potentials for implementing green-blue infrastructure measures within the test area have been analyzed. The aim was to highlight links to existing green networks and to general strategies of Vienna and to point out areas of especially high need for action. The analysis included the open space structure in regard to its private, semi-public and public character and especially the characterization of the streetscape concerning e.g. existing greening, division and public usability, parking situation and the quality of stay.

With respect to urban climate and social aspects the Wilhelminian style block development area “Kreta” has been identified as the area with the highest need for taking measures. Apart from that this area is surrounded by current urban development that will change the context and role of this city area in the near future. With the opening of two new bridges and a new connection to public transport in the north it will form an important link between the future development site and the currently temporary used area of the Kempelenpark and to the recreational area of Laaer Berg in the south-east. The potential map (see **Figure 1**) illustrates the important superordinate (green arrows) and internal district connections (orange arrows), adequate streetscape sections for restructuring (violet areas) and the location for especially important areas for quality of stay e.g. in front of educational buildings (dark violet hatch).

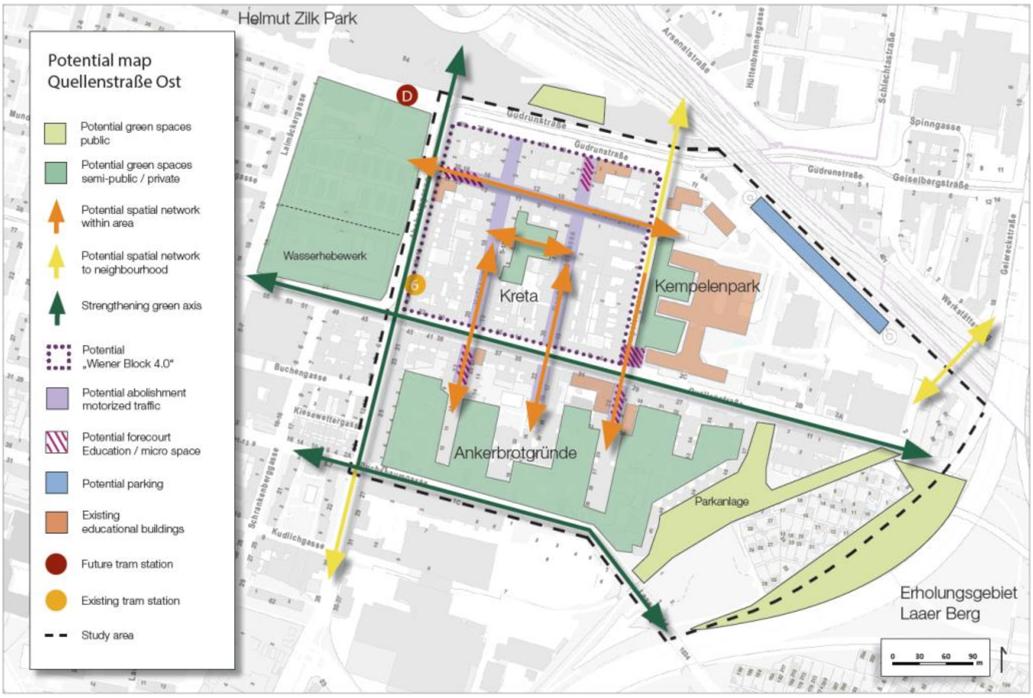

Figure 1. Potentials for improving the green space in the test area Quellenstraße Ost in the 10th district of Vienna.

4. The Living Lab in LiLa4Green

Parallel to the scientific analysis of the potentials, a participatory process in form of a Living Lab has been started. There is no unique definition of Living Labs (LLs), but commonly cited characteristics of Living Labs are openness, realism, empowerment, spontaneity, sustainability and value [12] [13] [14] [15]. One of the key criteria of urban LLs is the geographical embeddedness [16]. Urban LLs represent ecosystems of open 'urban' or 'civic' innovation and are situated in a real urban context where the process in focus is taking place. In our Living Lab for more urban green ("LiLa" for Green) we discussed its meaning in the specific project context and formulated the following definition: Our LL aims to find solutions to urban issues such as the effects of climate change, resilience and sustainability and focusses on citizens and stakeholders as core elements of an urban LL from a holistic view (ecological, economic, social, technical, spatial).

During this LL process it is examined how a smart user participation can be organized and designed in order to raise awareness within the public regarding mitigation and adaption measures to climate change. By combining innovative methods of social science with the latest digital technology an ideal dissemination of information with regard to the diverse functionalities of green and free spaces is to be facilitated. Therefore, also new methods of assessment (e.g. crowdsourcing) and visualization (Augmented Reality) will be tested. These new forms of smart user participation and the visual depiction of measures and their effects aim to ensure a broad acceptance within the public for green-blue infrastructure. The Living Lab in Lila4Green is constituted by a range of different activities that open the research project to stakeholders and citizens.

The LiLa4Green-LL started with a design process including a screening of suitable participatory methods and strategies and a workshop during which the research team collectively developed a shared practical understanding of our LL, clarifying the context, goals, key questions and initial design of the LL-process. The first step of the Living Lab was taken by hosting a "Start-Workshop". Within this meeting we gathered knowledge, constraints and needs together with relevant stakeholders (representatives of municipal agencies and local institutions) and collected information on spatial and social potentials within the project area. Furthermore, it was discussed what the participating stakeholders can "give and take" to/from LiLa4Green, emphasizing the importance of mutual benefits. The participating stakeholders made their commitment to take part in the upcoming process including the "Green-Workshops" and to support the project with their knowledge.

Figure 2. On-the-street activation for participation in the Living Lab.

Figure 3. Mapping of hot spots and cool spots in the case study area Quellenstraße Ost.

The corner stones of the LL are four major events called "Green Workshop". These will take place roughly every 6 months, bringing together the research team, stakeholders and citizens. Leading up to our first "Green Workshop" in October 2018, we conducted several on-the-street "activation" activities: we visited the project district with our cargo bike, built up a temporary space for conversations using pictures, signs with questions and a deck-chair (see **Figure 2**) and approached people walking by. To initiate conversations we used small, game-like activities like a "bean-poll" about people's perception of heat waves or a mapping of hot and cool spots in the area (see **Figure 3**). These conversations aimed at mobilizing people for the "Green Workshop" and to gain a better understanding of the area and its inhabitants.

The first "Green Workshop" (see **Figure 4**) was designed to kick off the LL-process and focused on sharing information, building mutual understanding and establishing social connections. At the beginning of the event all participants were asked to answer a brief survey about their perception of urban heat and potential solutions. At the end of the project, this survey will be repeated in order to detect changes in their perception. We then conducted a few simple exercises to allow people to get to know each other briefly. The first half of the workshop was set up as a "Knowledge Bazar", with the research team offering information to stakeholders and citizens about the topic of urban heat effects and sharing first insights from the so far conducted research. Posters, a memory set and a flyer have been prepared as playful and easily understandable starting point for the discussions. In the second half of the workshop we conducted a "World Café" and swapped tasks: now the stakeholders and

Figure 4. Participants of the first "Green Workshop" in October 2018.

citizens offered their local knowledge and ideas about the spatial and social environment of the project as well as ideas for potential solutions.

In May 2019, the second “Green Workshop” took place. As the first workshop revealed the desire of the citizens for action, the research team decided for a first intervention on-site by designing and implementing a green parklet in the streets. In the design studio project “Green up - Cool down” at the Landscape Department of the Technical University of Vienna students developed seven different design concepts for parklets which were presented at the second green workshop (see **Figure 5)**. After the presentations and a timeslot for discussions, all workshop participants formed a jury and voted for their preferred parklet design by awarding points to their favourite concept. In this way a co-decision process was established defining which design will effectively be implemented by the students in summer 2019. Further, local initiatives such as the Materialnomaden (re-use of building material), the local carpentry, kindergardens and the Stadtraum Kempelenpark are involved in consultation, maintenance and supporting the acceptance of and identification with the parklet.

Figure 5. Different design concepts for parklets presented in the jury process of the second “Green Workshop”.

In the second part of the workshop, a first application of a smart interaction tool was set up and tested with the workshop participants (see **Figure 6**). The chosen tool was a lightweight Augmented Reality (AR) tool that visualizes a greening project as it will look like after its realization. Users can view the AR model of the greening project superimposed on the real physical location on their smartphone. To lower the barrier to use, no installation and registration is required. Users can express their opinions about the project, and the tool stores user opinions and interactions in an existing civic participation tool (www.smarticipate.eu). In the sense of co-creation, the users where asked for feedback on applicability, user-friendliness and added value of the tool. Generally, the tool was well received and attracted a lot of interest. A quick survey revealed that it helps people to imaging how greening measures could look like. For some of the participants, the handling of the tool was still too complicated, which was a valuable input and will be incorporated in the further development of the tool.

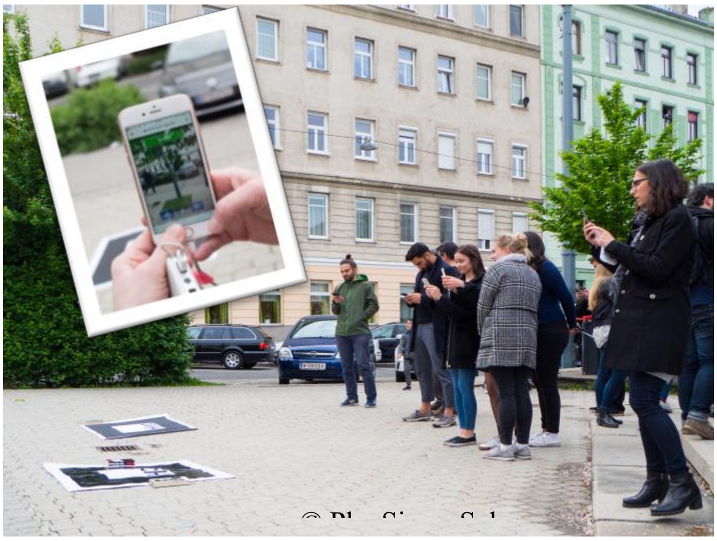

Figure 6. Participants of the second “Green Workshop” testing the AR application in the street.

5. Discussion and lessons learned

Four major insights from the LL process in LiLa4Green could be gathered so far:

1) **Continuity, co-decision-making and setting concrete actions** is essential for successful participation. During the mobilization process in the streets many people could be encountered who were interested in the subject. Yet it was hard to gain their commitment for joining the "Green Workshop". While they verbally supported the idea of greening their neighborhood, their interest did not translate into willingness/ability to participate in the "Green Workshop". Participants of the first "Green Workshop" were mainly acquired through tapping into local networks. The willingness to participate appeared to be much higher in the second "Green Workshop". One reason was that the LL process was already well established and continuously promoted through various channels. A second reason was the real opportunity given to the citizens to decide and co-create, which attracted additional participants. The participants in the LL had the chance to discuss the design solutions and be part of the decision which design will be implemented on-site. Through close collaboration with the residents the willingness to adopt – that means care for – the built design object in front of their building could be enhanced and enabled an emotional binding to "their" green island. The green parklet will work as a pilot project for later implementation activities of LiLa4Green and will help to foster the awareness and acceptance for such green-blue infrastructure measures in the close neighbourhood.
2) Participation needs a **professional accompanying process**. As a key component of LLs is experimentation and co-creation, the process has to be kept flexible. Nevertheless or exactly for that reason, such a process needs a guiding structure and profession management. In LiLa4Green, one partner is exclusively responsible for the LL process, which requires knowledge and resources. The first "Green Workshop" aimed at establishing a core group for the LL-process, including locals, decision makers, regional agents and scientists for gaining a better understanding on the context of microclimate, green and urban spatial planning. A shared idea of this Living Lab was developed. Between the workshops info-mails kept the participants updated and networking activities took place. The results and aims verbalized by the citizens in the first workshop were taken up and built the base for the second workshop. This approach appeared to be successful as the members of the core group also participated in the second "Green Workshop". This highlights the importance of aligning the "what, why and how" of participatory research activities carefully. Besides, a professional process management guarantees, that the results of these activities will be transferred into the documentation of the LL as a complementing source of learning. In that way lessons learned in the LL process is gathered and will not be lost.
3) It is crucial to create a **low-threshold level** for participating in a Living Lab process. The second green workshop proved that the participation process benefited from further on-the-street-activities, as well as from the mobilizing effect of local participants and stakeholders. Furthermore, the offering of co-creation (ICT-solution testing) and co-deciding (jury for the parklet) integrated into the workshop set-up built a pull-factor for the participants. As a result, 55 people showed up for the second "Green Workshop". The design offered a combination of low threshold activities and options to more deeply discuss and create solutions together.
4) For mobilizing and obtaining the local knowledge of the heterogeneous population in the test area **different approaches and sources** are needed. So far, the LL process made clear that it is rather difficult to reach all those residents that normally do not participate in a planning process. It requires perseverance, networking and visible activities for attracting attention. Thus, raising awareness for green-blue infrastructure projects and increasing stakeholder acceptance demands a wide range of communication and interaction measures. In Living Labs, face-to-face communication, supported by information material, is the dominant channel for information exchange and interaction. The low threshold activities on the street are a valuable methodology for gaining insights into people's perceptions and collecting local knowledge. However, this form of event requires potential stakeholders to actually come to a specific location at a specific time. The project team discussed and evaluated alternative ideas for intelligent information and interaction and decided to embed the

information dissemination and interactions in the physical space of concern in order to be closer to the everyday´s life and daily routes of people. As it is very time-consuming to be on site and directly address people, the project team decided for additionally applying a “smart” way of user participation and integrated a smart interaction tool by using Augmented Reality, which was well received by the participants of the second workshop.

6. Conclusions

Two well known facts could be verified for the City of Vienna by analyzing meteorological measurements and applying microclimatic simulations: first the frequency of urban heat waves and tropical nights are dramatically rising, and second densely populated areas are particularly affected by climate change. However, it could also be demonstrated that even in most densely built urban structures potentials for new green infrastructures can be found. Particularly the streetscapes as well as facades and rooftops offer a variety of possibilities for greening measures. However, for realizing those potentials, existing legal, technical and administrative barriers have to be overcome. Though the streetscapes are mainly public in character, they are currently dominated by the moving and stationary traffic. Moreover, a range of built-in installations under the sidewalks as well as, particularly in existing building structures, heterogeneous property relations often hinder the implementation of greening measures. In this regard, be it buildings or streetscapes as potential settings for measures, it is essential to bring decision makers and citizens on board. Without the integration of users within the process, the realization of urban green networks in built-in structures is not expedient and might not prove long lasting.

Therefore, the first step on the way to a greener city that is less affected by heat is to raise awareness of the manifold functionalities of green infrastructure in the city especially with regard to the streetscape. Secondly, solutions have to be developed, implemented and monitored together with local stakeholders that fit the specific framework conditions.

To this effect, a Living Lab proved to be a very appropriate approach to support the overall process and to combine classical participation methods as well as new, smart ICT-tools in an experimentally way. The process thereby facilitated the inclusion of a broad range of users (residents, users of buildings, architects and planners, housing subsidies, neighbours/social environment and politics and administration, etc.) with new and smart methods of participation to enhance the possibilities for the realization of green city infrastructures also in existing urban structures. So far, the experiences made during the Living Lab proved that it does not only serve as exhibition space for various measures to adapt to climate change, but also poses a networking opportunity. For the project LiLa4Green the Living Lab includes competence networking, dissemination and citizen cooperation in the form of integration of future users into new and old technologies and projects. Interaction with public stakeholders and involving local residents in open innovation processes (co-creation) leads to shortened iteration processes of technology developments and applications with a high level of acceptance. The Living Lab helps to bring information face2face to people and to gain acceptance for technologies and solutions.

The ongoing LL process already showed positive effects regarding the visibility of the issue (UHI, greening the city) within the area and the networking between single activities and actors. The biggest challenge appeared to be to reach those citizens who are not yet interested in the topic and to motivate them to participate in an organized workshop. It got clear, that it is crucial to meet the people on the level of their needs and in their everyday life context – “in the street”. It is a long-term process, continuity is needed, various efforts for mobilization have to be made, new ICT-tools are helpful for reaching additional population groups directly on the street and action in form of physical interventions designed in a co-creative way are essential. All these crucial components have been considered and applied in LiLa4Green. So far, the Living Lab established proved to be successful and will be continued in the next two years.

The Potential of Greenable Area in the Urban Building Stock

Stangl R[1], Minixhofer P[1], Hoerbinger S[1], Kermer L[1]

[1]Institute of Soil Bioengineering and Landscape Construction, University of Natural Resources and Life Science, Vienna, Austria

rosemarie.stangl@boku.ac.at

Abstract. In the context of establishing green infrastructure in cities, urban retrofit has presumably larger area potential than ground-based green. To support the large-scale advancement of urban green, the assessment of greenable potential plots in the building stock, both on horizontal and on vertical scale, provides first indispensable indications for decision-making. However, reliable and solid data to the state of the buildings is currently not available. The research study Urbane GmbA explored a new methodological approach, based on publicly available geo-data, and applied it at two study sites in high-density urban quarters in Vienna. The combination of a GIS-based analysis with digital and on-site photos allowed for the creation of a Level of Detail 2 (LOD2) 3D-model and subsequently the estimation of the green retrofit potential of roofs and facades. Comprehensive maps with the data of the 2D building footprints provide valuable information for planners, including building characteristics and greenable area potential. The approach proved to provide more comprehensive information including building characteristics fundamental to the planning and decision-making process. The achieved results are merged with an evaluation matrix generated for attributing available facade and roof greening systems. This allows for more focused decision support for the retrofit of the building stock towards more sustainable and resilient district development.

1. Introduction

The quantitative increase in urban green areas is no longer the sole vision of environmentally conscious minorities. In 2015, the Paris Climate Agreement put the necessity for actions to confine the effects of climate change on the political agenda of national authorities. Many countries reacted with national climate protection and adaptation strategies.

Natural solutions have to become an integral alternatives or additions to grey infrastructure for the regional development [1]. With its research and innovation policies on Green Infrastructure and Nature-Based Solutions the EU strives for innovations based on natural and nature-inspired solutions to bring sustainability and resilience into the cities [2]. In Vienna, the city's Urban Heat Island Strategy (UHI-STRAT) aims to expand Green Infrastructure as an effective measurement against the effects of urban heat islands and proposes a variety of technical and strategic measures for planners, architects and administrators [3]. City planning and development will have to increasingly deal with the renovation of long-lasting architectural heritage and the results of an excessive building culture where so much undeveloped and natural land was lost to building projects. The restructuring of urban areas to incorporate more vegetation in horizontal and vertical orientation has a higher potential for success if the existing building stock is considered in addition to the construction of new (green) buildings. The potential of vertical areas is believed to be especially high. MA 22 estimates a potential net area of 12,000 ha facades, which can be used for the installation of green walls. This is well over a third of the total net area. In comparison, the potential net area for green roofs is only 1,800 ha [4].

The assessment of the potential of greenable area is the basis for the conception and planning of vertical and horizontal green on small and large scale. Reliable basic data is of the utmost importance to increase urban green infrastructure in the building stock (in streets, urban quarters and on district level). At the moment, the necessary data is only available in a very restricted way as the currently available instruments and various fragmented approaches, in part isolated solutions, reach their limit with their practical application. For example, the Viennese Gründachpotenzialkataster (cadastre of potential green roof area), based on the survey of roof inclination via airborne laser-can images, shows only a very small potential for green roofs. Important technical (e.g. statics) and legal parameters (e.g. preservation order, protection areas) were not included in the assessment or analysed. An adequate adaptation of the current cadastre would be necessary, but will be not released due to the economic expenditure for the individual users.

To fill this void, a new methodological approach was developed and applied at two study sites in the frame of the research project Urbane GmbA. The created maps provide comprehensive information for the planner regarding building characteristics and potentially greenable area.

2. Methodology

2.1. Description of the study sites

The study was conducted in two districts of distinct characteristics. The study site Neulerchenfelderstraße is situated in the 16th district of Vienna. It includes the street and its adjoining building stock. The site is characterised by a versatile building structure. Historical buildings alternate with modern ones along the street. The ground floor zone is strongly influenced by the retail trade, while the upper floor zone is mainly used as living space. In the public open space, there are barely public green areas. The adjacent sidewalks are often very narrow, which can represent an obstacle for the implementation of ground based green facade retrofits. The study site Innerfavoriten – Kretaviertel is situated in the 10th district of Vienna. Most of the buildings are from the years after 1945. The site is characterised by large blocks of flats and individual smaller historical buildings. Many of the large residential buildings are community buildings. Both, the ground floor zone and the upper zone are mainly used as living space.

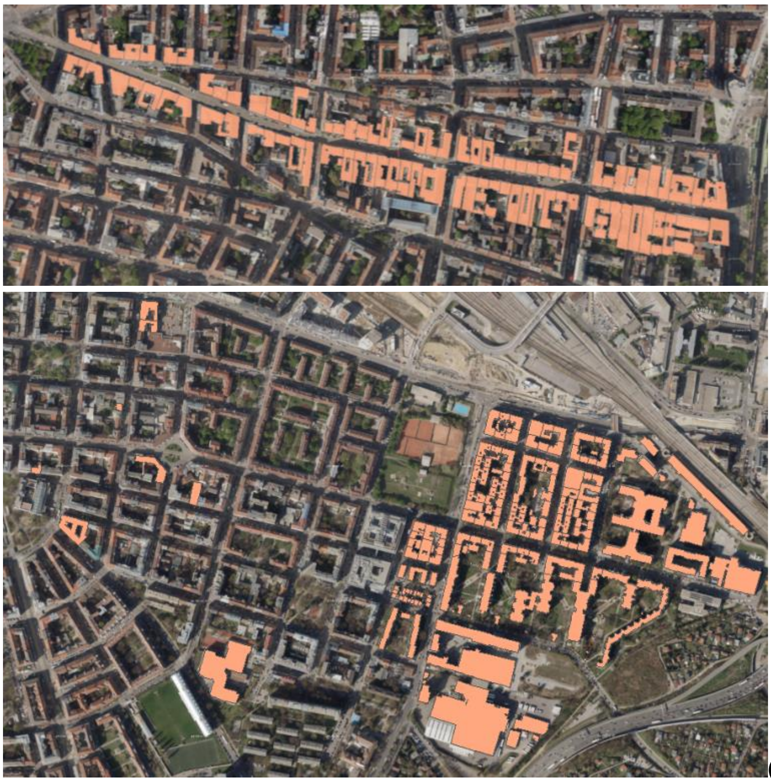

Figure 1: Study areas (A) Innerfavoriten – Kretaviertel and (B) Neulerchenfelderstraße

2.2. GIS-based system analysis

GIS-based analysis was performed and combined with analyses of photos, taken of each building in the study areas. On the basis of a Level of Detail 2 (LOD2) 3D-model the slope and exposure of the roof surfaces were calculated and the green roof retrofit potential was estimated. In combination with the photo analyses, the net-area facade retrofit potential was assessed. In order to describe the ground connection of the facades, the surrounding land cover was attributed by means of vicinity analysis. Subsequently, all data was transformed to 2D building footprints in order to make them easy to integrate in existing geo-date bases of the city of Vienna.

2.2.1. GIS-based survey of the green facade retrofit potentials.

The surrounding land use can provide first indications of the feasibility of green facade retrofit potentials. The relation of the facade areas to the adjacent land use was calculated by means of neighbourhood analyses in ArcGIS. For this purpose, the facades of the 3D-model (LOD2) were first separated from the other wall elements. The next step was to reclassify the land use map and assign the respective attribute to the facades. In total, seven categories were formed (see Table 1). The categories were selected to allow an initial assessment of the external effect as well as the feasibility of the potential greening methods. The pavement width is a very important parameter for the feasibility of pot and soil based vertical greening systems. To form the first two categories, "pavement width < 2.2 m" and "pavement width ≥ 2.2 m", areas that were disclosed as "pavement" in the FMZK (Flächen-Mehrzweck-Karte; map of the multi-purposes of areas) were analysed on basis of their width. The category "pedestrian zone" includes potentially greenable facades with a very high external effect. Facades in the category "green area" have a high potential for soil based systems as a direct contact to the soil can be established without any measures to re-open sealed surfaces. On the contrary, areas in the category "private parking and traffic areas" are connected to sealed surfaces and measurements and soil based measurements are not possible without de-sealing measurements. Additionally, the implementation of greening projects can be complicated by the current use as a parking space or traffic area. Facades in the category “consolidated area” will also lack of initial soil contact, which means the areas need pre-treatments in terms of allowing permeability. An additional attribute, namely “no soil contact – flat roof”, classifies all facades which adjoin to a flat roof. This means the potential lies with pot based systems. After the classification, the gross area of the various types of facades was calculated for each building within the project area.

Table 1: List and description of all categories for the survey of facades based on soil contact

Categories for the survey of facades	**Description**
Pavement width ≥ 2.2 m	Facades connected to pavements with a minimal width above 2.2 m
Pavement width < 2.2 m	Facades connected to pavements with a minimal width below 2.2 m
Pedestrian zone	Facades connected to traffic areas classified as pedestrian
Consolidated area	Facades connected to consolidated and sealed surfaces
Private parking and traffic areas	Facades connected to traffic areas on private property (e.g. entry ways, parking areas)
Green area	Facades connected to green areas (all green areas and additional unsealed surfaces)
No soil contact – flat roof	Facades with no soil contact, which direct contact to a flat roof

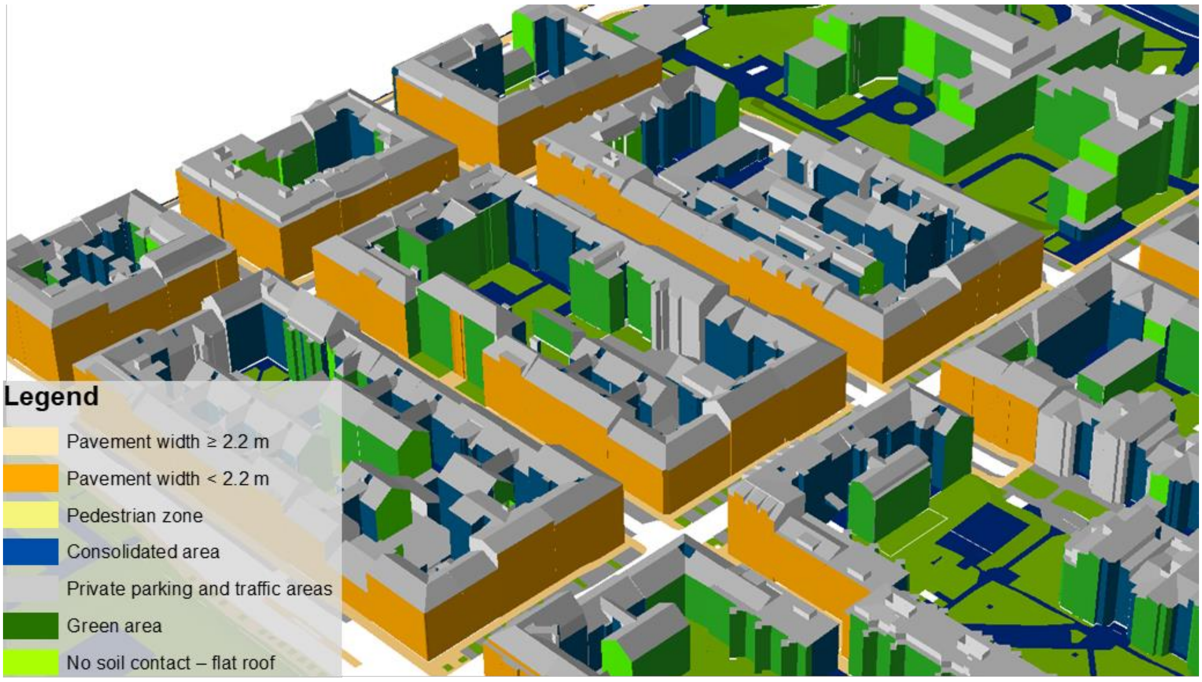

Figure 2: Facades in the study area Innerfavoriten – Kretaviertel classified by the surrounding soil use

2.2.2. GIS-based survey of the green roof retrofit potentials.

The Guideline on Green Roofs in Vienna (2009) notes that the roof slope is a significant factor of the usefulness and profitability for the installation of a green roof . The category limits are based on the recommendations of the Guideline for Green Roofs [5] and the Gründachpotenzialkataster [4] and modified within the project. The direction of the roof is an important parameter to describe plant habitats. Therefore, the direction of the roofs was calculated and integrated in the classification (see Fig. 3). A new category for very steep roof areas (15.1°-45°) in exposed sites (135°-225°) was created to gather these areas as they will have a very low potential for the installation of green roofs. As an additional information, the roof cladding was assessed based on visual interpretation of aerial images.

Table 2: Classification of the roof areas to assess the potentially greenable plots and a description of the categories.

Classification of the roof areas		
Slope	**Exposition**	**Description**
0° - 5°	0° – 360°	In this category, roofs can be equipped with extensive and intensive green roofs with relatively low effort [4].
5.1° - 15°	0° – 360°	Possibility for extensive green roofs [5].
15°.1 – 45°	0° – 134.9° and 225.1° – 360°	Slopes above 15° require a special shear barrier to prevent slippage of the structure. Extensive green roofs can be installed at roofs up to an inclination of 45° [5].
15°.1 – 45°	135° – 225°	Roof areas with a southeast to southwest exposition (135 - 225 degrees), which are strongly to very strongly inclined. These roof areas are classified as "exposed". The installment of green roofs is very difficult.
> 45°	0° – 360°	Green roofs are usually not possible anymore [5].

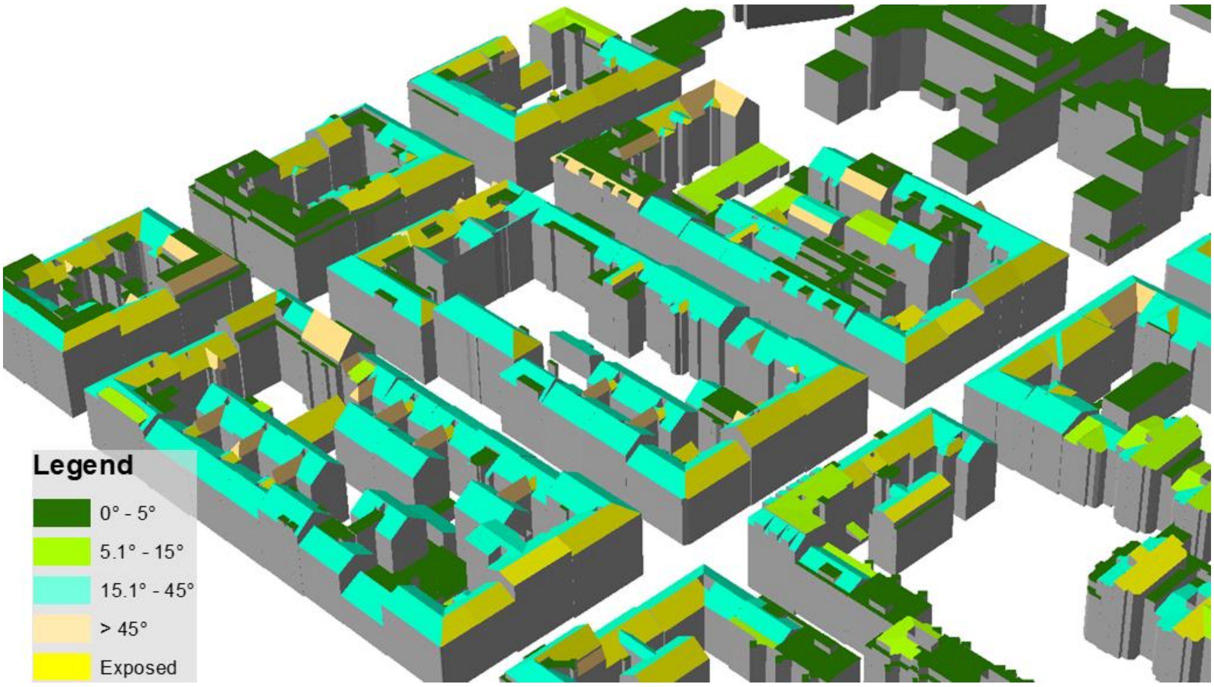

Figure 3: Slope and exposition as a basis for the assessment of the potentially greenable plots

2.2.3. Image based analysis of the buildings in the project area and intersection with the GIS analysis

The geo-data and the results of the GIS-based analysis were verified by an on-site inspection. Images of the external facades were the basis for further collection of the relevant data. The facades were sub-classified in ground floor and upper floor zone. All structural elements, that could possibly influence the decision for or against a green façade installation, were recorded. This includes balconies, stucco, logos, frescos, billboards, display cases and garage entrances. Subsequently, the total area of the structural elements was estimated in 25% intervals. Additionally, Google-Maps 3D complemented the survey, especially for inner courtyards, where in most cases access is difficult. Highly structured facades with a high cover ratio of structural elements have a lower potential for greenable area. Facades with a cover ratio ≥ 75% get the attribute "structured, covered facade".

Facades with a historically representative character will most likely have special requirements for the implementation of green walls. The assessment was subjective and did not include legal boundaries.

The number of windows was assessed to calculate the window area in comparison to the total facade area. The windows were categorised in regard to their building period and multiplied with a factor to obtain the total window area. The estimated window area was then subtracted from the gross facade area of the 3D model. Subsequently, the results were intersected with the building outlines and presented cartographically. Buildings under preservation order were excluded from the potential analysis.

3. Results

The greenable area potential was calculated for both project areas. Table 3 and 4 give an overview of the total potential area in the project areas broken down to the defined categories. Categories with a generally higher potential are colored in green. Differences are obvious when comparing the two study areas. The study area Neulerchenfelderstraße is smaller, with less buildings (89 against 134), and the building development structure varies from Innerfavoriten - Kretaviertel. There, a few freestanding buildings are in contrast with the closed perimeter block development in Neulerchenfelderstraße.

The ground floor zone in the study area Neulerchenfelderstraße has a lower potential than the upper floor zone. This can be a result of the intensive use of the ground floor zone. These facades often end in a very narrow pavement, which is a barrier for the installation of soil based systems. The sum of the potentially greenable area for inner courtyards is notably higher. Facades within the category "no soil contact – flat roof" have a high potential for pot-based systems. Both project areas present frequent green oriented facades. This means the potential for the application of soil based systems is high. Both study areas have big, flat and only slightly inclined roof areas. Gravel roofs are very interesting for the installation of green roofs as after the relatively easy exchange of the gravel, most often no alternations to the building statics and roof waterproofing are necessary to adjust for the green roof structure. Flat or slightly inclined roofs with gravel are the preferred roof areas for retrofitting green roofs. It was not applicable to include other structural building requirements to the analysis such as roof seal, insulation, brim height or accessibility in this survey.

Table 3: Potential of the greenable area in the study area Neulerchenfelderstraße

Project area Neulerchenfelderstraße		
	Category	**Greenable potential area [ha]**
Facade area	**Total area – facades**	**6.44**
	Pavement width ≥ 2.2 m	0.92
	Pavement width < 2.2 m	0.70
	Pedestrian zone	0.12
	Consolidated area	2.69
	Private parking and traffic areas	0.61
	Green area	0.87
	No soil contact – flat roof	0.53
Roof area	**Total area – roof**	**3.75**
	0° to 5°	1.50
	5° to 15°	0.42
	15° to 45°, no south exposition	1.74
	0° to 15°, gravel roof	0.09

Table 4: Potential of the greenable area in the study area Innerfavoriten – Kretaviertel

Project area Innerfavoriten - Kretaviertel		
	Category	**Greenable potential area [ha]**
Facad e	**Total area – facades**	**17.74**
	Pavement width ≥ 2.2 m	4.85
	Pavement width < 2.2 m	0.07
	Pedestrian zone	5.58

Project area Innerfavoriten - Kretaviertel		
	Category	**Greenable potential area [ha]**
	Consolidated area	1.37
	Private parking and traffic areas	4.65
	Green area	1.22
Roof area	No soil contact – flat roof	**10.19**
	Total area – roof	4.2
	0° to 5°	1.16
	5° to 15°	3.91
	15° to 45°, no south exposition	0.92

4. Conclusion

There is a need for supporting instruments to facilitate a more detailed survey of the potentially greenable area in the urban building stock on the neighborhood level. The study explored open source data for greening potential assessment and synthesised available applications. The presented approach is based on publicly available geo-data and was designed to enable the assessment of area potential for greening buildings on a larger scale. The results signify an advanced estimation of roof and façade based greening area potential and do not represent absolute values. They allow for more solid information on area potentials than provided in hitherto available instruments.

The numerous publicly available geo-data was a sound basis for the development of a GIS-based method. General information on the buildings (e.g. building outlines, location) is extensively available for the entire urban area of Vienna. The LOD2 3D model was used to calculate the gross façade area. In high resolution, the FMZK offers a lot of information on the surrounding land use of the buildings.

The presented approach allows for the creation of first indication maps, offering valuable information for planners and decision makers. However, it does not cover all necessary information on building requirements. The building characteristics were not or not extensively available as, e.g. referring to the building period of individual objects and their use, or are not provided in the required resolution.

The vertical greenable area potential is not yet recorded for the city of Vienna. Specific information on geo-data basis is lacking. In overall terms, a considerable need for geo-data is apparent to carry out an exact survey of the façade greening potential. The tested scheme needs further advancement since information on the structure, static condition and façade features is currently missing. The future integration of energy performance data and costs would be an additional asset for evaluation application on district level. An enhanced cadastre could further serve local authorities as decision support for green infrastructure development prioritisation and for financial support programs.

Abstract. The implementation of urban Nature Based Solutions (NBS) projects is deeply determined by the novelty of the concept. Its innovation is both an opportunity and a challenge: as a new concept, it generates uncertainty due to lack of technical and operational preparedness, but it also allows to deploy innovative approaches, new ways to address old problems and more inclusive practices. Nature4Cities project has systematically conceptualized the barriers and drivers on NBS projects implementation by a review of the state of the art. To see how these barriers can be overcome by governance strategies, different urban and environmental governance models have been mapped and characterized to assess their suitability for different NBS projects. Five clusters have been identified where models are grouped according to the involved actors, their position in the spectrum from high to low government involvement and their level of participation. This theorical model has been applied to real cases to check the incidence of the different clusters. Results show that urban and environmental governance is a map where the different models coexist in different degrees regarding some key axes such as level of innovation, polycentric vs. monocentric, involved sectors, level of participation and scale. Collaborative, multisector, polycentric and adaptive governance models address significant number of previously identified cross-domain barriers showing their suitability. The work presented in this paper can be the basis to define new institutional and governance arrangements that will foster multi-stakeholder involvement, citizens' engagement, leveraging both public and private funding of NBS in cities

1. Introduction

Nature Based Solutions (NBS) are defined by the EU as "*solutions that are inspired and supported by nature, which are cost-effective, simultaneously provide environmental, social and economic benefits and help build resilience. Such solutions bring more, and more diverse, nature and natural features and processes into cities, landscapes and seascapes, through locally adapted, resource-efficient and systemic interventions"* [1]. They can enhance sustainable urbanisation, restore degraded ecosystems, support climate change adaptation and mitigation and develop strategies for improvement of risk management and resilience [2]. But, NBS is a new complex concept that is not totally clear for practitioners. The concept is frequently confused with other concepts such as biomimicry, sustainable development or green infrastructure. This loose definition of the concept and its novelty could be and opportunity for more flexible and inclusive dialogue and innovation [3], but also a challenge due to the diversity of required knowledge, stakeholders to be involved and challenges to be addressed [4]. Some authors believe that NBS concept includes the concept of integrative governance and participatory approaches to co-design, co-creation and co-management [5] and this could be one of the key differences that distinguish the concept from more traditional and top-down conservation approaches [6]. Governance could be an ambiguous concept also and there is not an agreed and clearly defined governance theory [7]. In this paper we will use the term “governance” to refer to collective action arrangements designed to achieve the implementation of NBS projects, and government to refer to the formal organisations of the “public sector” as in [8]. In Nature4Cities (N4C) project the different urban and environmental governance models have been mapped and characterized in order to assess their suitability for different NBS projects. An Implementation Model Data Base for an extensive range of Nature-Based Solutions has been developed as open-source with the purpose of illustrating the single characteristics, the concerned NBS and the governance, financial and business aspects related to each Implementation Model (IM) identified. The process allowed gathering a large amount of information, which facilitates the systematization of the implementation modalities through which single NBS can be applied in specific urban contexts.

2. Methodology

For the literature survey a snowball approach has been followed. In a first step some primary documents have been identified [4][9][10] taking into account the research outputs that have been generated for similar research project [3][11][12]. These documents guided the posterior literature review to specific fields and issues. The literature review has been complemented by the results of several interviews, on-line surveys and workshops were conducted targeting experts, urban planners and municipality workers. Finally, the results have been verified comparing them with the experiences of the partner cities participating in N4C project. After developing the theorical model, a database with different real cases was built in order to link the predetermined theoretical models with best practices and to study the incidence of them in practice.

3. Barriers and drivers

NBS-oriented urban planning can be considered a process of socio-ecological change. These processes are part of very complex systems with incomplete understanding and profound uncertainties [13] in need of interdisciplinary research [4], social engagement and feasible financing schemes. The literature shows that the main type of barriers for their implementation are the knowledge, governance and economic ones.

3.1. Barriers of NBS implementation (Process Inhibitors)

The identified barriers in the knowledge, governance and economic domains are highly linked to the novelty and complexity of the approach, since that amplifies some of the traditional barriers of urban planning. In addition to the lack of knowledge and evidence generation, integrated solutions, such as NBS, highlight the limited coordination among different actors with divergence of interests, competences and powers, especially in the public sector when different departments are required (urban planning, buildings licensing, infrastructures, water and waste management), all having their own targets, regulatory frameworks and budgetary constraints. Several reasons linked with this complexity and novelty can affect also the cost-effectiveness perception of NBS, such as technology maturity (subsidies to support technology maturing periods proved to be unsuccessful) and market uptake (some new products may be economically competitive only if commercialized at a significant scale). The following table shows the summary of the barriers and the correspondent literature sources (main and secondary).

Table 1. Identified barriers for NBS oriented planning (M=Main literature source, S=Secondary literature source)

CATEGORY		DESCRIPTION	SOURCE		CODE
			M	S	
Knowledge barriers					
Uncertainty	Operational unknown	Due to the newness of the approach there is a lack of protocols for design, implementation and maintenance for NBS projects.	[9]		BK1
	Performance unknown	Lack of evidence regarding the quantitative benefits of NBS, especially from policy makers and citizens’ perspective. Designers may encounter		[14] [15]	BK2

		difficulties in implementing NBS when compared to traditional solutions, since they are more familiar with the later from technical and legal compliance.		[16]	
Accessibility to information	Information overload	Municipalities are already overloaded with knowledge making new concepts and approaches as NBS more difficult to reach.			BK3
	Unusable presentation of results	Presentation of scientific results in formats that are incomprehensible or not accessible to urban hinders the knowledge transfer between science, policy and planning.		[17]	BK4
Technical inadequacy	Lack of ready-to-apply scientific results, concepts and technologies	The lack of ready-to-use technologies, scientific results and concepts and simple and overarching theoretical framework makes the implementation and communication of NBS difficult even if a certain policy receptiveness exists. People in charge of design, implementation regulation and permit granting of NBS would need specialized training.		[17] [18] [19] [20]	BK5
Governance barriers					
Disconnection between short-term actions and long-term goals	Short-term action and decision-making cycles	Usual short-term decision-making and action cycles within municipalities do not match with the whole life cycle of NBS projects (planning, implementation, maintenance processes and sustainable financing)			BG1
	Establishment of long-term responsibilities	Responsibilities for the maintenance could remain unspecified and actors who will be implied in the maintenance are not implied in the decision and design leading to difficulties not previously foreseen.	[9]		BG2
	Gentrification	The willingness of improve life and urban quality with NBS projects in a short term could lead to risk of gentrification in a long term.			BG3
Institutional barriers	Lack of coordination	Lack of coordination between traditional departments traps knowledge in "*sectorial silos*" hampering e implementation of NBS which usually requires transdisciplinary coordination		[18] [20] [21]	BG4
	Lack of flexibility of decision-making structures	The decision-making structure of municipalities where the different departments have clearly defined responsibilities could not be suitable for multilevel, multiscale and multi-thematic projects as NBS.	[9] [10]		BG5
	Bureaucracy and unsupportive legal frameworks	Lack of knowledge due to the novelty of NBS as concept. Excessive legal rigidity, bureaucracy and lack of specific regulation (e.g. difficult agreements in multi-property dwellings).		[17]	BG6
Complexity of governance structure	Goal misalignment	Different goals of stakeholders within partnership arrangements could hinder collaboration.			BG7
	Apathy	A high number of stakeholders could generate inertia and apathy.			BG8
	Role ambiguity	A high number of involved stakeholders can cancel out some process enablers related with collaboration through unclear responsibilities	[10]		BG9
Participation and awareness	Perception	The perception of nature as source of problems and the fear due to uncertainty can hinder the participation of the citizens			BG10
	Lack of participation	Top down processes with no real citizen participation makes the NBS more difficult to accept by the citizens.			BG11
Economic barriers					
Perception of the benefits	Under appreciation of benefits	Benefits of NBS are perceived as mostly public and 'soft' and not directly related with economic growth-oriented issues as creating jobs and attracting investments.			BE1
	Short term vision	Lack of insight that investment now will prevent costs later. Economic benefits are long term			BE2
	Vandalism	Robbery or destructive actions, especially during early stages, could prevent the viability of NBS.			BE3
Budget constraints	NBS not a priority	City budgets for green development and the maintenance of green spaces often face severe budget constraints, while staff and related expertise is decreasing.	[9]	[17] [22] [23] [24]	BE4
	Lack of funding knowledge	Financing mechanisms are available, but they are complicated to apply for requiring additional administrative staff and time resources and, more importantly, require co- financing			BE5
Risk perception		Lack of incentives and motivation to attract private investment			BE6

3.2. Drivers of NBS implementation (Process Enablers)

Parallelly, in literature can be found drivers and process enablers related to the knowledge, governance and economic barriers that take advantage of the co-benefits of the NBS approach. In the following table these drivers are summarised.

Table 2. Identification of drivers for NBS oriented planning (M=Main literature source, S=Secondary literature source)

CATEGORY		DESCRIPTION	Literature		CODE
			M	S	
Knowledge drivers					
Generation of evidence	**Lesson learnt in implemented projects**	Successfully implemented projects generate useful evidence regarding the benefits that can be used by other projects. Lessons learned from less successful projects are proved to be instrumental for an effective integration of NBS in urban planning.	[9] [11] [25] [26]		DK1
	Research on benefits	Generation of quantified information and knowledge regarding benefits (direct and indirect)			DK2
	Research on cost effectiveness	Research on cost effectiveness of implementing NBS might help to justify new investments and to promote long-term funding or public-private arrangements.			DK3
Collaboration	**Networks**	Demonstration projects create collaborative networks and communities of practice that cross institutional boundaries and are drivers for legitimizing practices and approaches		[27] [28]	DK4
	Co-creation	Solutions to be developed could be based in collaboration between designers, citizens and companies in the early stages			DK5
Information accessibility and sharing	**Knowledge platforms**	Knowledge platforms focused on cities, accessible and open, can be used for knowledge gathering, aggregation and cocreation. Develop online NBS impact calculation tools.		[11][29] [30] [31] [32] [33]	DK6
Awareness	**NBS ambassadors**	NBS ambassadors can promote NBS by making benefits and risks communicable to citizens and politicians. Strategically selected NBS could work as flagship projects			DK7
	Climate Change	Climate change is perceived as a new criterion for decision making and can be a driver for changing priorities and the vision of urban planning, raising awareness and changing			DK8
	Ecological memory	Processes that enrich and regenerate ecological memory can improve the understanding of different perceptions of urban nature and lead to higher levels of ownership of NBS projects by local communities.		[34]	DK9
Governance drivers					
Process efficiencies	**Collaboration**	The combination of the different strengths coming from different sectorial affiliations of a diverse stakeholders' partnerships lead to improved efficiencies	[9] [10] [11] [35] [36]		DG1
	Coordination role	A specific role that can serve to improve the coordination between departments can help to plan and implement transdisciplinary and multifaceted projects as NBS.		[37]	DG2
	Action- thinking approach	An action-thinking approach (problem-based governance) could help to focus on a better use of existing finance instruments and to coordinate biodiversity and climate change efforts in implementing strategies on NBS.			DG3
	Capacity building	Capacity building can balance the uncertainty that comes from the newness of the NBS approach.			DG4
Self-governance	**Emerging partnerships**	Innovative NBS projects can learn modes of self-governance from emerging partnerships between civil societies in cities		[38]	DG5
	Grassroots innovations/transition initiatives	Grassroots innovations and transition initiatives as collaborative networks of citizens play a significant role in advocating and practicing NBS in cities as re-establishing green urban commons providing on-the-ground evidence of the multiple benefits		[39] [40]	DG6
Co-creation and participation	**Reflexive/adaptive governance**	An approach thought to include flexible ways to maximize learning opportunities and the experimentation and careful monitoring it is especially suited to overcome barriers related with uncertainty, complexity and system dynamics. Multiple actors possessing different types and degrees of knowledge could engage in a reflective way to update their planning, governance, knowledge production practice over time to continuously address arising risks and uncertainties. More reflexive approaches to urban and environmental governance bring together other drivers as networks and NBS ambassadors.		[9] [4] [36] [41]	DG7
	Involvement of urban government	The involvement of local governments is crucial for opening space for innovative approaches and solutions like NBS through a rapid transfer from concepts to action. An urban government can facilitate collaborative arrangements without losing its government role. Its new dual role (steering and orienting when partnerships exhibit capacity for delivering and regulating and directing when strategic planning is required)		[22] [42] [43] [36]	DG8
	Cross sectorial spaces and partnerships	Enabling cross-sectorial partnerships for NBS design implementation and maintenance. Creating different institutional spaces for cross-sectorial dialogue and interactions of different stakeholders for strengthening/fostering adaptive co-management and knowledge sharing about urban ecosystems.		[18][26] [44][45] [46][47] [48]	DG9
	Co-production	Design knowledge co-production processes to bring openness, transparency in governance processes, and legitimacy of knowledge from citizens/civil society, practitioners and policy stakeholders		[44] [48] [49]	DG10
	Tools to build a common vision	Stakeholders from different natures and backgrounds are unlikely to share a common vision. One way to reach the goal might be to include NBS in local planning and zoning regulations.		[50]	DG11
Economy drivers					
De-risking	**Sharing risks**	Collaborative arrangements enable the distributed responsibilities that can generate a shift from risk aversion to sharing the perception of risk of new approaches like NBS projects	[9] [10]	[51]	DE1
	Public de-risking	Due to the newness of the concept NBS is now in a beginning phase in the field of urban			DE2

	strategies	regeneration. This phase requires a great government support, due to methodologies and ways are not yet completely defined.			
Government support	**Provisioning of incentives to attract private investment**	The provisioning of incentives and/ or the removal of administrative barriers allows the creation of partnerships between government and businesses where citizen associations can participate also. The resource and governance synergies that can be generated in those partnerships can create new opportunities for an efficient uptake of NBS. Encourage methods to transfer the benefits of common goods provided by NBS to the initiators of NBS (e.g. tax reductions or subsidies). Public subsidies and tax cuts can stimulate private investments and make NBS more attractive		[36]	DE3
	Removal of administrative barriers				DE4
	Public-private partnerships	The inclusion of companies and private sector in the implementation and management of NBS projects can help to overcome budget constraints and limitation of resources.		[52]	DE5
Create conditions for new business models and finance schemes		Divesting from dominant solutions as the one and only focus, can leverage private and public funding in strengthening NBS and can create conditions for new business and finance models			DE6
Cooperative competition		A fair competition between private stakeholders, specially between companies, that does not hinder the collaboration, makes some processes more efficient and successful.			DE7
Mid-Long-term financing		Allocation of a sufficient budget for implementing and maintaining NBS projects can give sustainability in tight financial periods. Widely using natural vegetation helps to decrease the costs associated with vegetation care.		[20][9]	DE8
Real estate		Increased commercial and domestic property prices and attraction of businesses		[53][54][55]	DE9
Self-financing and self-management		Self-financing and self-management projects can be sustainable and resilient and are less dependent of external changes.			DE10

3.3. Verification with surveys, case studies and pioneer experiences

The barriers and drivers identified in the literature survey have been checked with:

- Results from the report "Elicitation of needs and definition of urban and landscape planner requirements" developed within Nature4cities project [56] in which six experts from 13 countries were consulted through semi-structured interviews and 75 completed questionnaires were analysed by experts with strong development background in the fields of urban and landscape planning regarding, specifically, NBS.
- Case studies from partner cities (Ankara in Turkey, Milano in Italy, Alcala de Henares in Spain and Szeged in Hungary).
- Pioneer experiences investigated in Spain, France, Austria, Germany, Switzerland, Italy, Turkey and Hungary.
- The verification of the barriers and drivers towards real cases was not homogeneous. The key parameter used pertained the previous experience in NBS projects. When this experience is not predominant (as in the interviews and surveys) the barriers were more evident. The Knowledge and Economic Barriers are the ones that are more recognized although only one of the identified barriers is identified in almost all cases (BK1: Operational unknown). The implementation contexts with more experience in NBS (such as Çankaya and German speaking countries) are more inclined to perceive the possible drivers compared to less experienced cases (e.g. most of the urban planners and municipalities interviewed).

4. Governance Implementation Models

Critical decisions about NBS projects (design, costs, location, scale or levels of management intensity) involve a wide range of stakeholders who surely have different ideas and backgrounds. Moreover, a 'nature-based' perspective has to adopt a 'society-based' perspective also in order to incorporate the notion that human beings have shaped the landscape [57]. These involvement of different groups can bring substantive, instrumental and normative benefits to the process of planning and delivering improvements in environmental management [58] and to the decision regarding role, scope and appropriateness of NBS interventions that will require governance models that can enable NBS with an inclusive, long-term and balanced approach [59].

4.1. Clustering and characterizing Urban NBS Governance Structures

The different urban and environmental governance models that can be found in literature cannot be packed in clearly delimited boxes. Urban and environmental governance is a map of spectrums where the different models coexist in different degrees regarding some key axes [60]. Four dimensions have been considered to define our typology of governance models.

1. Polycentric vs. monocentric governance: One of the most important current trends in environmental governance is the shift from centralized control to the incorporation of lower-level administrative units and social groups into more democratic decision making processes through co-management, community-based natural resource management, and environmental policy decentralizations [61] [62]. Polycentric systems have advantages (resilience by redundancy, efficiency by competition, participation and accountability, facilitation of learning processes and experimentation and cross-scalarity) and disadvantages (economies of scales may be difficult, more complicated decisions, duplication of efforts and dispersed responsibilities) to be take into account in governance models for NBS implementation[63][61]

2. Initiating actor: One classical way to characterize the governance structures considers the main actors promoting and interacting within the governance structures. Traditionally governance has been identified with the governmental institutions at different levels. However, non-governmental or private actors can also be involved in governing public goods like green infrastructures [7]. The typology of actors that are considered in this paper are classified in three main sectors: government, community and market. The initiative will come from one of these sectors and this will be one of the key parameters that will determine the nature and rules of the arrangement and the overall management of the intervention.

3. Levels of participation: Arnstein in 1969 described a ladder of participation writing about citizen´s involvement in planning processes in the United States. The ladder has eight steps that range from non-participation to citizen power. The first two steps (*Manipulation* and *Therapy*) are not participatory approaches. Their goal is to manage to achieve public support for already made decisions through public relations. The next step is what Arnstein called "Tokenism" and comprises *Informing, Consultation* and *Placation.* These steps are one level higher in the legitimation scale, although the power is still retained by the government (by means as one-direction information flow and ritualized and not decisive participation). In the last step, *Delegated power* and *Citizen Control,* public has the power to assure the accountability or even to plan and manage without intermediaries. The intensity of participation can be also be classified according to the range of parties included in the decision making process, the intensity and direction of information flows and the level of influence in the decisions to be made [64].

4. Governance concepts and steering modes for clustering: The governance framework and its capacity to tie different areas and levels of government, has been identified as a critical factor for the success of integrated interventions such as NBS [65]. Glavovic, mainly based on the work of Hartley, differentiates three broad conceptions of governance that theoretically have evolved sequentially but in practice co-exist, overlap and compete [66]: "*Traditional public administration*", "*New Public Management*" and "*Networked Governance*". Van der Steen et al. added a fourth governance concept: "*Societal Resilience"* [67] *(XX) and* . These four concepts have been used to make the clustering of the types of governance models (see Figure 1): government –led traditional governance models (Cluster 1), market-oriented governance models (Cluster 2), community-based governance models (Cluster 4) and collaborative governance models (Cluster 5). Two additional key dimensions are the degree of involvement of public actors (government) vs. private sectors (communities and markets) [68] together with the hierarchical/non-hierarchical distinction. Using this two axes, Hall [60] classifies four frameworks of governance regarding their steering modes. This classification provides the fifth cluster: private-private partnership that considers all governance models between community and market sectors. Based on the previous references and in the triangle connecting government, market, and community, also used by Lemos and Agrawal [61], a framework for governance model analysis and clustering has been developed (see Figure 1).

4.2. Mapping and characterising the models of governance

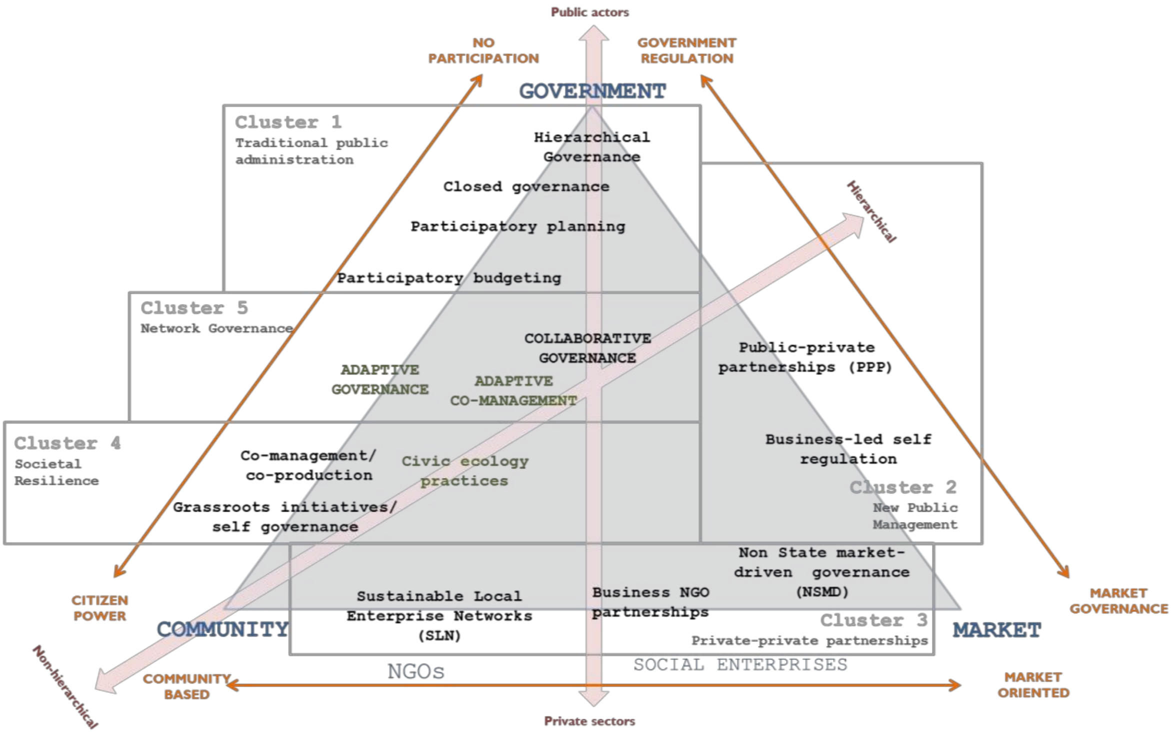

Figure 1. Mapping and clustering of governance models for NBS oriented planning

Many problems and urban challenges addressed by NBS (climate change, loss of biodiversity, resource scarcity…), are too broad and too complex to be solved by the government alone. It is necessary to move the focus from individual actors to network structures, to be able to inform about practices that support the emergence of purposeful network structures for ecosystem governance [69]. The identified governance models are not static or definitive. They can coexist in the same initiatives or change during the different stages of the projects. The Figure 1 shows the different analysed governance models clustered in 5 clusters and distributed according to the involved actors (government, community and market), their position in the spectrum from high to low government involvement and their level of participation. In the following sections, the different models are analysed from different perspectives: how they emerge, involved actors, the degree of government involvement, rules, contextual conditions and tools that can be used. Each cluster is also studied regarding the barriers that can help to overcome, drivers that can be triggered. Their suitability for NBS projects has been determined by assessing the capacity of these urban governance structures to allow processes required for the implementation of NBS such as engagement of different stakeholders, intersectoral coordination, transdisciplinary knowledge generation, socio-ecological innovation and continuous improvement and learning.

4.2.1. CLUSTER 1: Traditional public administration. The first cluster comprises government- and producer-oriented governance models. With different levels of low-moderate participation, the community role is mainly to be a client while the role of the government is to be the commander. The needs and problems are defined by professionals and since a key goal is to maintain stability they are uncertainty averse.

Table 3. Characterisation of Traditional Public Administration governance models (Cluster1)

	CLUSTER 1: Traditional Public Administration		
	Hierarchical governance	**Closed governance**	**Participatory planning & budgeting**
KEY WORDS	Centralized, government led, top-down, hierarchical	Hierarchical, closed participation, top-down	Hierarchical, open participation
HOW EMERGES	Default governance regime	Government defines the problem and the participants	Usually required by law.
INVOLVED ACTORS	Government. Citizens and community are always at the receiving end.	Access is restricted. Governmental actors are organised and complemented with a few non-governmental selected actors.	Government, citizens, NGOs
GOVERNMENT INVOLVEMENT	Leading role	Leading role	Very high
RULES	Instrumental vision on policy Administrations hierarchically controlled by electorally accountable governments. The interaction rules give government a leading role, whereas non-governmental actors follow. Coercion by the government is the predominant interaction type	Government has the power because it controls the resources that can be mobilised. The non-governmental actors can influence if the government allows it. Restricted cooperation. Government assigns certain tasks to the involved nongovernmental actors and then monitors them.	Hierarchically participation. There is a need to formalise the rules of the game and provide well established supporting tools (like websites, guidelines) to rebalance the information asymmetry. The stage when the stakeholders are involved depends of the level of collaboration.
CONTEXTUAL CONDITIONS	Often fails to provide effective solutions for highly contextualized situations	In cases of environmental issues with potentially catastrophic impacts, the predominance of "less than democratic" expert politics could be justified	Some countries have adopted national level instruments to promote different forms of public consultations at local levels providing guidelines and tools.
TOOLBOX	Top-down directives or command-and-control policies.	Top-down directives or command-and-control policies.	Neighbourhood planning. Participatory budgeting. E-tools for citizen involvement Workshops, professional moderation of debates. Interactive mapping
REFERENCES	[57] [75]	[57] [62] [76]	[23] [74] [77] [78]
BARRIERS	BG3, BG3, BG7, BG9, BE1, BE3		
DRIVERS	DG2, DG8, DE4, DE8, DE9		
SUITABILITY FOR NBS	**Low.** Often falls short in efforts to coordinate governance across large-scale ecosystems that cross multiple jurisdictional boundaries. Innovation is limited to some large-scale national and universal innovations being not enough for local innovation required. Large step-change improvements could be possible initially, but less capability for continuous improvement		

4.2.2. CLUSTER 2: New Public Management and CLUSTER3: Private-private partnerships. The idea beyond the involvement of market actors in environmental collaboration is to overcome the inefficiencies of government action by injecting competitive pressures through market actors that are regarded as capable of achieve bigger profitability in the utilization of environmental resources [61]. The different models for this kind of arrangements could be placed in a spectrum that goes from an almost fully public sector governance to an almost private sector governance.

Table 4. Characterisation of New Public Management and Private-Private Partnerships governance models (Cluster 2 and 3)

	CLUSTER2: New Public Management		**CLUSTER 3: Private-private partnerships**		
	Public–private partnership (PPP)	**Business-led self-regulation**	**Non-State Market-driven governance (NSMD)**	**Business–NGO partnerships**	**SLENs (Sustainable Local Enterprise Networks)**
KEY WORDS	Marked-oriented, competitive, top-down	Business-led, decentralized	Market-oriented, decentralized	Hybrid governance, decentralized, non-hierarchical	Self-organizing, complex adaptive systems
HOW EMERGES	Usually from a flexible, opportunistic approach, drawing from experiences in other cases. Not always the most evident solution, but a widely acknowledged crisis can trigger the arrangement.	When government is not perceived anymore as the only source of legitimacy and market forces are strong enough.	NGOs develop their sets of responsible business practices due to the difficulty to influence the government providing recognition in the marketplace to responsible companies	A reactive approach is adopted by companies in the beginning, but partnerships could evolve, where pressures from NGO lead to go from mere compliance to strategic actions	Provide an integrating opportunity for stakeholders to acknowledge a shared asset base and construct a virtuous cycle

INVOLVED ACTORS	Government + private sector	Business sector. Efforts may be undertaken to include community	Environmental and social stakeholders participate with business interests	Markets + NGO	NGOs + civil society members + companies.
GOVERNMENT INVOLVEMENT	Can range from high to low involvement.	Announcers and commissioners	Not necessarily	Medium-low	Not mandatory.
RULES	Private sector involvement does not eliminate public sector responsibilities. Continued government involvement in certain services helps ensure the efficiency of markets by reducing capital risks, increasing access to information, and reducing monopoly	Utilization of market exchanges and incentives to encourage environmental compliance. Corporate self-regulation initiatives create their own (usually voluntary) rules and procedures to guide corporate behavior.	Steering by market parties, regulation on basis of supply and demand. The viability of NSMD is determined by whether it can achieve legitimacy to operate. Authority emanates from the market	Depending of the type i) threat-induced, compliance or charity-driven responses, ii) transactional partnerships for improving profitability or market share, iii) businesses move beyond bottom-line iv) other key stakeholders are involved	Require at least one for-profit business to anchor the network and ensure that it is financially sustainable.
CONTEXTUAL CONDITIONS	PPP are deeply context based.	In neo-liberal contexts	General dissatisfaction with old policy instruments; neoliberal institutionalism and free trade agreements and a requirement for market innovations.	Differences in organizational cultures between business and NGOs due to differing missions and accountability systems.	Depend on mobilizing all four key assets: human, social, financial and ecological (natural) capital.
TOOLBOX	Outsourcing. Joint Venture Public-Private Partnerships	Voluntary agreements, third-party certifications, eco-labelling, corporate social responsibility	Forums for exchanges of expert information, databases of experiences and best practices. Norm generation and community building	Sponsorship. Short-term problem-solving. Sustained dyadic Eco-labelling. Industry sustainability standards.	Re-conceptualization of roles.
REFERENCES	[33] [49] [71]	[80], [81]	[62] [79] [80] [81] [82] [83] [84]	[86] [88]	[89] [90]
BARRIERS	BE2, BE6		BK4, BK5, BG7, BG10, BE1, BE2, BE5, BE6		
DRIVERS	DK3, DK4, DG3, DG9, DE1, DE6, DE7, DE9		DK7, DK8, DK9, DG1, DG3, DE6		
SUITABILITY FOR NBS	**Low-medium** depending the scale of the NBS project (the smaller the scale the easier to implement only market-oriented approaches). Risk aversion of the private sector often result in a choice for proven technology rather than for innovative solutions (such NBS).		**Medium-high.** But currently the required conditions for the more complex models are met only in rare cases. This implies the need for a significant change in relationships between enterprise-based activities in the developing world and broader social, economic and political systems in which they are embedded.		

4.2.3. CLUSTER 4: Societal Resilience and CLUSTER5: Network Governance. Societal Resilience comprises the governance models in the higher steps of the participation ladder when communities have the power for planning and managing without (almost) intermediaries. The Network Governance instead, aims to add the community and local voices to environmental governance models supported by the government with the hope to solve complex problems and allowing a more equitable allocation of benefits [61].

Table 5: Characterisation of Societal Resilience and Network governance models (Cluster4 and 5)

	CLUSTER 4: Societal Resilience			**CLUSTER 5: Network Governance**		
	Co-management	**Civic ecology practices**	**Self-governance/grassroots initiatives**	**Collaborative governance**	**Adaptive governance**	**Adaptive co-management**
KEY WORDS	Open participation, decentralized management, social learning	Small scale, local	Bottom-up, polycentric, self-organisation, self-management	Collaborative, multi-level, polycentric	Environmental governance, decentralized, polycentric, bottom-up	Community-based, resource management, polycentric

HOW EMERGES	When initiated by non-government, government supports implementation. When initiated by the government stakeholders are invited	Often are initiated by lay persons, generally as a community-based response to urban decline or sudden disturbances like hurricanes and war	Decision-making about societal development is no solely in the hands of government, but companies, scientists, media, new social movements and community.	Usually the model is initiated by the government trying to incorporate new resources, efficiency, knowledge and competences to solve complex problems.	May require "windows of opportunity" that appear as significant boost in capital or legitimacy	Usually triggered by a crisis.
INVOLVED ACTORS	Local authorities, citizens, NGOs, researchers	Scientists and NGOs helps to ensure larger impacts and longer-term sustainability, but it is not mandatory	Local authorities, citizens, NGOs, researchers	Involves a large group of governmental and non-governmental actors that engage in competitive and/or stimulating governing activities.	Requires a structure of nested institutions and cross-scale institutional diversity connected by formal and informal networks	Diverse set of stakeholders, operating at different levels, often through networks from local users to international bodies.
GOVERNMENT INVOLVEMENT	Medium	Not mandatory	It could have a semi-passive role	Government retains the formal authority	Medium.	Medium.
RULES	Local authorities have to take the responsibility for the urban environment which means that there is a limit for decentralization as far as public goods and services are concerned	Local authorities have to take the responsibility for the urban environment which means that there is a limit for decentralization as far as public goods and services are concerned	Grassroots movement have their own dynamic and they are an inherently unpredictable. Institutional diversity and multi-scalarity.	Actors are only loosely bound to one another. The model is formally organized and meets collectively. Participants are included in decision making process. Transaction costs are high.	Largely builds on human relationships and trust.	Leadership is essential by providing innovation, building trust, making sense, managing conflict, linking actors, compiling and mobilizing broad support for change. Iterative learning and action
CONTEXTUAL CONDITIONS	How co-operative management schemes are formulated and implemented depends on the task at hand and the responsibility shared	They reflect local environments and cultural traditions.	An active society is requirement.	Theoretically the model can be implemented at local, regional, state, national and even global levels (although at global level the decisions are voluntary)	Developed democracies and high-income countries where policy tends to leave room for and support innovation and bottom-up initiatives	Tailored to specific places and situations
TOOLBOX	Collaboration. Experimentation.			Analytical-deliberative approaches. Participatory evaluation. Collaborative scenario-building exercises. Urban Transition Labs	Assessment of multiple and non-monetary benefits. Qualitative, multi-criteria, iterative and experimental approaches.	Collaboration. Experimentation. Bioregional approach to resource management
REFERENCES	[74] [31], [94] [32] [37] [41]	[23] [95]	[65] [96] [73]	[21] [54] [57] [65] [86] [93] [99] [100]	[55] [61][101] [102]	[30] [41] [91] [102] [103][104]
BARRIERS	BG7, BG9, BG10, BG11, BE1, BE5			BG2, BG7, BG9, BG10, BE1, BE2		
DRIVERS	DK9, DG6, DG10, DE10			DK1, DK2, DK3, DK4, DK5, DK9, DG1, DG7, DG8, DG9, DG10, DE1, DE2, DE3, DE4, DE5, DE6, DE7		
SUITABILITY FOR NBS	**High.** Management of natural resources is one field especially well fitted for these types of governance. Reflexive governance is a model that may be the one applicable for social-ecological innovations such as NBS.			**Very High.** Collaborative governance is an approach thought for dealing with uncertainty, complexity and dynamics, therefore totally suited for NBS projects. "Transaction costs" (costs of consultations, reaching agreement, and enforcing such agreements) could be high		

5. Implementation model's database and results

After developing the theorical model, a database with different real cases was built to link the models with best practices and to study the incidence of them. To systematize all the information, all the identified cases were included in the same "card template" which constitute the narrative. Implementation Models were organized in 56 detailed cards containing: i) Short description of the NBS with picture, ii) Implementation context (location, scale, urban density), iii) Classification/typology, iv) Urban challenges addressed, v) NBS Stakeholders and Governance, vi) NBS financial aspects, vii) Business model, and vii) Enablers and inhibitors. The complete database is available on-line [70]. The Implementation Model (IM) collection has been built at first taking into consideration the availability of information regarding a series of practical experiences that refer to different IM. The main aim was to have a catalogue with a reasonable number of examples. The database now comprehends 56 detailed examples. The analysis was conducted based on online and free information. All the existing databases (i.e. the EEA database [71], Naturvation database [72] and others) are based on the description of NBS classification, scale, and dimension of the expected effects and not on the way in which they can be realized and carried out as full projects. The aim of this database was to give the possibility to users to consult a list of real projects crossing different variables (features or characteristics) in order to build further levels of knowledge about NBS.

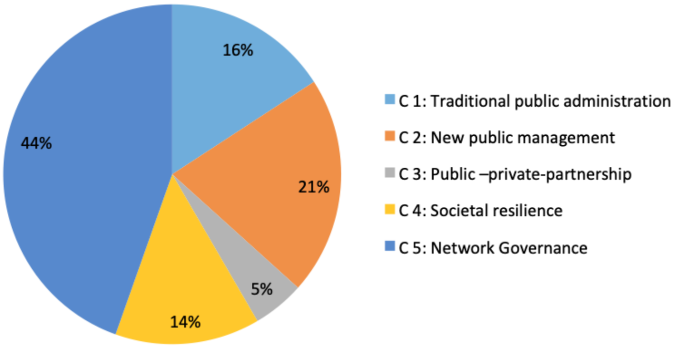

Figure 2. Governance Models incidence in the NBS IMs

The results that emerged from the governance models in the IM database (see Figure 2) showed that the more usual governance models are the ones from the Cluster 5 – "Network governance" (around 43% of the cases). Although, this confirms the theorical conclusion that this type of governance is the most suitable for NBS oriented planning (see Table 5), this correlation between the suitability of the governance models and their incidence in real cases is not so evident for the rest of the models. The second is the Cluster 2- "New public management" (21%) and the third is the Cluster 1- "Traditional public administration" (16%) with a theoretical suitability level of "low" or "medium low". The frequency of these types of governance could be more related with the traditional inertia of government structures than with the suitability of them.

6. Conclusions

The implementation of NBS projects is deeply determined by the opportunity and challenge that involves the novelty and complexity of the approach. As a new concept, it generates uncertainty due the lack of technical and operational preparedness, but it also allows to deploy innovative approaches, new ways to address old problems and more inclusive practices. Collaborative, multisector, polycentric and adaptive governance models have been considered the more suitable governance models for NBS projects, especially when urban scales are addressed. Drivers related to network governance models (such as coordination, co-production, cross-sectorial cooperation and reflexive/adaptive governance) are drivers that address a significant number of identified cross-domain barriers showing the suitability of these kind of governance models for NBS projects. The study of 56 real cases have demonstrated that the type of governance models that fulfils these requirements, "Network Governance" models, is decisively prevalent as compared to the other governance models. This result demonstrates that the collaborative and adaptive governance together with the scale-crossing borders are relevant aspects and play a crucial role in the regulatory and decision-making framework when it comes to NBS implementation in urban contexts. However, frequency cannot be considered as the only indicator for suitability. The significant incidence of less suitable but more traditional governance models, shows the high inertia that remains in urban planning. The work presented in this paper could be the basis to define new institutional and governance arrangements and new finance and business models, that will foster multi-stakeholder involvement, citizens' engagement and empowerment, leveraging both public and private funding of NBS in cities.

Acknowledgement

This work has been developed in Nature4Cities project that has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 730468. The authors would like to thanks to Nature4Cities partners for the support received.

Abstract. Continued urban growth, densification and the constantly increasing number of days with excessive heat provide challenging conditions for urban green infrastructure (UGI) and intensify the Urban Heat Island effect (UHI). Therefore, new approaches are required to improve the urban ecological function of buildings and to provide high-quality (urban) open spaces that affect the meso- and microclimate in a positive way. Based on the research project "Green Resilient City", this paper shows how climate simulations can support landscape and urban planning and development. A proof of concept for a multiscale tool set for the evaluation, regulation, and optimization of green and climate-sensitive urban planning projects is the overall aim. The tool-set combines a Green and Open Space Factor, as an urban planning index and controlling instrument, as well as three climate simulation models on different scales in order to harmonize them: the GREENPASS® as an optimization instrument on parcel and neighborhood level, MUKLIMO_3 on neighborhood and city level and Cosmo-CLM as evaluation tools on mesoclimatic and regional level. Several advantages arise from the unprecedented combination of these four instruments: It transfers the use of climate models to the planning process, enables the testing and optimization of different UGIs with a focus on how they can influence the climatic performance of the proposed design of an urban development or retrofit project and serves as a scientific basis for urban planning decisions on a political level.

1. Introduction

Half the world's population lives in cities and migration to urban areas is ongoing globally [1,2]. The United Nations estimate urban population to reach 68 % by 2050 [3]. Urban growth and the increasing densification of urban areas with high-density housing and the increase of impervious surfaces threaten green and open spaces. In addition, to the loss of urban green spaces [1] and urban green infrastructure (UGI), there is a constantly increasing number of days of excessive heat due to the interaction of Urban Heat Island (UHI) effect and the climate change related higher temperatures [4]. The UHI effect describes the difference in temperature between the cooler surroundings and the hotter dense built-up urban areas. The main cause for the UHI are sealing of soils and building coverage, as they store energy radiated by the sun. Cities are, therefore affected twofold: the increase of urban growth and the temperature increase due to climate change.

The reduction of the urban heat load is thus a central challenge for future urban development and a number of cities are therefore considering adaptation measures, including the City of Vienna. Additionally, in Vienna, the urban climate has changed noticeably, especially in the last decades [5]. The year 2018 was a record-breaking year with 42 tropical nights counted in Vienna Inner City and it was the fourth warmest summer in Vienna for more than 250 years [6].

Urban green infrastructure as a strategy for achieving resilience against weather extremes and a sustainable, functioning urban system is indispensable in urban planning. Even more so as social and economic demands can be met in addition to ecological ones since society benefits from the ecosystem services provided by UGI. Urban ecosystems are particularly important for the city residents in terms of their climatic (e.g. reduction of the UHI effect), ecological (e.g. increase in biodiversity) and social (e.g. benefits for health, well-being, recreation) function and they contribute significantly to the quality of life in cities [7–10].

Urban structures and green areas influence the urban climate on different spatial scales. For example, roof greening as individual measure of a single building has positive, but limited effect on microclimate. On the other hand, if several roofs within an urban quarter are greened, the range of influence is already greater and can positively affect large areas of the city. If there are several quarters within a city where UGI is sensibly combined, the effect reaches far beyond and can have a positive influence on the entire urban climate and surrounding area [11]. Thus, the sum of several small-scale changes can have a combined impact on the entire city. In order to have a positive influence on the urban climate, urban planning requires new, holistic approaches that take account of different levels of scale. As urban development is also a multi-level planning approach, steering and decision-making tools must be reconciled with the different planning levels.

To address these issues this paper answers following research questions:

- How should a tool set, consisting of several instruments (planning tool and climate simulation models), look like in order to be able to control and evaluate green spaces in the city?
- How can climatic performance be represented by the tool set?
- Which different planning levels can be addressed by the proposed tool set?

2. Methodological approach and introduction of instruments

In an interdisciplinary and transdisciplinary, collaborative approach the research team developed a novel tool set demonstrating its feasibility in a proof of concept. The various input parameters of the individual instruments (Green and Open Space Factor of Vienna, GREENPASS®, MUKLIMO_3 and Cosmo-CLM) were compared, adjusted and coordinated. The focus of the study lays on coordinating different scale models by analyzing data interfaces, harmonizing input parameters and setting the same reference time periods to examine the possibility of using a multi-scale tool set. The aim is to find out whether different, independently used and validated climate simulation instruments can be combined into a multi-scale tool set in order to support everyday planning in the future as an overall instrument. It will be evaluated if the combination of the individual simulation models with the Green and Open Space Factor of Vienna (GFF) can work as proposed in the tool set and deliver useful results to support green and climate-sensitive landscape and urban planning.

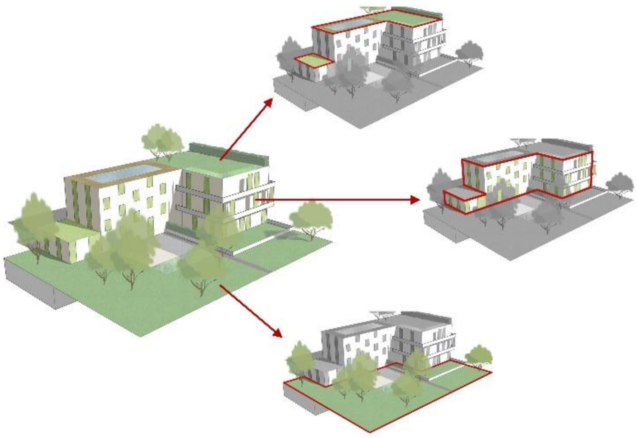
2.1. Green and Open Space Factor of Vienna (GFF – "Grün und Freiflächenfaktor")

Following the example of other cities (e.g. Berlin, Helsinki, Seattle, Stockholm, London) [12–16] a green and open space factor (GFF – in German: "Grün und Freiflächenfaktor") was developed for Vienna. Reacting to the fact that the fraction of green areas decreased especially in the last 15 to 20 years in Vienna, it is now aimed to maintain, and also to expand, existing UGI, because private and semi-public green and open spaces have positive effects for the entire city through ecosystem services.

At present, the floor-space-index (GFZ – in German: "Geschoßflächenzahl"), together with other measures (e.g. degree of sealing, building density, building height, etc.), is the determining factor for urban development. The GFF for Vienna is the counterpart to the floor-space-index. In addition, the GFF considers the ecological, climatic and socio-economic aspects of UGI by factoring in the different ecosystem services and selected elements of UGI. Each of the category contains individual UGI elements and is underlined with a specific factor determining the final GFF.

The calculation method of the GFF of Vienna gives a ratio of the UGI (in square meters) to the respective reference area on the ground floor, façade or roof (Figure 1). Due to the different reference areas, a differentiated consideration of the UGI elements (green and open space, façade greening, roof greening) is possible, as a function of the building size and height.

Figure 1. GFF and its respective reference areas (ground floor, façade and roof)



2.2. Climate simulation tools on different scale levels

The possibilities of the instruments for simulation and evaluation of urban climate are comprehensive and varied, but not yet tailored to the needs of landscape and urban planning. Three different simulation tools, developed and individually validated in previous research projects[1] have been selected to cover the different climatic impact areas and planning scales: the GREENPASS® as an optimization instrument for the microclimatic effects of green infrastructure at parcel and neighborhood level, the MUKLIMO_3 urban climate model as an evaluation instrument for the local scale impact on city level and Cosmo-CLM as a regional climate simulation model to provide projections on large-scale climate developments. In the course of the research project "green.resilient.city", the individual climate simulation instruments are coordinated, cross-validated and harmonized in order to adjust the input and output parameters (Figure 2). On the basis of a first case study (situated in an urban development area: **aspern** Seestadt), GFF and GREENPASS® were adjusted and used jointly in an urban planning competition. The effects of integrating these two instruments by increasing the use of urban green infrastructure could be shown by the urban climate model MUKLIMO_3 on larger scale. In further

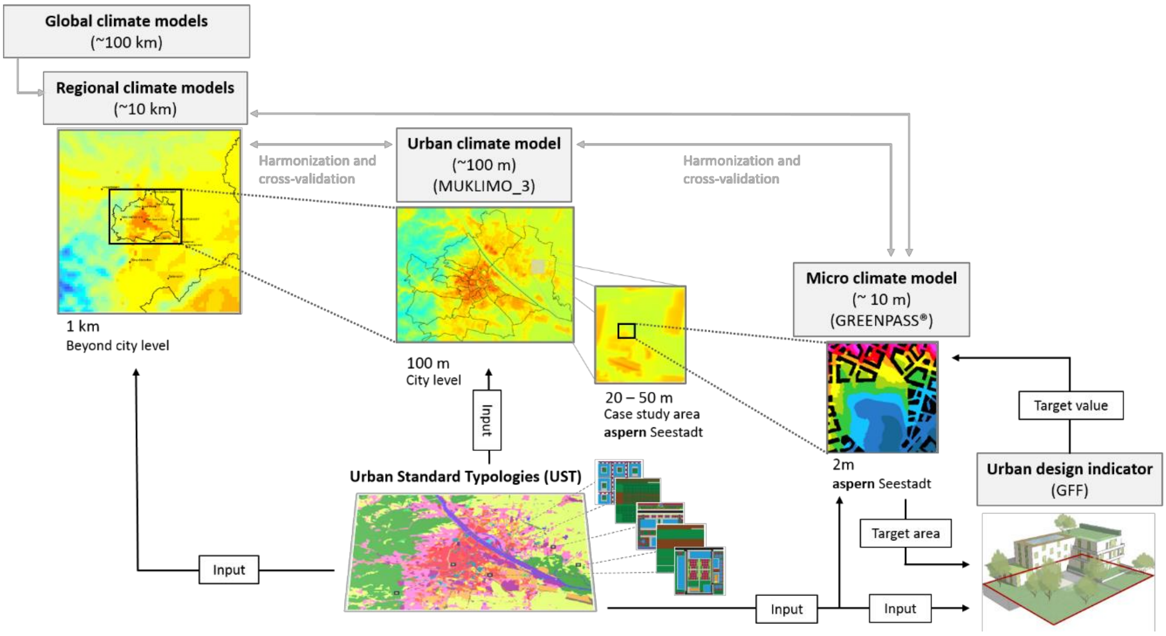
steps, harmonization with the regional climate model Cosmo-CLM and cross-validation of all instruments will be carried out.

Figure 2. GFF and climate simulation tools on different scale levels – downscaling of climate simulations to local scale (Source: Own representation based on ZAMG, 2019)



2.2.1. GREENPASS®

GREENPASS® defines standardized processes to assess and evaluate the climate resilience and cost-efficiency of architecture and urban planning. It combines the holistic high-resolution numerical simulation software ENVI-met with area analyses, evapotranspiration models, cost analyses and qualitative indicators [17]. ENVI-met was developed at the Chair of Environmental Meteorology Group at the Johannes Gutenberg University in Mainz [18–20]. In several European research projects (e.g. "Biotope City is Smart", "Nature4Cities"), the prerequisite for the planning use of the microclimate simulation software was created and linked with other models. Urban and object planning projects up to a size of 40 ha (with an internal resolution of 2 m) can not only be simulated, but can also be analyzed and optimized with regard to thermal comfort, rainwater management, costs for construction and maintenance, CO_2 storage, cooling degree hours, water demand and ecological quality.

For project quick assessment and mesoclimatic urban climate simulations, so called urban standard typologies were developed which assign specific land use data to an urban structure [21].

2.2.2. MUKLIMO_3

Urban climate model MUKLIMO_3 and the cuboid method developed by the German Meteorological Service (DWD - "Deutscher Wetterdienst") allows the investigation of urban heat load with spatial resolution of about 20 m to 200 m and on a time scale, which is suitable for the daily development as well as for the climatological analysis of UHIs. Based on topography and land use data, the urban climate model MUKLIMO_3 [22–25] simulates the radiation balance, wind, humidity and temperature distribution in the city, taking into account potential atmospheric conditions during periods of heat. Using the cuboid method [26] that combines high-resolution urban climate model output with long-term climate information from monitoring stations or regional climate projections it is possible to calculate climatological indices such as mean annual number of summer days, heat days or tropical nights for the 30-year climatic periods. Furthermore, the model can be used to assess the effects of different climate change adaptation measures, including the implementation of green infrastructure or unsealing of sealed surfaces.

2.2.3. COSMO-CLM

The German regional climate model Cosmo-CLM with special urban extensions (CLM-URB)[27–29] which integrate anthropogenic heat emissions [30,31] and a high-resolution sealing layer [32], is used to provide high-resolution climate scenarios. That allows simulations with a resolution of 1x1 km for the greater Vienna area (100x100 km). The simulations are calculated in four nesting steps at 50 km, 10 km, 4 km, and 1 km horizontal resolution. The first three runs are performed with the standard Regional Climate Model Cosmo-CLM. The urban extensions are applied in the 1 km run, with two additional input fields: the urban fraction (URBAN) and annual-averaged anthropogenic heat (AHF). By applying the urban extensions, the UHI effect can for the first time be mapped relatively fine-scaled with regional climate models in the context of large-scale climate developments. For the simulation of the past and the model evaluation ERA40/ERAInterim forcing data are used. AIT performs high resolution model runs for the greater Vienna area for various time slices until 2100. Model output is stored as hourly, daily, monthly, seasonal and yearly values and can be transferred to ArcGIS maps on future climate scenarios for Vienna.

3. Results - Requirements for a tool-set for a climate-sensitive urban development and its elaboration

3.1. Interface definition and data transfer to harmonize the instruments

The GREENPASS® urban standard typologies (USTs) represent an essential link between microclimate and mesoclimate simulations. These USTs have been developed in several research projects (e.g. “Green4cities”) and allow the abstraction of global urban structures. International case study cities (Hongkong, London, Santiago de Chile and Vienna) were analyzed using GIS data and aerial photos [33]. In a first step a set of USTs for each city was elaborated and finally merged to one set of global applicable USTs. Existing sets of USTs have been respected, as the Local Climate Zones published by Oke [34] which are limited to Northern American urban structures. In addition, the GREENPASS® USTs are more detailed in regard to the differentiation of areas, surfaces, materials and green infrastructure, which supports the calculation of the GFF. Furthermore, each GREENPASS® UST is available in four varieties: a worst case, status quo, moderate greening and maximum greening scenario. The scenarios describe the level of integration of urban green infrastructure, ranging from no green for the worst-case scenario to dense green at the maximum scenario. The mesoclimatic simulation models require land use data, such as the degree of sealing, canopy area, etc. The USTs provide this information as a basis for mesoclimatic simulations, not only in one but in four different greening scenarios. This unique approach allows to quickly exchange the scenario for a selected urban area and to increase or decrease the level of integrated urban green infrastructure without changing the building structure.

3.2. Combination of the instruments to form a multi-scale tool set

To incorporate city-specific information on urban structures provided by the USTs into the MUKLIMO_3 model, physical parameters like the degree of soil sealing, percentage of built-up area, percentage of vegetation (trees, low vegetation, green roofs) that are available for each UST category are translated into characteristic land use information that can be handled by the urban climate model. Model simulations at 100 m spatial resolution are performed to investigate urban heat load distribution in Vienna, based on the land use information gathered from the USTs. Subsequently, by implementing variations of the USTs that mainly consider different types of greening measures, their cooling effect can be assessed through an analysis of modification in urban temperature distribution on a daily basis or a modification of climate indices considering 30-year climatological periods. In order to harmonize the different climate models, MUKLIMO_3 model output (temperature, relative humidity, radiation) can be used as input for the microclimate simulations carried out with ENVImet. Similarly, model output obtained by the regional climate model Cosmo-CLM may serve as background climate information for the derivation of long-term climate indices with MUKLIMO_3. Integrating micro-scale urban fabric related information into the regional climate model Cosmo-CLM is challenging. The first step for identifying interfaces between micro- and macro-scale was to incorporate the sealing values of the USTs as input parameters into Cosmo-CLM. Test simulation runs have shown a high sensitivity of the model to changes in the degree of sealing. In further steps, plant cover, Leaf Area Index (LAI) and average building heights will be additionally integrated.

The GFF and GREENPASS® differ in the level of detail. The two instruments were coordinated by means of a tabular comparison. Due to the harmonization, the GFF contains all relevant UGI types used in GREENPASS® with only some exceptions. The GFF is partly more detailed, as social criteria are also included and evaluated. The higher level of detail is the logical conclusion due to the smaller area of use (parcel level). The combination allows the GFF to be calculated for each UST using GREENPASS® greening scenarios. The results show how much greening is possible for each typology. Based on this, target values can be derived which can be used to control the amount of greenery at parcel level.

3.3. Coordination of the tool set with the urban planning levels

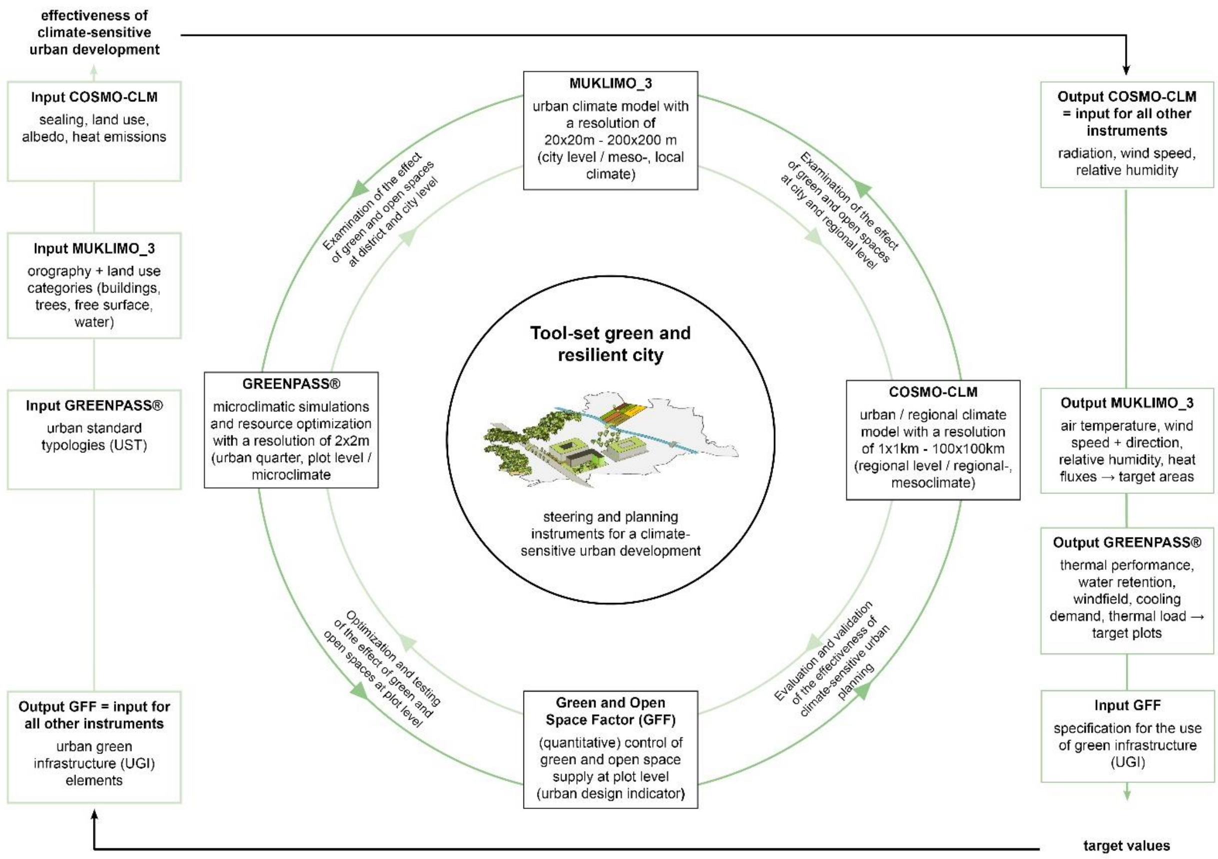
In order to develop a tool set suitable for everyday use in urban planning, the steering and evaluation instruments must be harmonized with the multi-level planning approach of urban development. Therefore, all relevant planning levels and areas of the city must be covered. In summary, these are: (1) metropolitan area (2) city (3) urban district and larger urban development areas (4) urban quarter, smaller development areas (neighborhoods), and the parcel level. These planning levels influence each other, therefore all instruments used must be coordinated within the planning tool (Table 1).

Table 1. Comparison of multi-scale climate simulations and urban planning levels

Planning levels and planning instruments	Climatic levels and spatial resolution	Climate simulations
<u>Beyond city limit/metropolitan area/regional</u> Regional development concepts and strategies	<u>Regional-/meso-climate</u> (1-10 km)	COSMO-CLM
<u>City</u> Urban development concept	<u>Meso-/local-climate</u> (100 m – 1 km)	COSMO-CLM/ MUKLIMO_3/ (GREENPASS®)
<u>District</u> Land-use- and development-plan; Urban development competitions and guidelines	<u>Local-/micro-climate</u> (20-100 m)	MUKLIMO_3/ GREENPASS®/ (GFF)
<u>Urban quarter/parcel</u> Developer completion; Urban development contract; Building permission	<u>Micro-climate</u> (0,5-20 m)	GFF/ GREENPASS®

In contrast to their local impact, the instruments described also show differences in their climatic impact. As explained in the introduction, the sum of measures at microclimatic level can achieve a large-scale effect. In order to improve the climate effectively, control instruments are needed at every scale level. By merging them, the planning levels and climatic scales are linked with each other. This leads to a proposal for a multiscale toolset (Figure 3) for meso- and microclimate regulation, optimization and evaluation in relation to the different levels of urban planning.

Figure 3. Proposal for a multi-scale tool set for climate-sensitive landscape and urban development



*3.4. Application on the basis of a case study in an urban development competition in **aspern** Seestadt*

Case studies are used to test the implementation and applicability of the proof of concept. One of these is located in **aspern** Seestadt, one of the largest urban development areas in Vienna. In **aspern** Seestadt a two-stage urban development competition "Quartier Seeterrassen" was accompanied by the research project and the joint use of the instruments was successfully tested. The GFF and the GREENPASS® were combined and applied in several phases of the competition process (Figure 4).

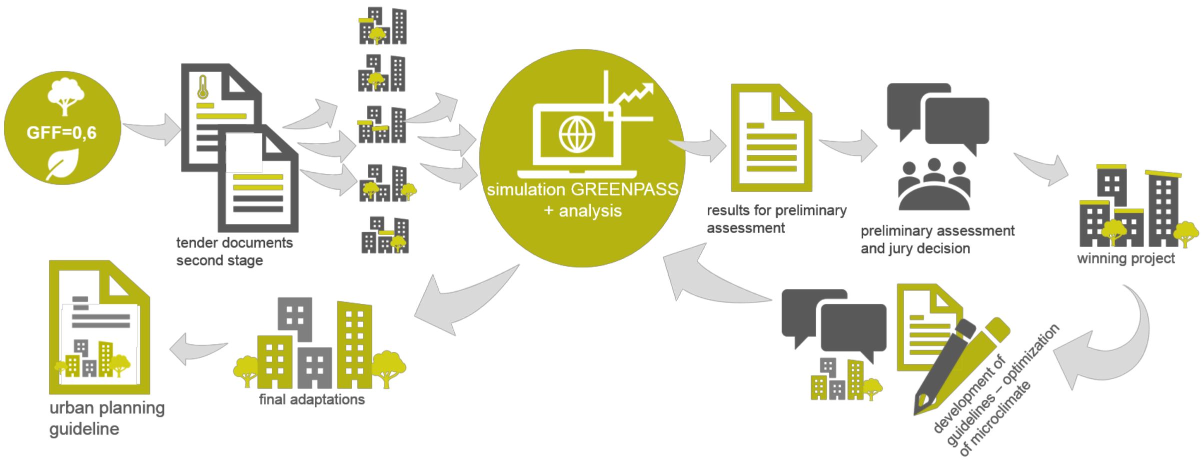
In the tender documents for the first competition phase, the special focus on the microclimate was already announced in the form of general dos and don'ts for a climate sensitive urban development. The existing master plan for the entire **aspern** Seestadt was simulated in order to show the climatic performance of the current state of planning. Based on this, qualitative recommendations regarding the urban structure were given. In addition, as a part of the preparation phase for the second stage of the competition, quantitative specifications were defined with the GFF. A target value was set in order to achieve a sufficient degree of greening.

In the course of the preliminary assessment of the contributions to the competition, the GREENPASS® was used to simulate, compare and analyze the effectiveness of the use of green infrastructure and the effects of the development structure of the various competition entries and compliance with the GFF target value was checked. These results were prepared and served the competition jury as a basis for decision-making.

The monitoring and optimization did not end with the awarding of the prize to the winning project. Based on the results of the previous simulation, adaptations for the winning project were formulated and optimizations made by various specific measures. As there are many different requirements regarding urban development and usability within the framework of an urban development competition, the winning project had to be optimized from a microclimatic point of view. In a workshop with the planning team (architects and landscape architects) adaptations were worked out. Building structures were slightly modified, breakthroughs in the perimeter block were defined for optimal air circulation, groups of trees were moved and façade greening was added to mitigate heat islands and optimize PET (physiological equivalent temperature). The winning design was revised and simulated again to make the optimization measures visible. It was gratifying to see that after the adaptations it became the best design both from an urban planning and a microclimatic point of view. The planning area was additionally simulated with MUKLIMO_3 in order to demonstrate the climatic effects on the entire quarter.

In the urban development guideline, which has to be taken into account when designing the individual building sites, both qualitative recommendations from the GREENPASS® simulations and quantitative specifications with the GFF were included in order to achieve a climate-sensitive urban development. With the GFF, a target value for UGI was anchored in the urban planning model for further planning and implementation processes. It has been shown that the monitoring and optimization of an urban development project by the tool set is feasible and shows positive results. In another case study, the applicability of the whole tool set in existing urban structures will be examined.

Figure 4. Workflow for the implementation of GFF and GREENPASS in an urban planning competition



4. Discussion

The GFF enables a (microclimatic) assessment of buildings, open spaces and UGI at parcel level. On the one hand, it enables accompanying urban planning procedures in order to compare and evaluate submitted development proposals. On the other hand, the need for optimization can be identified for existing built structures. The GREENPASS® can represent the climatic performance of individual building sites or urban quarters. For planning this means the following: By linking and coordinating these two instruments (GFF and GREENPASS®), the microclimatic impact of changes to individual UGI elements at site level can be simulated for an entire urban quarter. Since the urban climate model MUKLIMO_3 and the regional climate model Cosmo-CLM were also linked in the tool set and coordinated with the USTs, the output parameters of the GREENPASS® can be used in these instruments as an input. The advantages of implementing the USTs in the climate simulation models are the intersection with urban structural information and building types. The evaluation with regard to individual UST types makes it possible to generate general statements. Furthermore, greening scenarios can be integrated into the simulations. Thus, it can be shown which building type in combination with which greening type is climatically particularly effective.

The tool set can also be used in reverse order, from large scale to parcel level. The use of Cosmo-CLM and MUKLIMO_3 as climate simulation models on city level and its surroundings, allows the representation of UHI effect and intra-urban hot-spots under current and future climate scenarios. This results in target areas where improvements must be achieved in order to maintain a high quality of life for the residents. These findings can be embedded as initial conditions for the GREENPASS®. Through different greening scenarios, the GREENPASS® can demonstrate how much more UGI is needed within a city quarter. By considering wind direction and wind speed, the GREENPASS® indicates on which parcels specific measures have to be taken. The GFF can then control the use of UGIs on exactly these parcels by specifying target values. The sum of several microclimatic improvements leads to a positive influence on the urban climate.

The tool set supports political decisions with a scientific basis. It serves the city to foresee climatic developments and effects of urban development changes and to demand and achieve targeted measures. As there is not one holistic instrument for analyzing the urban climate at different planning levels and no steering instrument for UGI at parcel level in Vienna yet, the combination of different climate simulation models with the GFF can make a significant contribution to green, resilient urban planning.

5. Conclusion

In summary, it can be stated that the proposed tool set is applicable for the entire city and differentiates between the individual scale levels. Currently, the tool set consists of several components (GFF, GREENPASS®, MUKLIMO_3, Cosmo-CLM) that have to be operated individually. The combination into a single, coherent instrument requires further research. The possibility of controlling, evaluating and optimizing makes it suitable for both urban development processes and for conversions of existing urban structures. Building on this, links can be established to the relevant urban planning instruments in order to develop a regular urban planning instrument to consequently implement a steering tool for green infrastructure in (planning) administration.

martine.laprise@epfl.ch

Abstract. Within the context of post-industrial European cities, the regeneration of urban brownfields contributes to limit urban sprawl by increasing cities density while revitalizing neighborhoods. Yet because of their complex nature, urban brownfields regeneration projects (UBRP) are not automatically sustainable. To foster the integration of sustainability objectives into these projects dynamics, an operational monitoring tool was created. Entitled SIPRIUS+, this tool is a collaborative web-based software combining sustainability indicators adapted to UBRP issues and several management functionalities. Test applications conducted on case studies and presented to the related stakeholders gave positive insights about the potential of SIPRIUS+ to provide decision-making support. However, because of the long duration of UBRP, some aspects inherent to monitoring were not verified and the tool not piloted in real conditions. In order to confront SIPRIUS+ with the reality of the practice and its end-users, the tool is now being implemented for an 18-month period in the Gare-Lac neighborhood project located in Yverdon-les-Bains (Switzerland). The paper investigates how SIPRIUS+ is actually implemented into the project's ongoing urban planning procedure. Then, we analyze preliminary feedbacks to measure the level of adoption of the monitoring approach by the different stakeholders and to identify points of improvement.

1. Introduction

Now that it is clear that urban sprawl generates negative impacts on the environment as well as on the economy and the society, post-industrial European cities must steer towards strategic densification of their built-up areas [1]. In this context, the regeneration of urban brownfields is identified as a major opportunity to increase density within the already built fabric and, at the same time, to revitalize declining neighborhoods [2]. This recognition has spread since the last two decades and many land uses policies across Europe foster urban brownfield regeneration projects (UBRP) as a sustainable land take solution [3]. In Switzerland, the revision of the federal law on land planning (LAT) in 2014 introduced new measures to limit urban sprawl by promoting the densification of the urban fabric [4]. As a direct consequence, public authorities must now prioritize urban development within inner areas of the city, using in particular strategies such as the regeneration of urban brownfield [5].

In today's context looking towards the sustainable city, UBRP have to include environmental, social, economic, and governance considerations. However, even though urban brownfields regeneration is a sustainable land take solution at a territorial level, these operations are not automatically sustainable per se [6]. This is explained first by the inherently complex nature of UBRP: on one side the brownfield site complexities (real or perceived contamination, buildings of variable quality, intermediate neighborhood scale, social stigma, etc.) and, on the other side, the regeneration project complexities (long duration, several stakeholders with different objectives, rigid legal framework, etc.). This adds to the multitude, and sometimes even divergent, parameters of the concept of sustainability to be integrated into the UBRP. Taking simultaneously into consideration these intricate aspects goes far beyond the limits of intuition. To overcome this complexity and to foster a continuous, structured, and proactive integration of sustainability objectives into the project dynamics of UBRP, it is necessary to put systems in place to act on the basis of sound information and to collect it as appropriate [7]. In that order, an operational monitoring tool was created as an outcome of a four-year research project realized at the Ecole Polytechnique Fédérale de Lausanne (EPFL).

Entitled SIPRIUS+, this tool is a collaborative web-based software combining sustainability indicators adapted to UBRP issues and several management functionalities supporting continuous and structured monitoring. We tested SIPRIUS+ on case studies in Switzerland, France, and Belgium and presented the results to the related stakeholders. It gave positive insights about the potential of the tool to provide efficient support for stakeholders involved in the decision-making process of UBRP [8]. However, because of the long duration of UBRP, some aspects inherent to monitoring were not verified and the tool not piloted in actual conditions. In order to confront SIPRIUS+ with the reality of the practice and its end-users, the tool is now being implemented as a pilot experiment for an 18-month period in the Gare-Lac neighborhood project located in Yverdon-les-Bains (Switzerland).

This paper investigates this ongoing pilot experiment. To put the subject into context, the next section presents the functioning of the tool by showing some examples of monitoring visualization results and the outcomes of the interaction with the involved stakeholders. Then, section 3 explains the strategic implementation of SIPRIUS+ into Gare-Lac’s urban planning procedure. Section 4 analyses the preliminary feedbacks, which allows to measure the level of adoption of SIPRIUS+ by the various stakeholders and to figure points of improvement for the next phase of the pilot experiment.

2. The operational monitoring tool

The operational monitoring tool SIPRIUS + is an online hybrid tool that combines two approaches: on one side an indicator system along with its evaluation methodology (from the field of the built environment) and, on the other side, a sustainability monitoring software (from the field of business management). Although the issues of the two fields may differ, the principles underlying the monitoring remain the same. The hybridization of these two existing know-how results in a tool using a synergy of the most relevant elements from both disciplines. Thus, while being specifically designed to deal with the issues raised by the integration of sustainability objectives into UBRP, SUPRIUS+ uses several efficient monitoring functionalities (reporting, visualization, planning, management, communication, etc.). More precisely, it enables a comprehensive, continuous and structured assessment and monitoring of a series of quantitative and qualitative holistic sustainability indicators in three categories: Context indicators (21 indicators), Project indicators (23 indicators), and Governance indicators (11 indicators) [8].

Thanks to these tailor-made indicators, SIPRIUS+ offers not only a view on the project environmental, social and economic performances (Project indicators) but goes also beyond traditional evaluative logics at the neighborhood level. On the one hand, it integrates parameters whose influence exceeds the physical limits of the site (Context indicators). For example, indicators related to mobility, environmental impact, proximity to amenities or urban mixing contribute to the project integration on the environmental, social and economic levels within the local fabric. On the other hand, the tool looks at the project management and its dynamics between the multiple actors of the project, as well as the temporal stakes of the process of regeneration (Governance indicators). For example, indicators such as the temporary uses of the brownfield or the degree of participation of the population help the project managers to measure and adjust the various actions in place, which can contribute to change the brownfield site perception and promote acceptance of the regeneration project.

Taken together, these indicators embody the urban strategies used by UBRP to promote the transition towards more sustainable cities. The monitoring of sustainability, using evaluation of indicators and management functionalities, makes it possible to transcribe these various urban strategies and to visualize their performance through time. Thus, monitoring results can contribute to decision-making, that is the trade-offs to be made according to the UBRP's priorities. To support this idea, we expose here the monitoring results of three representative case studies of UBRP [9]. Indeed, test applications of the SIPRIUS+ tool - previously adapted to the contexts and practices of Belgium, France, and Switzerland - were carried out on the Val Benoit project in Liège (BE), the Pôle Viotte in Besançon (FR), and the Gare-Lac neighborhood in Yverdon-les-Bains (CH). Hereafter, we report the outcomes of the interactions with the stakeholders involved in the case studies.

2.1. Monitoring visualization

SIPRIUS + is a complete monitoring tool, which allows a variety of synoptic visualizations displays of all or part of the indicators in order to facilitate communication according to the target audience. As an example, Figure 1 shows the repartition display for the Expected final situation of the UBRP, that is to say, the foreseeable performances at the end of the regeneration project depending on the elements known at the time of the evaluation. In this case, data are taken from the Masterplans of the three case studies (monitoring performed during 2017 [9]), knowing that some specific indicators were not relevant to the UBRP. The results are distributed according to their levels of performance - Limit Value (VL), Average Value (VA), Target Value (VT) and Best Practice Value (VB) - and represented by a universal color code (from red to dark green). This easy to interpret and to communicate way at looking at the results is a gateway into the monitoring of the UBRP.

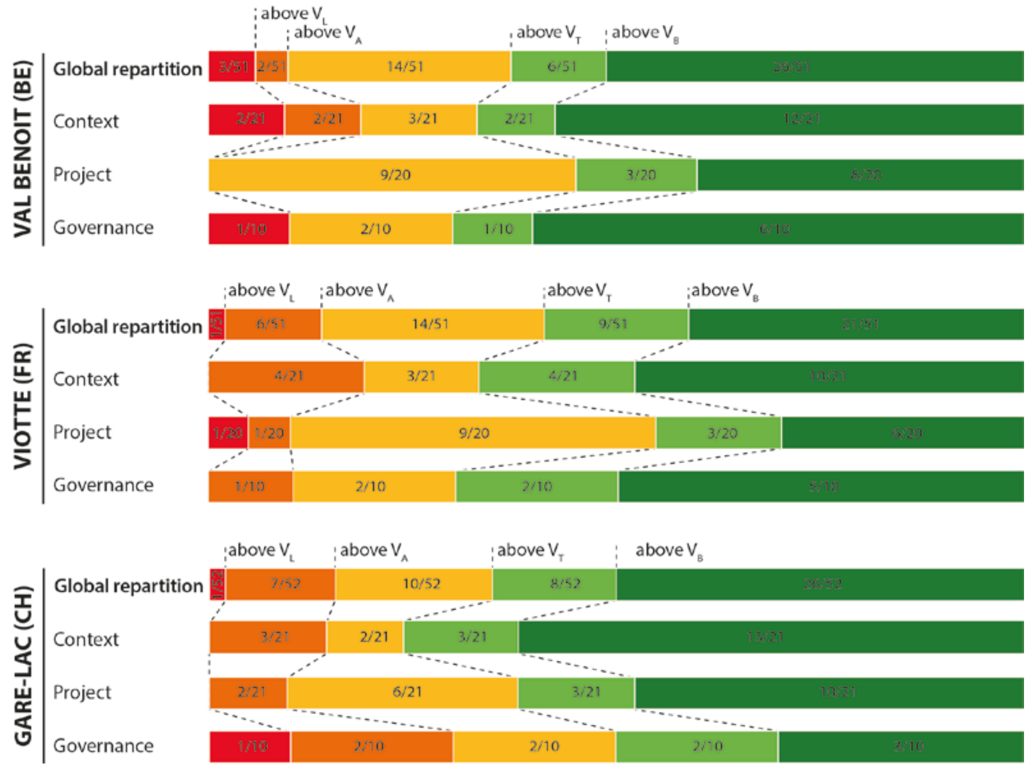

Figure 1. SIPRIUS+ repartition display for the three case studies.

From a monitoring point of view, it is especially interesting to focus on more detailed evaluation results. It makes it possible to see the effects that certain sustainability objectives set by the regeneration project may have on the site improvement, what are precisely the risks, the challenges, and the opportunities. Figure 2 shows the evolution display of three indicators: Context indicator "C2.1 Average annual emissions of NO_2", Project indicator "P5.6 Quality of outdoor spaces", and Governance indicator "G7.1 Degree of information access". We observe that the monitoring proposed by the SIPRIUS+ tool allows an evaluation of the Objectives, the Initial situation, the Current situation, and the Expected final situations. These monitoring results are, by definition, the portrait of a situation in a given moment and are subject to change according to the evolution of the projects. It can be used to compare in an iterative way different options of a UBRP, especially during the preliminary phases when the project is the most flexible and offers room for the integration of high sustainability targets. As a general rule, SIPRIUS+ is not designed to compare projects in different locations, nor to rate projects as certain labels.

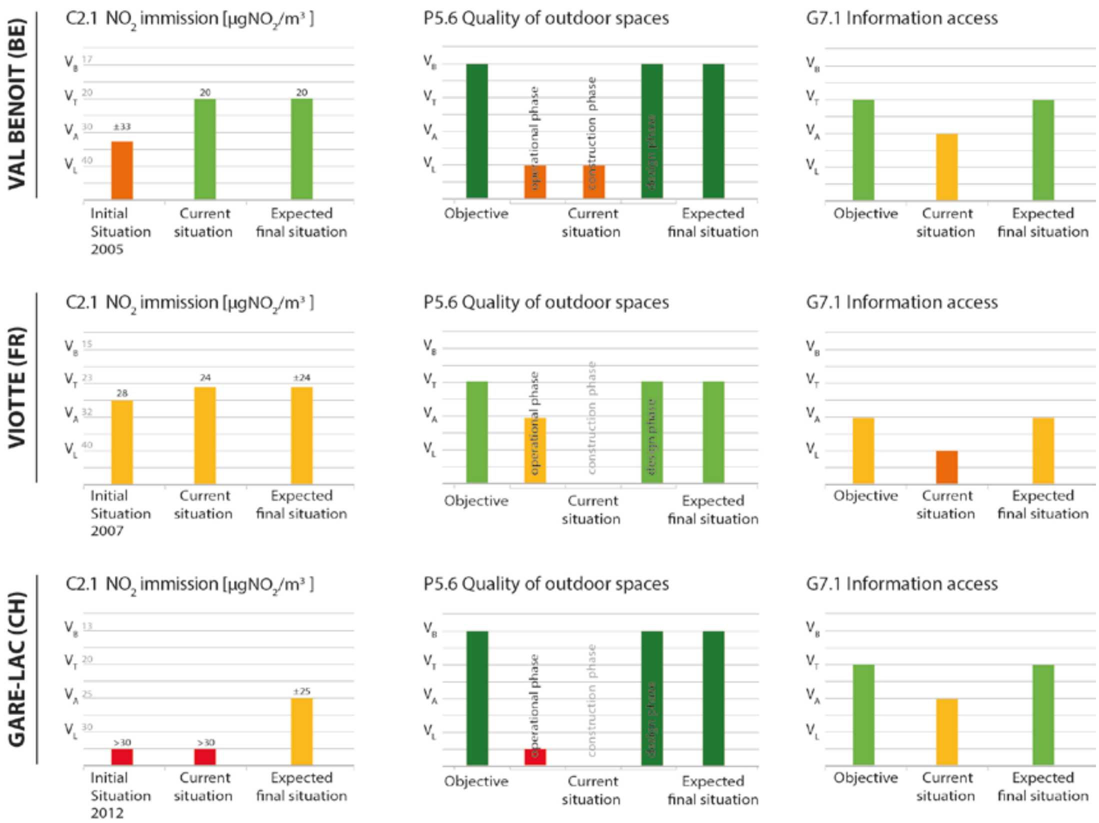

Figure 2. Evolution display of a Context, Project and Governance indicator for each case study. For exhaustive evaluation results see [10].

2.2. Interactions with stakeholders

The three tests applications confirmed the adequacy of SIPRIUS+ to UBRP specificities as well as the proper functioning of the tool [8]. However, because the concept of monitoring involves taking into account the long-term process of UBRP and because SIPRIUS+ team mostly performed the tests applications, some aspects could not be tested. Therefore, as a complementary test phase, we organized interactions with the involved stakeholders of each case study, which took the form of roundtable discussions. The aim was to face the tool and the test-application results to the future end-users. The participants shared a positive perception about the potential added value of SIPRIUS+, qualifying it as a "dashboard" contributing to the decision-making process. They recognized its potential to facilitate the integration of sustainability issues into the project dynamics 1) by simplifying communication in an interdisciplinary manner, 2) by facilitating follow-up of objectives from the initial situation to the regenerated site, and 3) by fostering a virtuous cycle of iteration of the UBRP. It also emerges from these interactions that if the use of such a tool implies a change in UBRP management, to include this practice appears not only possible but also realistic and desired.

3. From theory to experimentation: strategic implementation of SIPRIUS+

Convinced by the potential of the tool, the stakeholders involved in the Gare-Lac neighborhood UBRP in Yverdon-les-Bains (Switzerland) contacted the SIPRIUS+ team to pursue the monitoring already initiated. This pilot experiment started in July 2018 and will allow, during an 18-month period, to confront SIPRIUS+ with the practice reality and its end-users. This section explains the strategic implementation of SIPRIUS+ into Gare-Lac's urban planning ongoing procedure.

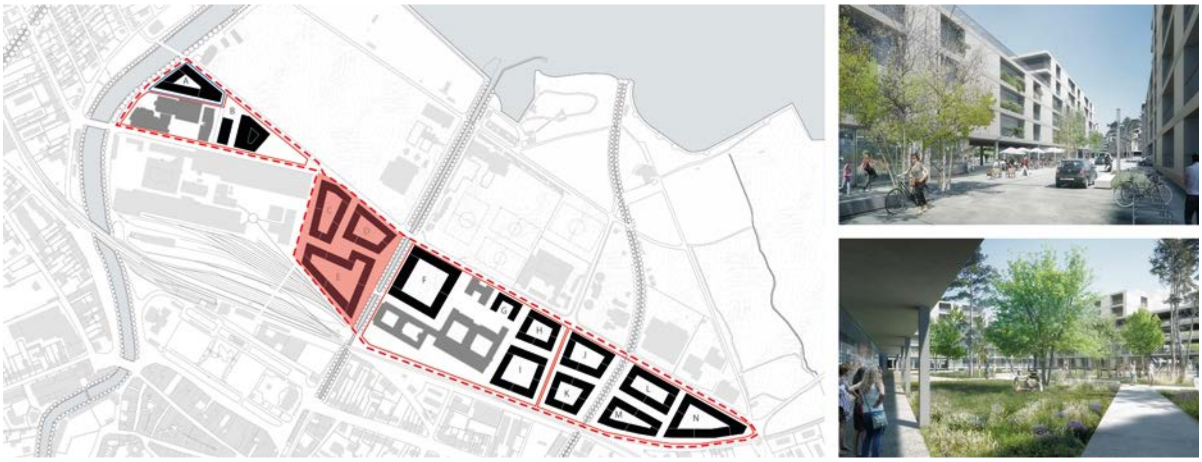

Figure 3. Master Plan of the Gare-Lac neighborhood with Ancien-Stand sector in red (left) and perspectives showing architectural, mobility, and landscape quality principles (right).

3.1. The urban planning procedure

Starting from 2006, the multidisciplinary team led by Bauart Architects and Planners Ltd. developed a Masterplan to transform a 23ha urban brownfield into a new sustainable neighborhood called Gare-Lac (Figure 3). Adopted in July 2015, the aim of the Masterplan is to give guidance for a new mixed-use neighborhood providing space for about 3800 inhabitants and 1200 jobs [10]. In particular, the Masterplan requires an optimal density with a ratio of 1,7 Floor space/Plot area, high architectural and landscape quality, and conformity with the primary energy consumption efficiency and CO_2 emission reduction objectives of the 2000 Watts Society [11]. The future neighborhood is composed of 14 plots, organized in 5 sectors. Each of these sectors will be subject to a land use plan (PA - Plan d'Affectation) in order to develop in further detail the Masterplan. This phasing has for advantage to reduce the risk of deadlock related to technical constraint or opposition, to facilitate discussion with landowners, and to sequence the UBRP development. However, it implies major coordination issues between the different PAs to maintain the principles and objectives provided by the Masterplan.

Starting from 2018, the steering committee (COPIL – Comité de Pilotage) composed of the Urbanism Department of Yverdon-les-Bains municipality, the Association for the development of Northern Vaud, and the Operational Group for Urban Centers from the canton of Vaud launched the planning of the PAs to come. The first PA to be developed is the 3,7ha Ancien-Stand sector (Figure 3). It consists of a two-steps public tender procedure. For the first step, it asks for the setting-up of consortiums composed of multidisciplinary offices with competencies in architecture and urbanism, landscape architecture, mobility, environmental studies, and property expertise. The consortiums will have to develop and make a proposition for the PA Ancien-Stand according to the Masterplan. Then, for the second step, the selected consortium will collaborate in an iterative working logic with COPIL until the final approbation of the PA. COPIL will ensure, among other aspects, the overall PA planning and implementation as well as PA compliance with the Masterplan principles and sustainability objectives. It will be supported in this regard by SIPRIUS+, as a pilot experiment.

3.2. Strategic implementation of the monitoring tool

SIPRIUS+ is designed to monitor sustainability objectives at the neighborhood scale using Context, Project, and Governance indicators. Indeed, the first test-application on the Gare-Lac neighborhood (section 2) - which will serve as a reference for the design of PAs - was performed taking into consideration data from the entire site and the surrounding. Hence to get the same results, the monitoring of the PA Ancien-Stand will have to follow the same methodology. Taking that into consideration, the involved stakeholders could perceive monitoring and evaluation as time-consuming and data collection as cumbersome [12]. Although it is of primary importance for this current urban planning procedure to check conformity with the Masterplan sustainability principles, the monitoring of not one, but several propositions of PAs simultaneously, appears in fact oversized.

To overcome this apprehension, we proceeded here to the strategic implementation of the tool within the PA Ancien-Stand planning procedure adapted to each of the two steps. In that respect, the annex of the call for tender document encloses exhaustive information about SIPRIUS+. It includes SIPRIUS+ catalog of indicators, which gives a detailed description of each indicator, data required to evaluate it, how it is evaluated, and the related references. It also includes the final report showing the results of the test-applications previously realized by SIPRIUS+ team [9].

3.2.1. Selection step For the selection step, in order to gain in efficiency, it is asked to the consortiums to described the sustainability concept of their proposition, what is their understanding of the monitoring principles, and how they will organize to provide the data for each indicator in order to feed SIPRIUS+. COPIL will base its decision upon the propositions quality, which includes several parameters of which the integration of SIPRIUS+ monitoring approach in the project dynamics.

3.2.2. Iterative step For the iterative step, the selected PA Ancien-Stand will be evaluated following SIPRIUS+ usual monitoring methodology. This means that Context, Project, and Governance indicators are evaluated integrating the new data of the proposition and the data from the entire site. The selected consortium will provide the data according to the project evolution. A team of three urban planners from COPIL will perform the monitoring using SIPRIUS+. The aim is to limit in a first instance the number of users during the procedure until PA Ancien-Stand approbation. This strategic implementation of SIPRIUS+ is a significant aspect of the pilot experiment: it eases the workload of both parties and ensures an incremental use of the tool. Moreover, it provides a common basis creating a shared dialogue on sustainability objectives between the consortium and COPIL.

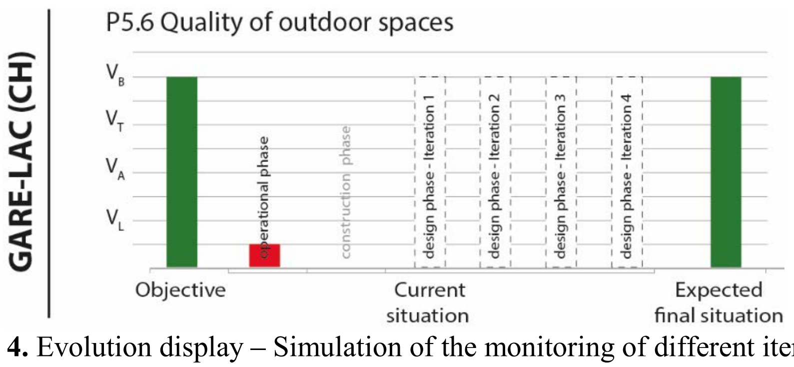

Figure 4. Evolution display – Simulation of the monitoring of different iterations

As an example, Figure 4 shows the monitoring of a Project indicator, which takes into consideration the "Current situation" according to the project advancement (exploitation phase, construction phase, and design phase). In this case, the PA Ancien-Stand corresponds to the design phase. Iterations of the project can be compared in real-time, which gives relevant information about the performances of the PA, consequences of given design choices, and probabilities to meet the sustainability objectives set by the Masterplan. This way, SIPRIUS+ can contribute to the iterative and collaborative working logic between the consortium and COPIL.

4. Preliminary feedbacks and discussion

The selection step of the PA Ancien-Stand planning procedure is currently nearing completion. In total, 10 propositions were received. Among them, four consortiums have not included, or not sufficiently included, the monitoring approach and SIPRIUS+ principles within their proposition. This shortcoming turns out to be critical in the selection of a consortium by COPIL. COPIL will disclose the name of the selected consortium during summer 2019.

This section gathers preliminary feedbacks on this selection step. These feedbacks were collected during an interview with the urban planners' team of COPIL, looking for information about the level of adoption of the monitoring approach in the urban planning procedure so far. We investigate here these preliminary feedbacks by confronting them to the potential added value highlighted previously by the stakeholders during the roundtables interaction (see the 3 points in section 2.2). Then, we identify points of improvement to maximize the benefits of monitoring for the next phase of this pilot experiment, the iterative step, and for further PA procedures.

4.1. Level of adoption of the monitoring approach

The interview revealed that the most qualitative propositions included monitoring principles in a proactive way, using SIPRIUS+ documentation as a "checklist" to verify compliance of the proposed PA Ancien-Stand with the Masterplan sustainability objectives as well as to communicate their performance. Similarly, COPIL uses SIPRIUS+ indicators during the selection step to control that the propositions cover a maximum of sustainability parameters.

It was announced during the interview that two of the three urban planners of COPIL who initiated the PA procedure are now being replaced. As a matter of fact, UBRP are long-term operations and the Gare-Lac neighborhood project is no exception to the rule. Because of that, stakeholders tend to change over time. In this context, the involved urban planners confirmed to rely on SIPRIUS+ to serve as a "dashboard": it will allow to share and transfer the long-term sustainability vision of the Gare-Lac UBRP and to keep up the Masterplan objectives through the project process, such as the 2000 Watts Society objectives.

Although, modest, these preliminary feedbacks are in line with the previously identified potential of SIPRIUS+ (section 2). As a support to decision-making, it can simplify communication in an interdisciplinary manner (point 1) and it can facilitate the follow-up of objectives during the UBRP process (point 2). However, because the iterative step has not started, it is not yet possible to judge the benefits of SIPRIUS+ to foster a virtuous cycle of iteration of the UBRP in that regard (point 3).

4.2. Improvements

This pilot experiment constitutes an innovative way to implement operational monitoring of sustainability objectives into the dynamics of UBRP. Indeed, it presents the advantage to defer on different entities the tasks related to monitoring and evaluation, easing the workload. In the same time, the use of SIPRIUS+ is not imposed but slowly introduced to the external parties, i.e. the consortium. That way, it avoids drastic changes in the usual practice and enhances the tool probability to be adopted later in the procedure. However, we noticed that not all consortiums included monitoring principles into their proposition. The reasons for explaining this neglect must be further investigated (misunderstanding of the monitoring principles, downplaying of sustainability objectives importance, fear of work overload, etc.). In any case, it shows that operational monitoring still a novelty in current practice; the PAs documentation to come could include a more exhaustive explanation about SIPRIUS+ approach.

SIPRIUS+ has the potential to offer a framework to promote the dialogue between the different stakeholders and the sharing of responsibilities on the project. For the time being, the strategic implementation limits the online access to SIPRIUS+ to the COPIL urban planners team. It may have the effect that members of the consortium feel not fully implicated in the sustainability monitoring of the project. Depending on this consideration, we suggest as an improvement to include later on one member of the consortium as a user of SIPRIUS+. This possibility will be discussed with COPIL upon the first round of iteration.

5. Conclusion

The transition towards a more sustainable built environment is the way forward. Urban brownfields regeneration projects (UBRP) can contribute to this important transition challenge but are not inherently sustainable. A research project proposes an operational monitoring tool facilitating the transformation of urban brownfields into tomorrow's sustainable neighborhoods. Entitled SIPRIUS+, the tool was tested on case studies and the results discussed with the involved stakeholders. In order to face SIPRIUS+ to the reality of the practice and to its future end-users, an 18-month pilot experiment is now ongoing on the Gare-Lac neighborhood in Yverdon-les-Bains (Switzerland). It is based on the strategic implementation of SIPRIUS+ into the urban planning procedure. It constitutes an innovative way to implement operational monitoring of sustainability objectives into the dynamics of an urban brownfield regeneration project. It eases the workload related to monitoring and evaluation and slowly introduces the tool to external parties. Preliminary feedbacks confirm the potential of SIPRIUS+ to contribute concretely to the actual practice by offering new means to integrate and follow sustainability objectives. For the purpose of continuous improvement, further investigations are expected at the end of the pilot experiment, including the analyses of the monitoring results as a support to the decision-making process.

Acknowledgments

We would like to acknowledge the financial support of the Urban Department of Yverdon-les-Bains municipality and the financial support of the Innoseed Explorer Grant. We thank the stakeholders involved in the Gare-Lac urban brownfield regeneration project, in particular Markus Bärtschi, Charlotte Malignac, Gabriel Jeanneret, and Filippo Sala.

Pocket Mannerhatten - City renewal on the basis of spatial sharing strategies, bottom-up participation and common good-based incentives

Niedworok F

Unterdorf 121, A 6135 Stans

fniedworok@gmx.de

Abstract. Cities worldwide and Vienna as well are facing an increasing pressure on space. Innovative strategies are required to tackle these challenges not only by creating new buildings but also by modernizing existing neighbourhoods. For decades Vienna counts on a gentle urban renewal approach. The question how to tackle new challenges, such as renewal towards energy efficiency, green spaces, alternative mobility or integration of multicultural lifestyles needs to be answered. The project Pocket Mannerhatten pursues the assumption that sharing building space across property outlines can offer an innovative approach for a city renewal. The spatial sharing is combined with a bottom-up-participation process and a compensation-oriented funding system. With the public funding program “Smart Cities Demo” (Austrian Climate and Energy Fund) a realization project will test the concept in Ottakring/Vienna. The multidisciplinary consortium accompanies the inhabitants realizing shared green spaces, community rooms, shared photovoltaic systems, car-sharing and Co-living apartments until the year 2021. In the future, these sharing and cooperation activities should become a city renewal strategy. Due to the slogan “who shares, gets more” and on the basis of a evaluated common good contribution not only monetary but also alternative, non-monetary incentives will be taken into account to foster urban renewal.

1. Introduction to the context and basic concept of the project Pocket Mannerhatten

What if the discourse about sustainability and resource-conscious thinking focus on an organisational approach of problem solving? What if we use our resources consciously in the way that we reorganize existing resources and share them? This essay will follow these questions as underlaying intention to discuss how creating links within an existing urban fabric can offer an approach to use space more efficiently and foster social networks. Urban developments with a growing number of inhabitants, increased land consumption and rising real estate prices clarify the necessity of a discussion about space as a common resource and about new concepts organizing it. The subsequent increased pressure on areas and spaces in cities, rising demand of affordable urban housing, public space and infrastructure as well as social changes and new claims for use and contemporary lifestyles underline this necessity and let municipalities and residents be challenged to find solutions.

As many other European cities, Vienna also faces these challenges. Innovative methods and strategies are required to tackle these challenges not only by creating new buildings but also by modernizing existing quarters in terms of ‘redensification’ or adaption for future needs. For example, the sharing economy creates innovative impulses in this discourse of resource consciousness and the real estate market already started to absorb concepts like co-living and co-housing especially for newly built urban structures [1]. The development and adaption of existing urban structures still needs to be addressed. Since the seventies Vienna counts on a gentle urban renewal approach which supported the development of numerous sub-standard Gründerzeit buildings [2]. Not only single properties but even clusters on the level of a city block with the aim to improve infrastructure, quality of semipublic spaces or too densely built neighbourhoods have been refurbished [3]. What still offers a potential development is the strategic implementation of specific spatial or functional links between properties creating new spatial qualities, uses and opportunities. The project Pocket Mannerhatten pursues the assumption that sharing building space, not only within but especially across property outlines can offer an innovative approach for a city renewal and create useful opportunities. This means that different building areas and functions are systematically linked to create synergies across property lines. Nonetheless it doesn't mean that land tenure and property rights has to be altered as it will be explained in the following. The 'sharing options' include merged courtyards or rooftops, linked green facades, elevators which are being used by occupants of several properties or collectively organized solar power plants or e-mobility solutions [4]. Furthermore the project concepts includes the assumption that spatial sharing opportunities needs to be developed through a participative planning process to create the necessary socialcultural preconditions for sharing. According to the project concept, the spatial sharing and participation process needs to be combined with a compensation-oriented funding system to foster the development and balance the possible additional effort of mediating and integrating further neighbouring stakeholders. All these issues and aspects are worked through by a multidisciplinary team together with the inhabitants of a city block, named "Block No. 61"(due to its serial number of all 260 examined cities blocks), in the 16th district of Vienna. The team aims to develop a pilot project for spatial sharing, a model for a suitable participation process and a public-benefit oriented system with alternative, non-monetary funding opportunities.

2. Characteristics of the urban fabric in Ottakring/Vienna

A significant portion of the built urban fabric of the Gründerzeit in Ottakring/Vienna is characterized by certain attributes which favour the opportunity to link built structures and its functions across their property outlines.

2.1. The street-network and parcelling of Gründerzeit quarters in Ottakring/Vienna

For example the street networks cuts out similarly shaped, rectangle building blocks measuring 120-125m in length and 60-65m in width. This comparatively continuous regularity is found also in the logic and size of the parceling subdividing the building blocks – see ´Figure 1´. The regularity supports the transferability of spatial solutions, for example worked out in a pilot project. The blocks contain mostly 12-16 parcels with the size of 400-500m² with a subdivision of 2 or 3 parcels on the narrow side and 3-5 parcels on the long side. This shows a quite small-sized, intensely structured parceling, for example compared to well-known communal housing complexes of the same time period, and is linked to the ownership structure. Mostly each parcel is owned by one or more private landlords.

It is obvious that the parceling causes a certain proximity of different entities of space, functions or use and question a potential interaction or connection between these different entities. Spatial connections between real estate require vicinity and adjacency. A property crossing rooftop terrace structure or circulation structure needs for example adjacency. A shared parking lot or different community rooms for recreational uses such as fitness, music or workshops and linked across the property outlines by shared access rights require vicinity.

The circulation and access system captures a specific role among all kinds of connections as it forms the precondition for connecting spaces. Austrian building codes demand a maximal length of 40m for the escape path to the exterior or nearest fire staircase. Gründerzeit plots in the examined district are most of the time around 20m to 30m long and only around 15m to 20m long, what shows, that the fire staircase outside of the regarded plot could be reached and connected circulation systems would be possible.

Figure 1. Aerial image showing the street-network and a closer view on the perimeter block fabric

2.2. Gründerzeit perimeter block and characteristic building types

Historic and present building codes defined the way of the perimeter block – see `Figure 1.´ which is characterized by a closed city block with each house adjoining the next one, bordering the street/pavement and forming a courtyard in the middle. The street line and building line unify façades on the side of the street and courtyard. In contrast the heights of the houses vary and also the way the courtyard houses are built as wings or additional single houses. Nevertheless this kind of compact, closed perimeter block offers spatial adjacency as promotive quality for connecting spaces and functions across plots. Although the built urban fabric is characterized by heterogeneity it allows to identify different types of buildings which are either repeated noticeable often or show similarities among them. Types of Gründerzeit buildings which are repeated are for example the corner building, street facing building without courtyard house, street facing building with single courtyard house, L-shaped building and H-shaped building.

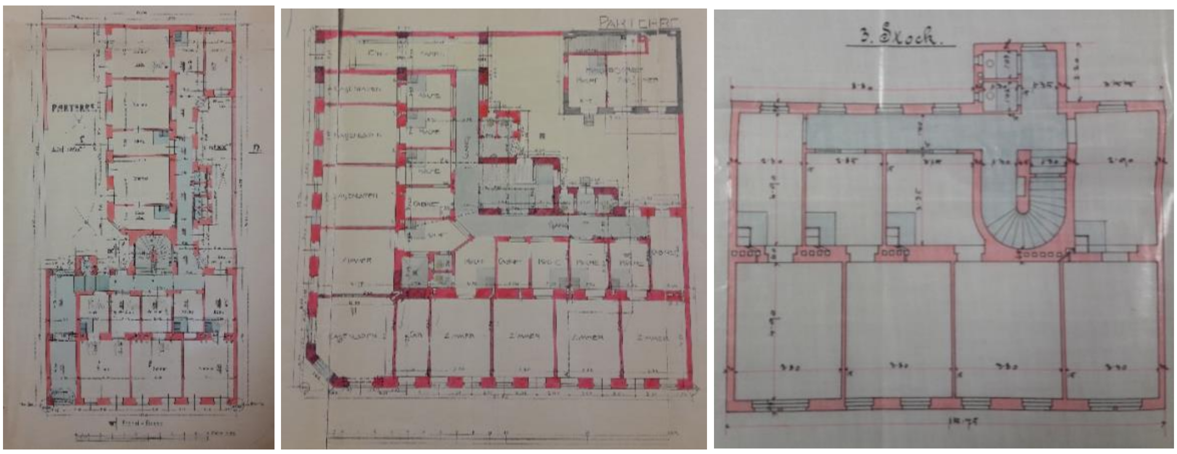

Figure 2. Several historical floorplans of Gründerzeit town houses with corridors blue-colored

In order to argue the capacity of the building structure to be linked the design of the circulation system should be highlighted, especially its positioning towards the courtyard – see ´Figure 2´. This aspects opens up the building to be extended through additional elements such as elevators staircase, bridges without interfering with existing floor plans of inhabited living units. Historically corridors offered shared facilities like water basins (Bassena) and small bathrooms with closets for the floor. In the course of refurbishment developments bathrooms and water supplies have been integrated into the living units and these small spaces had been repurposed. Today these small spaces are used as storage, space for technical equipment or are even empty. As they play no negligible role as functional addition to the living units they are to a certain degree detached and easier to transform then parts of the inhabited livings units. This creates a structural openness to dock on other spatial entities.

3. Opportunities of linking buildings and spatial sharing

Subsequently the question is what kind of connections and links within a built urban fabric can be considered.

3.1. Physical-spatial connections

Basically there can be defined links which have direct spatial impact when built definitions of space are altered in order to connect spaces and create or enlarge common space – see `Figure 3´. This could be: changed or new accesses, linked floor plans creating co-living flats, united roof terraces or courtyard gardens with removed fences and walls or newly built neighbourhood garage.

Figure 3. Floorplans with different physical-spatial connections on the basis of a common circulation

3.2. Functional connections based on access rights

Links between buildings can be created also by changing the logic of access rules and users domain while preserving the existing built structure. This establishes a functional bonding of neighbouring real estate. This bonding could be defined unilateral, for example one house offers a community room to the neighbours, or multilateral, for example two or more houses exchange the access rights of their community rooms.

3.3. Technical-functional connections of building services

Another category of connection is a pure technical-functional one, which means that technical building services such as heating, ventilation, air conditioning and energy supply are connected among parts of the city block. So far as it is possible to generalize these technical-functional connections they imply either an increased efficiency with scaled size of the technical facilities, for example photovoltaic systems. Or otherwise the increased diversity of the extended user group leads to an intensified utilisation of the system, for example when a commercial unit with peak energy consumption during daytime is combined with a living-unit with peak energy consumption beside working hours and on weekends.

3.4. Connections based on spatial references

Further on another category can be defined by sharing moveable goods which have a distinct spatial reference, for example cars, cargo bikes or partly temporarily built structures in public space like pocket gardens. Not necessarily space itself is shared but utilities for which space is needed. The shared use of these utilities can enable changed space requirements when for example cars and parking lots per inhabitant can be reduced on the basis of a car sharing pool.

3.5. Communication networks referred to a specific space

The fifth category which can be mentioned in this argument is the social network and its capacity of interaction, cooperation and communication. Primarily it is not about space, but about inhabitants, users and all other stakeholders referred to space and about their connections and interactions which impact space. An intensely linked neighbourhood will organized and cooperate in a complete different way the inhabitant space then the opposite. This last category underlines how crucial and significant the incorporation of sociocultural aspects is in this context.

4. Sociocultural constraints of linking and sharing space

Beside the mentioned spatial constraints of the urban fabric the sociocultural constraints for sharing are key. In an initial phase of the project Pocket Mannerhatten the analysis of the political administrative system including funding programs, stakeholders in real estate economy and house owners' motivation and action strategies of administrating their real estate helped to understand these constraints [5].

4.1. Constraints of the political-administrative system

The logic of the political administrative system and connected with it the mostly complex logic of permissions and funding programs considers either a single real estate or a single owning entity. It is obvious that the proprietorship form the basis of these socio-political constraints and consequently the proprietor owns the power of decision how buildings can be linked in terms of physical-spatial links of category 3.1. Especially all provisions which change space physically or the technical building services needs the approval of the landlord or if it is a group of landlords at least the majority of landlords. This doesn't mean that tenants inhabiting the real estate don't have opportunities to participate in sharing and linking real estate, but in a different way regarding the previously mentioned categories of sharing opportunities.

4.2. Intention and motivation of landlords as initiators

Therefore it is necessary to understand also what landlords motivates to share space or connect their real estate with each other. Due to the analysis done by Witthöft G and Hölzl D landlords can be differentiated in their way of managing real estate into twenty types. Among these action types there can be found for example “the Big Player”, large international profit orientated real estate companies without local bonds, “the Traditionals”, which live in their real estate, avoid change and new ideas, and regard the financial return as secondary or “the Motivated”, which inherit recently real estate, are young, decisive and eager to improve their real estate. The analysis shows that there are specific types of landlords which form a group characterized by a probable distinct openness and willingness to commit themselves to an intense dialog and negotiation for synergies or social qualities. In the research area “Block No 61” four landlords of the seventeen houses decided to take part in the current implementation project and work out solutions of sharing space. Three of these four use their property as either principal or secondary residence, which leads to the interpretation that inhabiting the real estate let a landlord be more probable to consider a variety of qualities and be open for alternative possibilities such as sharing space in a neighbourly network.

At the same time two fundamental motivations of sharing can be considered: one which is rooted in voluntariness and lifestyle culture and one which is rooted in economic benefits and necessity. Although sharing can enable economic benefits for the participants it should not deceive that the process of negotiation and communication to reach an agreement among the participants could be time- and consequently money consuming. If the participants organized themselves it requires respective abilities of communication and negotiation to establish a required foundation of trust, understanding, fairness and cooperation. At best there exists already suchlike environment in the neighbourhood. The examined neighbourhood network of “Block No 61” indicated a minor developed contacts across different real estates which is represented by two statements of landlords.

One landlord acknowledged after participating in one of the Pocket Mannerhatten workshops that she always considered the space defined by the walls of her apartment thinking of her apartment. After participating in the workshop she rather considers not only the building containing her apartment but the whole city block or neighbourhood. Another landlord living for years in his house stated that he would accredit the project Pocket Mannerhatten being a success already before something is built because he never got in contact with so many neighbours. The last statement makes also clear that mostly extrinsic impulses and professional support -not only in technical fields- can be needed to enable an initiative.

5. Enabling and fostering a renewal process based on space sharing

As explained in the paragraphs before, although the urban fabric offers preconditions which favour spatial connections of different categories and although there can be found landlords who are willing to develop and realize these spatial connections as decision-makers, some kind of incentives and promotion must catalyse the development. On the one hand more stakeholders makes the development process more complex and expensive and on the other hand there comes along a certain uncertainty of control with more stakeholders, especially in neighbourhoods with a high degree of anonymity. The question arises in which way the development can be catalysed.

In order to activate and address possibly interested landlords the project consortium Pocket Mannerhatten developed a certain concept of participation to be multiplied. This concept includes several steps of involvement in interviews, site inspections and workshops containing also a role game in form of a board game to experience or learn about spatial sharing strategies on the basis of a Gründerzeit city block.

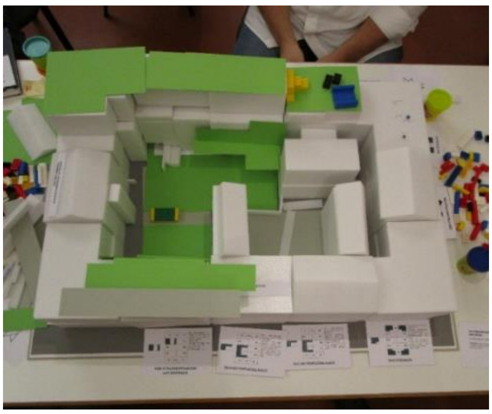

Figure 4. Impressions of a workshop with landlords playing a board game for spatial sharing

5.1.The role of Viennese institutions fostering city renewal processes

Traditionally the Viennese quarter management “Gebietsbetreuung Stadterneuerung” as key element for the gentle way of city renewal had been in charge of fostering different bottom-up city development initiatives and the question would be if this process could be multiplied through this institution. As public institution it is open to all residents and offers professional services of architects, city planners, lawyers and social workers. The local city quarter offices provide consultation and information regarding tenancy and building law, subsidies, refurbishment, initiatives in public space and coordinate participation processes as well [6]. Since the nineties the initial thirteen local offices, each responsible for certain districts, had been reduced continuously. Since January 2018 the remaining eight local city offices had been reduced to five local offices being in charge still for the whole area of the city of Vienna [7]. Against this background of economized, down-scaled public institutions it seems doubtful that existing public institutions such as “Gebietsbetreuung Stadterneuerung” might involve in additional areas of responsibility.

Another -partly public- institution is the non-profit organisation “Wiener Wohnfonds”, which is in charge of the city refurbishment as well and coordinates residents, property developers and city administration units. In contrast to the “Gebietsbetreuung Stadtsanierung” the “Wiener Wohnfonds” executes different funding programs for refurbishment and is less involved in local neighbourhoods. Interestingly these refurbishment funding programs know a across properties coordinated strategy for deconstruction of too densely built building structures as a special case to fund, but not as core strategy differentiate into different possible provisions. Both institutions represent required catalysts for the development: initiative, know-how and financial resources.

5.2. Alternative approaches and concepts for fostering city renewal

The project Pocket Mannerhatten follows two research questions in this context: is it possible to develop a non-profit or social business which complement the services of the “Gebietsbetreuung Stadterneuerung” in order to implement space sharing strategies beyond the pilot project and can there be found alternative resources other than financial one which help to foster the development as well.

The Viennese practice of urban contracts in the field of newly built housing and commercial complexes gives the opportunity to negotiate different special permission and to certain obligations benefiting the public. It is interesting to analyse that not only financial incentives are key to foster urban development, but also incentives which belong to the field of permissions, regulations or other provisions organized by public authorities. For somebody who would like to start a commercial unit it might be more important to be allowed to locate it at a certain place and if it is proved that existing restrictions count also for the individual situations. For somebody who builts housing units it might be interesting to be allowed to built one floor more or balconies facing the street to make a refurbishment attractive and profitable due to rising land prices. For someone who wants to establish a retail unit in a densely built area it might be valuable, if the public space around the unit offers parking lots for customers. For a group of residents who wants to organize electric car sharing it might be interesting to have a public recharging station and so on. For the city council and urban planning this approach would not only amplify possibilities of incentives for developments and let financial resources be spared but establish a steering mechanism as well.

Critical is to find a transparent, just and accredited method to evaluate, rate and assign these alternative incentives as there is no legal foundation or law in Austria which declares to assign certain alternative incentives for space sharing. The project Pocket Mannerhatten assumes that each provision for space sharing generates value or positive impact not only for its single real estate but also for an extended area or group of people. Of course this might differ dipending on the kind, on the scale and duration of provisions.

The ongoing project Pocket Mannerhatten proposes the term “common good potential” to discuss the additional value of linked real estates and space sharing addressing an area and a group of people beyond a single real estate and addressing the most extensive possible consensus what might be the “common good”. The logic of the term implies that not only any provision for space sharing which causes a wider area or group of residents to benefit or any provision which enables a more extensive consensus about the common benefit is ranked higher in a possible evaluation. But it considers the aspect of community itself with all its constraints such as justice and solidarity. It does so by defining how or what is understood as common and to what kind of community it refers, might it be the neighbourhood, the quarter or the whole city. By doing so the process of definition creates community and correspond to the spatial provision of linked buildings fostering interaction and cooperation of residents.

Is it used as basis for assigning incentives or funds this logic would lead to a kind of self-organizing domino-dynamic. The more areas and people participate, the more their provisions orientate towards contributing to the common good, the more intense will be the incentive. It is subject of the ongoing project Pocket Mannerhatten to research and develop a concept how space sharing provisions will be evaluated and opposed to possible incentives. Through different workshops, interviews and negotiations together with stakeholders of the city administration and participating landlords this common good based incentive system should be tested in the course of the project. According to the development of the project Pocket Mannerhatten as pilot project the concept with all its aspects should be integrated into the city renewal strategies of Vienne or multiplied to other cities.

Abstract. In developing countries, such as Brazil, the main destination of municipal solid waste is sanitary landfills. In Life Cycle Assessment (LCA) studies, the entire life cycle of the product or process is considered, therefore it is necessary to take into account the destination of the waste and by-products of the process in question. For a reliable and representative LCA study, these destinations have to be illustrative of the place where the study is conducted in. Regarding the treatment and disposal of organic solid waste, the main LCA databases, such as Ecoinvent 3.0, consider sanitary landfills modelled in European standards, which include processes that are not common in developing countries. In light of this reality, the aim of this study was to model a sanitary landfill that corresponds to the case of the said countries and provide a methodology to improve the significance of environmental studies, which can also be used with primary data. The model used literature data based on Brazilian reality, considering the operation of the landfill (transport and emissions and diesel usage in the spreading of the waste); biogas generation and treatment; leachate generation and treatment using stabilization lagoons and its emissions. When compared to landfill based on European reality, differences up to 80% can be observed in some potential environmental impacts.

1 Introduction

In Brazil, solid waste management is defined according to National Solid Waste Policy, instituted in 2010, which establishes principles, goals and responsibilities in this topic [1]. Among its main points, there is the elimination of open dumps, which is an inadequate waste destination, where there's no control over the type of waste deposited or the generation of byproducts. The utilization of open dumps as a final destination for solid waste leads to high damage to the environment and the surrounding communities.

These irregular dumps were the final destination of 68% of the municipal solid waste (MSW) in 2000 and 49% in 2008 [2]. The law that created the Policy determined that from 2014 the use of open dumps would be prohibited, but the waste from 1.560 municipalities, which represents 28% of the total number, still had the dumps as final destination [3]. Although this movement promoted more sustainable processes such as recycling, it still has low representation in the national waste destination scenario, given that only 32% of all produced recyclables were retrieved in 2017 [3].

Faced with this situation, the reduction in the number of dumps was followed by the increasing in sanitary landfills participation as final destination of the MSW, going from 17% in 2000, to 29% in 2008 and 40% in 2017 [2, 3]. Landfills are a common destination in developing economies and they seek the minimization of environmental impacts through soil waterproofing, construction of drainage and collection systems for biogas and leachate while it also has to have a joint closure plan and use for the area after its service life. These landfills aren't, however, designed to receive only inert waste, but also MSW, which in Brazil has the approximate content of 51% organic matter [2]. The degradation of these residues with high percentage of organic matter in the landfill leads to the production of by-products such as leachate and, above all, biogas, which can be harnessed energetically, although it is still incipient in the country [1].

As a way of comparing possible waste management strategies, there's the Life Cycle Assessment (LCA). This methodology is used for quantification of environmental impacts related to a product of service through the inventory of its used resources, waste generated and emissions in the complete life cycle of the product. The LCA allows the identification of hotspots, scenarios tests and comparison of alternatives, consisting of an important environmental management tool. An critical step of the LCA is the Life Cycle Inventory (LCI), where the inputs and outputs of the analyzed process are identified and quantified. Subsequently, the data present in the LCI will be converted into impact potentials. Therefore, special attention is needed at this stage because it will be determinant for the results and consequently for the conclusions of the study.

In order to consider the complete life cycle of the product or service, it is also necessary to consider the destination of the waste generated, and for this study to be representative, it should be illustrative of the place where the study is conducted. However, the application of LCA to evaluate the environmental performance of solid waste management systems is still elementary in developing countries [4, 5]. Given that the systems presented in studies from developed countries may not be suitable for developing countries [5], mainly because of differences in waste characteristics and because they include steps and processes that are not part of their realities, there is a clear need for more studies on the management of solid waste in the developing world. Currently, the work in this subject is concentrated in Asian countries [6].

The literature review conducted by Ibáñez-Forés *et al.* (2018) identified researches involving solid waste management in Brazil and showed that the vast majority of them didn't national data. Among the studies cited, Mendes *et al*. (2004) and Ibáñez-Forés *et al.* (2018) inventoried sanitary landfills using European data [7, 8]; The work of Reichert *et al*. (2014) also compared waste destinations and the modeled landfill was from a large municipality, where there is energy generation and commercialization from the biogas produced, which would not be applicable to small municipalities [9]; and the work of Leme *et al.* (2004) focused only on the generation and use of landfill biogas, using data from the Intergovernmental Panel on Climate Change [10].

The sanitary landfills available in LCA softwares are not compatible with Brazilian reality either, since processes modeled by the European Life Cycle Database (ELCD) and Ecoinvent 3 follow European standards. In the first one, for example, the considered treatment of leachate is through the use of activated carbon and flocculation techniques, and the second one considers the incineration of the sludge generated in the leachate treatment. None of these methods are representative in the Brazilian scenario and the use of these processes in a LCA study would not lead to a verifiable result.

Given the large number of Brazilian municipalities, 5.570, the number of sanitary landfills, 2.239 [2] and the growing trend of this number given the current national policy, it becomes increasingly necessary to access a landfill model for the implementation of other LCA studies, in order to produce results that are more representative of the country's reality.

Therefore, the goal of this work is the establishment of an emission quantification methodology to be reported in LCA softwares. Based on the characteristics of landfills located in small Brazilian municipalities and the commonly adopted waste management technologies, a life cycle inventory of a sanitary landfill was constructed, capable of better matching the reality of Brazil and other developing countries, to improve the relevance of LCA studies. The modeled process includes the operation of the landfill (transportation, fuel consumption in the disposal and compaction of the waste), degradation of the solid waste, generation and treatment of biogas and leachate. The implantation and decommissioning of the landfill were not considered.

2 Materials and methods

2.1 The LCA methodology

LCA is used to assess potential environmental impacts related to a product or process through the inventory of its resources, wastes and emissions. As a management tool, LCA makes it possible to compare the technical aspects and environmental performances of alternative scenarios, and to identify hotspots as well as opportunities for improvement in the life cycle under study.

As described in ISO 14040 (2006), an LCA study is organized in four stages [11]. The goal and scope definition stage addresses the purpose and scope of the study by establishing the system boundaries. The following items should be described: the goal of the study, the processes included and what basis is to be used, for example, the functional unit. The second stage is the life cycle inventory (LCI), which consists in the identification and quantification of the inputs and outputs of each unit process that takes place within the established system boundaries. In the impact assessment stage, the inventory is converted into environmental indicators for the impact categories that will vary depending on the method used. The final stage includes analysis of the results and assessment of conclusions based on the points mentioned in the definition of the goal and scope.

The present work focuses on presenting the LCI of a sanitary landfill that can be applied to small municipalities in countries under development so they can be used in LCA studies to improve its reliability.

2.2 Methodology for the construction of the Life Cycle Inventory of the sanitary landfill

In this stage, the sanitary landfill was inventoried with the methodology first developed in Gutierrez (2014) [12]. Since Brazil is a country of continental dimensions generalizations were made necessary based on nation-wide data to guarantee its significance. The landfill is equipped with systems to capture and treat the biogas (flairing) and leachate (in a system composed by an anaerobic lagoon followed by a facultative lagoon. A flow diagram of the process is presented in Figure 1.

Literature data focused on landfills for small municipalities was used to calculate the inventory for the processes considered in Figure 1, given that the goal of this study is to provide a general landfill model. However, if primary data is available, the methodology here presented can also be used to estimate the inputs and outputs, which would help to provide a more reliable result in specific situations.

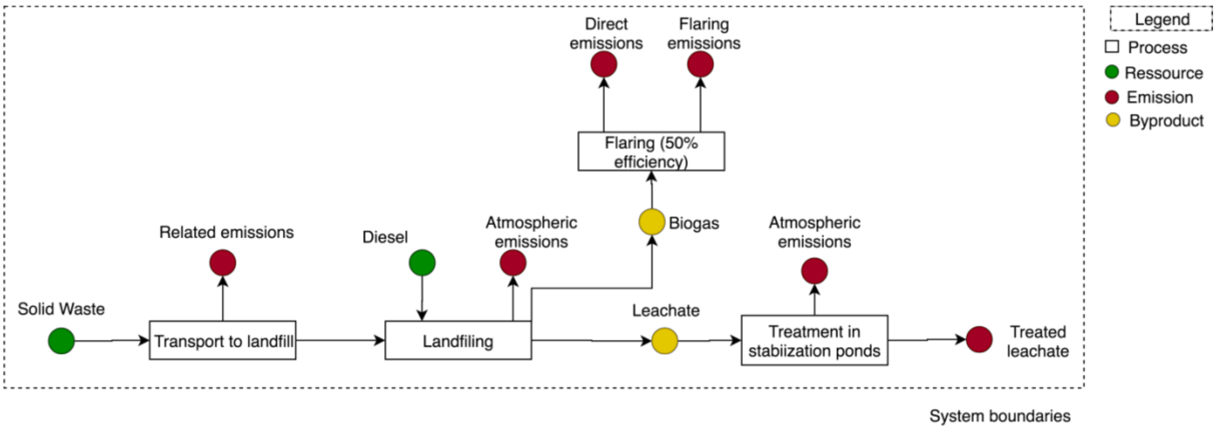

Figure 1: Landfilling flows diagram

2.2.1 Waste transport to landfill

The first stage considered is the waste transportation from the urban center to the landfill. The exclusive use of trucks (3,5 tones of load capacity) and the way-and-back distance was estimated to be 15 kilometers, which was considered to be a reasonable distance for a small municipality. The emissions related to the transport were reported within the software in the unit tkm – that includes the mass transported (in tones) and the distance travelled (in kms)

2.2.2 Waste spreading and compactation

These emissions refer only to the operation of the landfill, specifically to the stages of waste spreading, compacting and covering. The diesel consumption was taken into account according to Rodrigues *et al.* (2008), which measured the average use in a municipality with 25.000 inhabitants and the atmospheric emissions due to the diesel burning in the dump truck and the bulldozers used in the landfilling and covering of the waste [13, 14].

2.2.3 Methane generation

The methane production was calculated according to the degrading of biodegradable matter present in the solid waste. The estimated percentage of organic matter in brazilian MSW is 50% and 60% average moisture content. A 60% destruction of volatile solids (VS) in this MSW during landfilling is stated under a density of 237 $kg.m^{-3}$, following the production of 0,25 m^3 $CH_4.kg$ VS^{-1} [15]. It's then possible to calculate the biogas volume, considering the average methane content of 55% [16].

2.2.4 Direct air emissions

It was considered that 50% of the biogas produced was not captured by the drainage system, therefore released as direct emissions to the atmosphere [17, 18]. The biogas characterization presented in Tchobanoglous *et al.* (1993) was used, as it is in accordance with national experiences [16, 19].

2.2.5 Flaring emissions

A 50% efficiency was also considered for the flaring [20]. The losses were taken into account as methane emissions and the emissions deriving from the burning were based in the emission factors presented in Beylot *et al.* (2013) [21].

2.2.6 Leachate production

The software 'Water surplus for sanitary landfills' provided by the Brazilian National Institute of Meteorology (INMET) was used to estimate the leachate volume produced in small-sized landfills [22]. It was observed that in most simulations the water surplus represented approximately a quarter of local precipitation, so this percentage was used. This rate is also in accordance with the estimations proposed by the Swiss method of leachate prediction, based on the degree of compaction of the waste is its specific weight [23].

A mean annual precipitation of 1.500 mm was considered, disregarding other contributions and losses. The Environmental Company of the State of São Paulo (CETESB) indicates that for small municipalities the construction of the landfill using ditches is acceptable and even advised, so a depth 3 m for the ditches was estimated [24]. Using this data and the waste specific mass of 1,05 $ton.m^{-3}$, the necessary surface for landfilling a ton of waste would be 0,317 m^2. The water surplus of 375 mm (25% of the average precipitation considered) produced 0,375m^2 of leachate for every m^2 of landfill, or 0,119 m^3 of leachate per ton of waste landfilled.

2.2.7 Leachate treatment and emissions

The emissions to water refer to the leachate produced in the landfill after treatment in an Australian lagoon system (composed of an anaerobic lagoon, with a height of five meters and followed by a facultative lagoon, with a height of two meters), which is commonly used in the country. The large amplitude observed in the leachate composition data in national landfills led to the adoption of values related to a real landfill, located in the State of Minas Gerais, aged 1,7 years. A sanitary landfill with an approximate age of two years was considered since it is believed that, under Brazilian climatic conditions, landfills of that age are already close to stabilization in terms of biodegradability [25].

The efficiencies found in the treatment of the treatment ponds indicated values well above those proposed by von Sperling (2014) for the Australian lagoon system [26]. Dias (2012) shows in her research that the water retention time of the leachate in the real landfill was high, arriving, at some times of the year, to a value 15 times greater than the one of design, and discusses that this situation is common in the country [25]. In view of this uncertainty and in search of greater significance for the simulated landfill, it was chosen to follow the efficiencies suggested by von Sperling (2014), for the system which, although originally developed for domestic sewage treatment systems, has been a reference for leachate treatment projects.

The atmospheric emissions from the treatment of leachate were considered according to the International Panel on Climate Change (IPCC, 2006), which reports them in the form of methane emission] These emissions are presented as a function of the BOD removed by the systems (in kg BOD), pond height and maximum methane production capacity for domestic sewage (0,6 kg CH_4 .kg BOD^{-1}).

3 Life Cycle Inventory of the Sanitary Landfill

Table 1 presents the Life Cycle Inventory of the modeled sanitary landfill. The table refers to the landfilling of 1 ton of MSW.

Table 1: Life Cycle Inventory for a sanitary landfill

Process	Input/Output	Parameter	Unit	Value ($t.waste^{-1}$)
Landfill transport	Input	Solid waste	ton	1,00
		Distance	km	15,00
		Transport	tkm	15,00
Landfill operation (spreading/compating)	Input	Solid waste	ton	1,00
		Diesel	kWh	4,32
	Output	Biogas to flaring	ton	75,00
		Biogas as direct emission	ton	75,00
		Leachate	m^3	0,38
		CO - diesel burn	ton	3,59E-06
		NOx - diesel burn	ton	7,78E-06
		Particulate matter - diesel	ton	7,78E-08

		burn		
Biogas direct emissions	Input	Biogas as direct emission	ton	37,50
	Output	CH_4	ton	2,50E-02
		N_2	ton	9,08E-04
		NH_3	ton	2,27E-04
		CO	ton	4,54E-05
		SO_2-	ton	2,27E-04
Biogas flaring	Input	Biogas to flaring	ton	37,50
	Output	CH_4 - leak before flaring	ton	0,01
		NO_x	ton	6,51E-06
		CO	ton	7,60E-06
		Particulate matter	ton	2,45E-06
		SO_x (as SO_2)	ton	8,00E-05
Leachate treatment	Input	Leachate	ton	0,38
	Output	Treated leachate	ton	0,38
		CH_4 leak	ton	1,37E-05
		BOD	ton	3,82E-05
		COD	ton	9,12E-05
		TSS	ton	1,77E-05
		N-NH_3	ton	2,02E-05
		N-org	ton	1,50E-06
		P	ton	6,19E-07

4 Discussions

The inventory in Table 1 was inserted in the software SimaPro and analyzed using the ReCiPe 2016 method. The impact categories were chosen based on which ones would better demonstrate the processes involved in landfilling, such as diesel usage, transportation, emissions to air and water. Finally, the chosen categories were global warming, fine particulate matter formation, terrestrial acidification, freshwater eutrophication, and terrestrial and freshwater ecotoxicity. The results are presented in Figure 2.

As it can be seen in the graphs, the biogas leaks represent most of the impacts related to air emissions. The transport is responsible for the vast majority of the impacts related to ecotoxicity. which can be related to distance in which landfills are usually located. The potential impacts in eutrophication are mainly caused by the leachate treatment.

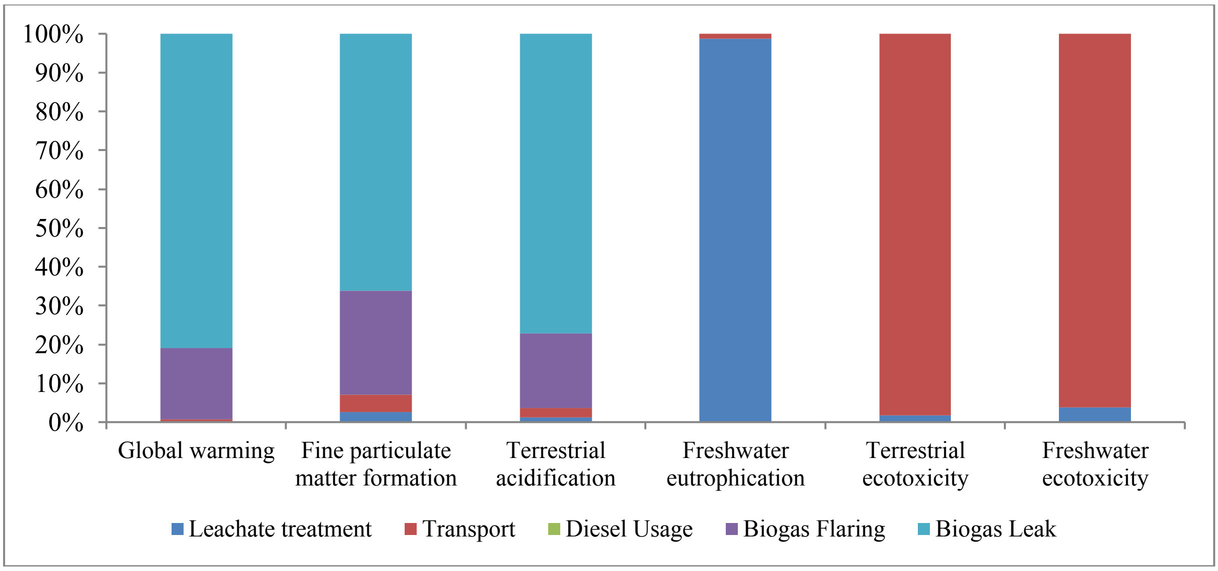

Figure 2: Sanitary Landfill analysis

Figure 2 presents the comparison of the modeled landfill with the one present in Ecoinvent v3 (*Municipal solid waste {RoW}| treatment of, sanitary landfill | APOS, U*). According to the information available on the database, the process considers the technology available in Switzerland in 2000 and includes short-term emissions to air via landfill gas incineration and landfill leachate; burdens from treatment of short-term leachate in wastewater treatment plant, including WWTP sludge disposal in municipal incinerator; and long-term emissions from landfill to groundwater after base lining failure [28].

The differences between the potential impacts of the two processes are visible in the graphs. The destination of the by-products, especially of the sludge, is a big difference between the models. According to the studies of Dias (2013), the Australian lagoons system design, initially intended for the treatment of domestic sewage, function mainly as an evaporation tank, with no sludge production in the bottom of the lagoon [25]. Sludge treatment, therefore, was not considered.

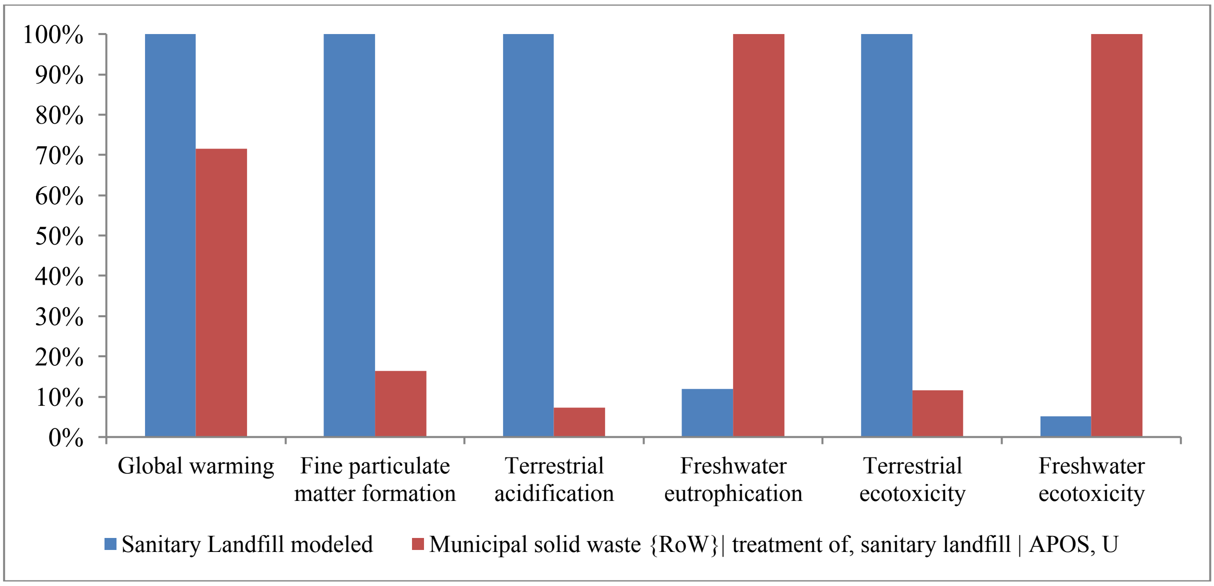

Figure 3: Comparison between the landfill modelled and one available in Ecoinvent 3

5 Conclusion

This work presented a model of a sanitary landfill that would correspond better to the reality of developing countries, especially in Latin America, aiming to improve the reliability of LCA studies. The life cycle inventory is based on average Brazilian data and literature data concerning the processes considered, focused on sanitary landfills for small municipalities. The methodology is adaptable to specific cases and can also be used with primary data to estimate emissions and environmental impacts.

When compared to a landfill available in the LCA database Ecoinvent v.3, based on European data, differences between the two could be observed. Regarding, fine particulate matter formation, terrestrial acidification, eutrophication and terrestrial and freshwater ecotoxicities, the difference in potential environmental impacts was greater than 80%. As for global warming, the difference was around 30%. These observations illustrate disparities between waste management technologies and how the usage of either systems can shift the conclusions of an environmental study, reaffirming the need of a representative model to estimate the environmental impacts of such technologies.

6 Recommendations

- Collection and use of primary data over literature data to improve the significance of the model.
- The consideration of leachate leaks to groundwater and soil.
- Obtaining regionalized data for the study site.

Bike Model District “Alte Neustadt” in Bremen

Dietz J, Hoppe M, Kollmann S, Mansfeld U

School of Architecture Bremen, City University of Applied Sciences,
Neustadtswall 30, 28199 Bremen, Germany

justus.dietz@hs-bremen.de

Abstract. How to transform existing urban structures into zero emission cities by 2050 - especially if money is rare? The School of Architecture Bremen (SoAB) at the City’s University of Applied Science have initiated an innovative and collaborative project for the further development of the university’s neighbourhood, the “Alte Neustadt”. SoAB participated in the national climate protection by bicycle traffic competition and was granted funding for the transformation of the district into Germany’s first bicycle zone. In cooperation with the city district, NGO's, cultural institutions, and other neighbourhood organisations, a network of bicycle streets in connection with new bicycle highways will be installed. By 2020 comprehensive new bicycle parking areas will be finished, as well as new cyclist and pedestrian friendly crossings over the main roads. The campus’ main street will be transformed into an “Open Campus” for the university and the neighbourhood. A multifunctional “Bike Repair Café” with cargo bike sharing and bike rental facilities will enhance the district’s transformation even further, thus creating a space to reflect environmental problems to be solved. The bike model district “Alte Neustadt“ is just a small step in the right direction, but a huge improvement of the district’s quality of life.

1. Introduction

Bremen was among the first cities in Germany to establish own cycle paths (Froitzheim & Lüers, 1988). The idea of bicycle boulevards – roads on which cyclists have the right of way – found its origin here and spread all over Germany.

Today, the people of Bremen use their bikes for one in four journeys. This means that the proportion of journeys made by bicycle in Bremen is well above the average of comparable cities such as Dresden, Dusseldorf, Frankfurt am Main and Leipzig (SUBV, 2013). Looking at the top ten list of bicycle friendly cities 2017, however, Copenhagen, Utrecht and Amsterdam lead the list, whereas Bremen is not even mentioned. A recently carried out study by the German Cyclists' Federation (ADFC) illustrates the German bicycle dilemma: Bremen is rated as the most bicycle friendly German City, compared to other Cities with an equivalent number of inhabitants (ADFC, 2018). Rated according to the German school grading system Bremen reaches a 3,5, which means something between “satisfying” and “enough”, far away from “excellent” or just “good”.

Things, however, are starting to change: in 2016, one of Bremen’s central districts “Alte Neustadt”, applied for funding to become Germany’s first bike model district on an initiative by the School of Architecture Bremen (SoAB). The application was supported by the municipality, NGO's such as the General German Bicycle Association, cultural institutions e.g. the local swimming pool, and other neighbourhood organisations.

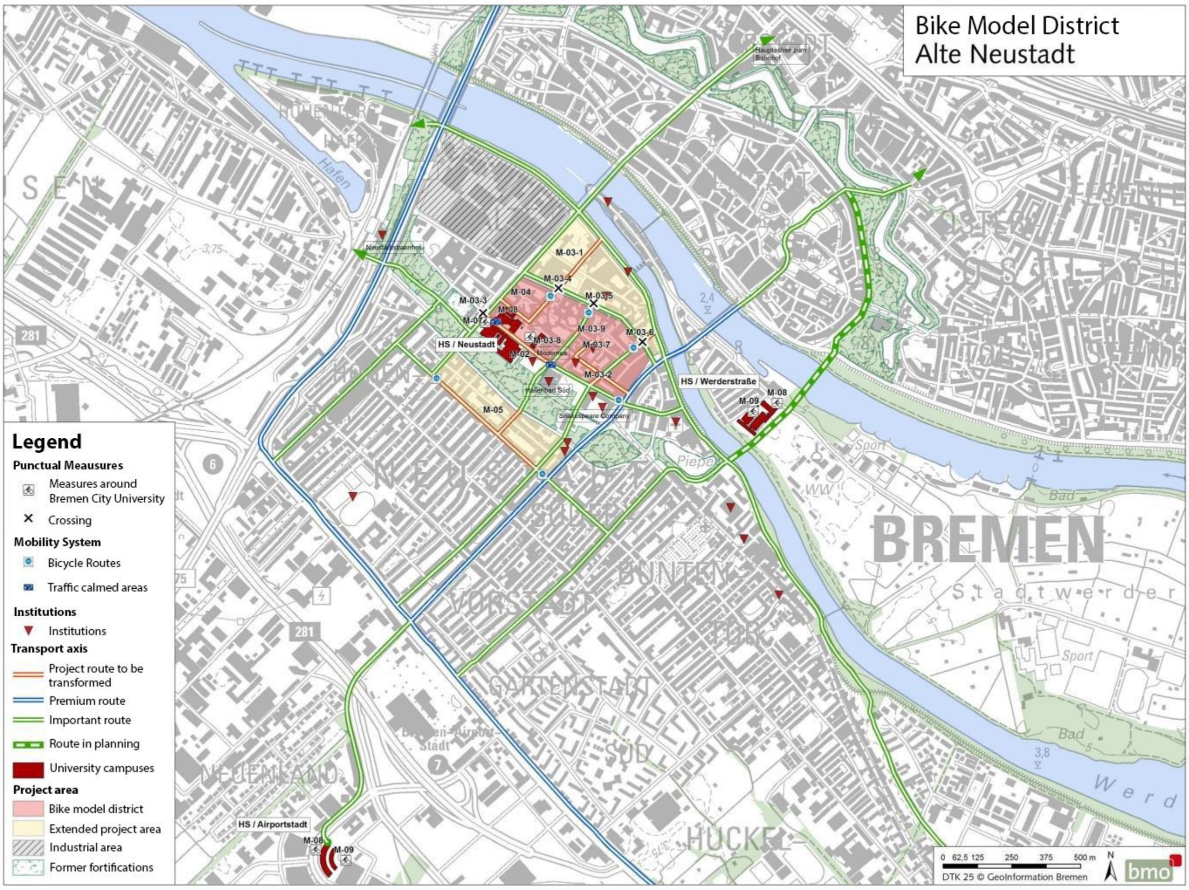

Figure 1 Bike-Model-District “Alte Neustadt” Bremen

2. Bike Model District “Alte Neustadt”

2.1. Objectives of the Bike Model District

The transformation of “Alte Neustadt” (Figure 1) into a bicycle zone aims to bring improvements not just for cyclists, but for all road users and residents by offering a coherent network of bicycle lanes, parking facilities, uniform signage and other facilities in order to make cycling the preferred mode of transport.

2.2. Ten Measures to be taken

In order to achieve equal mobile coexistence of the different traffic and interest groups in the district the following individual urbanistic and structural measures have recently been realized, constituting the new bike-model-district:

- *Bump-free Cycling*

Bumpy cobblestone streets get a paved strip or are completely redeveloped. Driving becomes quieter, safer and more comfortable for everyone.

- *Bicycle Boulevards*

Within the bike model district, a network of bicycle lanes becomes a cycling zone where bicycles are given priority over motorized private transport. Cyclists are allowed to cycle side by side, the general speed limit is 30 km/h, and car parking is clearly marked.

- *Network of Premium Bicycle Routes*

Bremen's traffic development plan for 2025 suggests several premium cycling routes within the city area These will connect the city districts over long distances, making them more attractive for cycling. The "Alte Neustadt" will be well connected to this premium route network, motivating especially students to come to university by bike (Figure 2).

- *More space and safety due to pavement enlargements*

Sidewalk enlargements at intersections and junctions and intersections make crossing safer for everybody, especially for younger children or slower people, by providing a better overview. At the same time, they keep the junctions free for larger vehicles of the fire brigade, refuse collection and delivery traffic (Figure 3).

- *Safe and Easy Crossing of Main Roads*

The crossing of the main roads on the edge of the bicycle zone will be facilitated for pedestrians and cyclists by measures such as pedestrian refuge islands, traffic signals and speed limits.

- *Bicycle Parking*

In the residential streets new bicycle parking facilities provide safe parking. At the City University's 3 campuses easily accessible and partly covered bicycle parking spaces will be created. In total, over 600 secure bicycle parking facilities will be installed.

- *Bicycle Repair Café*

A bicycle repair café will be built on the City University's Neustadtswall Campus. Housing a serviced workshop, a café, and space for small events, it will be the highlight of the bike model district. Addressing not only the students, but all interested people and cyclists, it connects the university campus with the neighbourhood (see 0for more detail).

- *Remodelling Neustadtswall Campus*

The main connection between the different university buildings, Neustadtswall, will be the centre of a redesigned campus. A raised road surface, the renovation of the sidewalks and a traffic-calmed area ensure an accessible and pleasant environment for more than 10,000 students and employees.

- *Rental Stations for Bicycles and Cargo Bicycles*

All three university campuses will be provided with rental bike stations that are connected to a city-wide rental bike network. The bikes, along with cargo bikes available at the Bicycle Repair Café, can be rented by everybody.

- *Air Pump and E-Bike Charging Stations*

Air pumps and e-bike charging stations will be built at all three university campuses, integrated into the covered bicycle parking facilities.

Figure 2 Network of Premium Bicycle Routes

Figure 3 pavements enlargements at crossings

This bundle of measures is expected to increase the percentage of students and university staff that come by bike every day as cycling will be far safer and thus more attractive in the future. Especially the cargo bikes provided at the Bicycle Repair Café will help to reduce the number of journeys usually carried out by cars, e.g. when students need to buy beverages for the next campus party.

3. The Bicycle Repair Café at Neustadtswall Campus

3.1. Intention

The heart of the Bike-Model-District will be the new Bicycle Repair Café at the City University of Applied Sciences' Neustadtswall campus. It will be completed by summer 2019. It will primarily serve as a meeting point for cyclists, not only for the university itself, but the surrounding neighbourhood as well. Visitors will find professional assistance for minor bicycle repairs. In addition, the Bicycle Repair Café will serve as a place for research and teaching, as well as an object of investigation for sustainable architectural concepts.

3.2. Design and construction principles

The building's design and construction reflect the ideas of sustainable building, especially in its geometry, structure and the choice of construction materials. The gross floor area of the wooden structure will be approximately 140 square metres. A compact building core containing ancillary and technical rooms divides the building into a café and a workshop area. Both areas can also be used as event rooms. The characteristic structural elements are the funnel-shaped wooden roof, made of prefabricated BSP-elements, as well as the transparent facades, which ensure a high degree of connection to the outside space.

3.3. Historical context

Situated in front of the university's historic main building (Figure 4), the historical context also had to be taken into account for the building's design. Since the neighbouring buildings are under a so-called "ensemble protection", the city's highest monument authority along with the city's design advisory

Figure 4 Situation of the new bicycle repair café in front of the university's historic main building

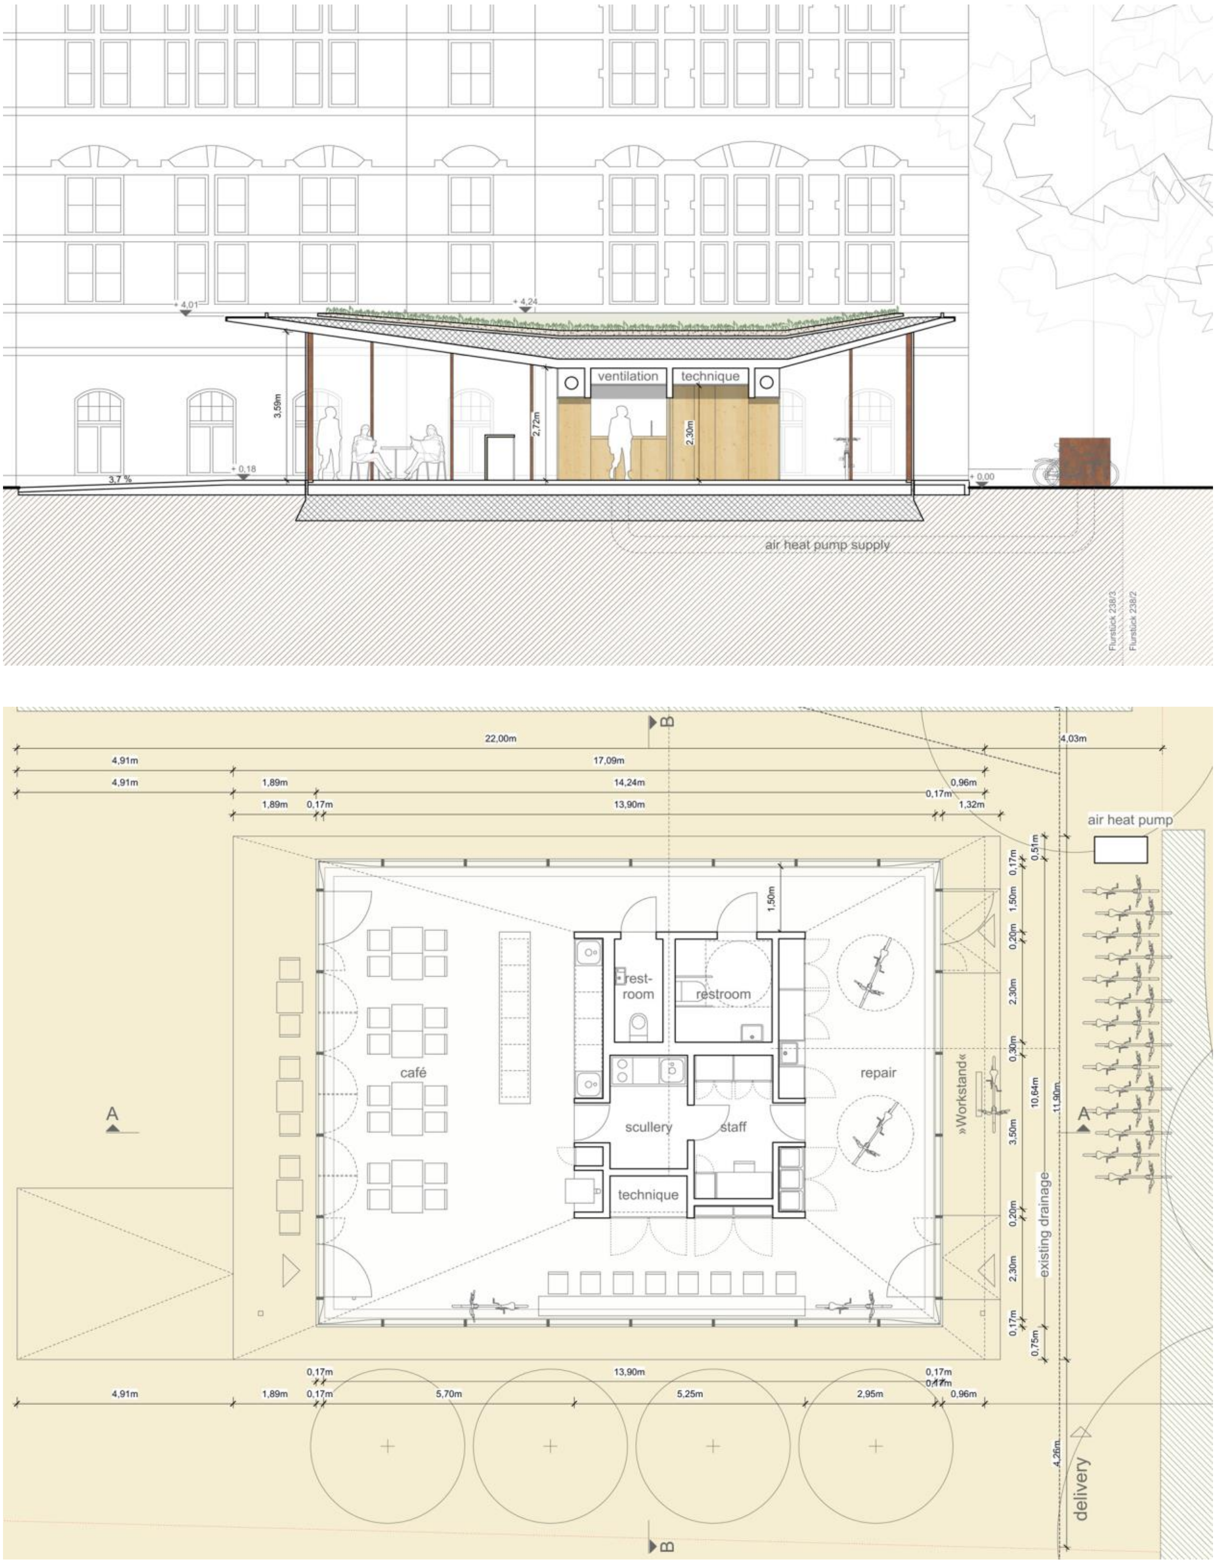

Figure 5 Section (above) and floorplan (below) showing the technical and structural core of the building, defining the usage areas

board were involved in the whole process. This means that monument protection and cityscape/urban planning requirements always had to be weighed against the requirements for an energy-optimized building.

The preservation of the trees on the forecourt of the listed main building was mandatory and maximum of transparency was desired. This stands in contrast to an energy-optimized building, because in summer too much energy is expected from direct solar radiation and in winter too much heat loss is expected from large glass areas. However, a careful analysis of the location, including detailed shadow studies for example, allowed both concerns to be combined and taken into account in the planning. In summer, large parts of the building are shaded by the neighbouring buildings and the existing trees. A further contribution to the shading of the north-west façade is made by the preserved ornamental apple trees.

3.4. Sustainability Concept

The overall intention is to reduce CO_2 emissions over the whole life cycle of the building, wherever possible. In addition to using materials from renewable resources or recyclable materials and an ambitious energy concept (3.4.2), the folding roof geometry also contributes to the sustainability of the building. It allows to use slimmer material cross-sections and thus saves material.

Furthermore, the Bicycle Repair Café will serve as a meeting point for students, university staff and neighbouring residents, opening up the campus to its neighbourhood, thus contributing also to the social aspects of sustainability.

3.4.1. Building envelope

The building envelope meets passive house standards (Ψ < 0,01 W/(m²K), n50< 0,6/h). The four facades are fully glazed with three-pane safety glass (U < 0,6 W/(m²K), g < 0,4). The facade columns behind them are made of untreated tubular steel and are therefore easy to recycle. The wooden roof construction is designed as a warm roof construction (U < 0,1 W/(m²K)) and carries a retention roof that regulates the climate both in the urban space and in the building. In summer it protects the building from strong heat input via the roof and in heavy rain it relieves the public sewerage network by absorbing part of the rainwater.

Table 1 Estimated U-values of building envelope

building component	U-value
opaque walls	0,1 W/(m²K)
transparent walls	0,6 W/(m²K)
doors	0,8 W/(m²K)
roof	0,1 W/(m²K)
Floor plate	0,15 W/(m²K)

3.4.2. Energy concept

The main idea behind the energy supply is to ensure that as little CO_2 as possible is emitted as a result of the energy requirements of the Bicycle Repair Café for heating, cooling, ventilation and hot water as well as for general electricity. The building is not regarded as an autonomous unit, but as part of a regional overall energy system. The energy supply is adapted to the

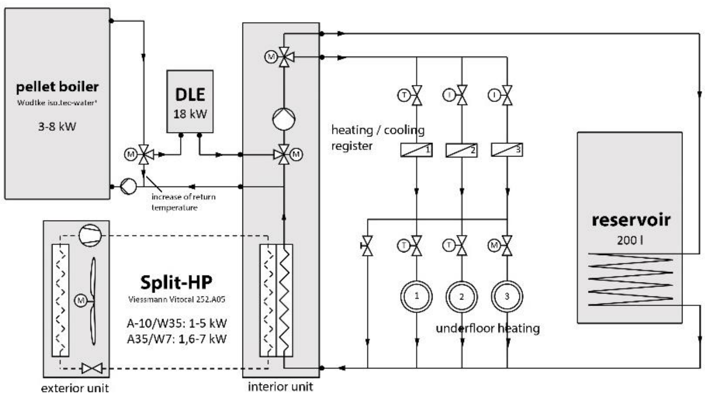

Figure 6 Hydraulic scheme

changing boundary conditions of the energy turnaround and takes into account the economic efficiency.

The energy concept pursued here for the Bicycle Repair Café is deliberately not based on current building definitions such as zero-energy or plus-energy house. These definitions allow an energy or CO_2 credit of the regenerative electricity generated at the building with its energy demand or CO_2 emissions in winter.

The Bicycle Repair Café is to be operated only from regionally available regenerative electricity. Heating and cooling are provided by an electric air heat pump. If there is a surplus of energy, this is stored in two battery memories and returned to the system when required. If no regenerative energy or stored energy is available, the pellet stove connected to the system is activated (Figure 6).

3.4.3. Materiality

For all components, two design variants will be compared before the execution, on basis of a life-cycle assessment, focussing in the primary energy demand (PE renewable, non-renewable) and CO_2 emissions.

Special attention is paid to the use of renewable raw materials. If the use of materials from non-renewable raw materials is necessary, easily recyclable materials or materials from recycled raw materials are used. Accordingly, the main construction is made of wood (BSP). The facade construction is made of untreated steel and is therefore easy to recycle. In general, composite materials are not used in order to ensure that recycling is as complete as possible. Foam glass is used for insulation materials, vacuum insulation panels in special situations, when thin, efficient insulation is necessary.

4. Expectations

The project is supported by various departments of City University of Applied Sciences Bremen. Several institutions contribute their individual expertise in the fields of climate-friendly architecture, building services engineering, building automation, structural design, etc. to the building development.

Table 2 Planning Team

	Institution
Justus Dietz Michaela Hoppe Steffi Kollmann Ingo Lütkemeyer Ulrike Mansfeld	School of Architecture Bremen, City University of Applied Sciences Bremen
Prof. Rolf Strauß	Nature and Engineering, Department of Mechanical Engineering, City University of Applied Sciences Bremen
Prof. Martin Speth	School of Architecture Bremen, City University of Applied Sciences Bremen / Drewes + Speth Engineers, Hannover

This involvement of several university teachers in the design and planning process ensures the integration of the experimental building into future teaching and research. Students will be involved in the post occupancy evaluation, e.g. recording the thermal behaviour of the building or mapping the resulting energy demand. The building will serve as a case study for life cycle assessments. Due to the easy accessibility of the technical components these can serve as practical examples for architecture and engineering students. Being open to the public, the building will also contribute to a better distribution of scientific outcomes to the public.

Climate-resilient urban planning and architecture with GREENPASS illustrated by the case study 'FLAIR in the City' in Vienna

Kraus F, Scharf B

GREENPASS GmbH, Vienna, Austria

florian.kraus@greenpass.at

Abstract. Urban growth and climate change are 2 of the main challenges worldwide [20]. Cities are growing rapidly while average temperatures are rising, and extreme weather conditions, as heavy rain events, are becoming more frequently. Soon 4 out of 5 EU citizens are living in cities [6]. The results are increasing costs for health expenses and infrastructure damages. Urban planning processes have to consider future climate conditions and the impact on people, buildings and the urban environment. Until today there was no simple solution to measure and calculate the climate impacts of urban developments. GREENPASS® is a technological breakthrough, the world's first software-based technology for climate-resilient and resource-efficient urban development. After 9 years of scientific research and development the technology can easily be used by urban planners as architects and be integrated into existing urban planning workflows and processes.

With GREENPASS® the impact of buildings, materials and plants on urban climate become measurable and comparable in a standardized way – powered by ENVI-met®. It supports optimization of investments towards effects of Green Infrastructure (trees, green roofs and walls, ...) such as cooling, thermal comfort, water retention and carbon sequestration. GREENPASS® allows to identify the optimal solution for any urban development. Supported projects receive finally a GREENPASS® certificate on their overall performance. The technology has already been applied successfully for more than 25 projects within Austria and Europe [3] and will be explained more in detail using the case study of 'FLAIR in the City' - the world's first GREENPASS® Gold-certified residential building, located in Vienna/Austria.

1. Background

Urban growth and climate change are 2 of the main challenges worldwide [20]. Cities are growing rapidly while average temperatures are rising. Along with climate change not only heat waves occur more frequently, but also heavy rain events that may cause pluvial flooding. Soon 4 out of 5 EU citizens are living in cities [6].

The results are increasing costs for health expenses and infrastructure damages. Urban planning processes have to consider future climate conditions and the impact on people, buildings and the urban environment. Green Infrastructure is accepted as one key measure of urban climate change adaptation and improvement of urban climate resilience. This has been acknowledged by many official entities as the UN, IPCC, IUCN, EEA, EC, national and regional governments and authorities [1][5][7][13][15][19].

While all the named guidelines and recommendations are of high value, they remain generic and conceptual. Planning processes request detailed information of benefits and costs of green infrastructure to allow decision making.

2. GREENPASS® technology

The GREENPASS® technology is the worldwide first software-based technology for climate resilient and resource-efficient urban planning and architecture. It has been developed in the last 9 years within international R&D projects with more than € 4. Mio of funding [7][8][14][15].

The GREENPASS® technology consists of the GREENPASS® Toolbox, GREENPASS® Software and GREENPASS® certification and includes ENVI-met® microclimate simulation for climatic inputs within the planning-, evaluation- and optimization process [10][11][17][18].

2.1. GREENPASS® toolbox

An international review of planning processes [7] revealed that worldwide, planning processes follow a standardized pattern, starting with preliminary design, followed by concept design and detailed design. To every phase of the planning process different resources (personnel and budget) are allocated.

The GREENPASS® toolbox (see **Figure 1**) accounts for that and provides tailored services for every phase of the described planning process in accordance with the given resources and budget [10]:

- Assessment for preliminary design phase (01): low detail grade and low resources available (budget and time)
- Pre-certification for concept design phase (02): low detail grade and moderate resources available (budget and time)
- Certification for detailed design phase (03): high detail grade and high resources available (budget and time)

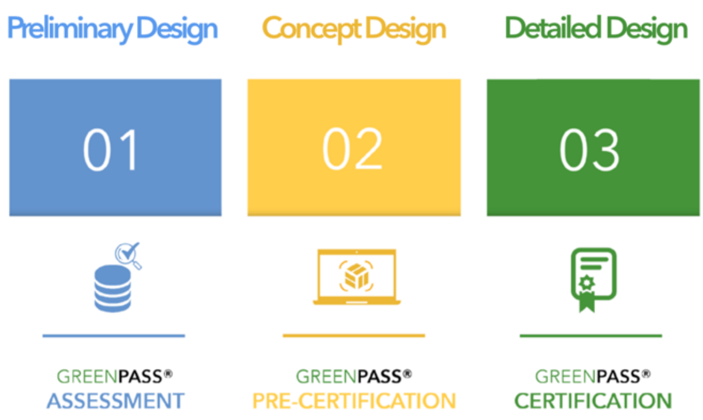

Figure 1. *GREENPASS® Toolbox delivers the tailored tool for the respective planning process phase for a worldwide application*

2.2. GREENPASS® Editor

The GREENPASS® Editor is an independent GIS-based software and the crucial interface between scientific world of microclimate simulation and practical planning world. Common planning data, like CAD (.dxf) or GIS (.shp), can be imported to the software in a straight and easy way. The planning project can then be edited within the software, e.g. assigning materials from a comprehensive data base (linked with ENVI-met®) to project elements, adding green infrastructures etc. The software finally automatically transforms the modelled data to a digital simulation model in ENVI-met® compatible data file format (.inx) [8].

2.3. GREENPASS® Certification

The GREENPASS® Certification is an ongoing optimization process with the aim to deliver the best results on climate resilience and return on investment. To that end it is comparable to many other fields of planning in the detailed design phase. The final design of the project is rewarded an official certificate.

The certification system is based on existing building certification systems like, DGNB, LEED or BREEAM. The comprehensive set of in total up to 28 certification indicators allow to analyse each project and progressively optimize it with regard to three overarching topics: climate resilience, water management and costs. The analyses provide detailed information on exemplary the effects of building structures, greenery elements and surface materials on the thermal comfort, the wind flow, water run-off, CO_2 sequestration, cooling degree hours, air temperature, water demand, and many more. And relates these to installation and maintenance costs for green and blue infrastructure [10][17].

Additionally, to the project plans, three standardized and rule-based reference scenarios are applied and simulated within the certification frame. The reference scenarios are based on the actual architectural planning inclusive landscape design, changing the materials and implementation of green infrastructures as follows:

- Worst case scenario: e.g. 100 % sealed with asphalt
- Moderate greened scenario: e.g. 50 % of flat roofs - extensive green roof, façade greenery with focus on S exposition, 50 % unsealing of private roads, sidewalks, parking lot, additional trees
- Maximum greened scenario: e.g. 50 % of flat and inclined roofs - intensive green roof, façade greenery with focus on S, W and E exposition, 100 % unsealing of private roads, sidewalks, parking lot, additional trees

These scenarios subsequently form the framework for the certification evaluation and support the optimization process. The official GREENPASS® certificate is a planning certificate and available in: Platinum, Gold, Silver and Certified (see **Figure 2**). Two years after completion of the building construction, the evaluated measures will be controlled by a reviser for quality management purposes, if they got implemented correctly and flourishing well. Otherwise, a re-certification will be offered or in worst case the certification will be officially revoked.

Figure 2. *Official GREENPASS® certification for building projects, districts and entire cities*

3. Case Study – 'FLAIR in the City'

'FLAIR in the City' is a residential building project with a size of app. 0.6 ha, located in the south of Vienna in 'Atzgersdorf'. The building plot is part of the 'Carré Atzgersdorf' masterplan for an app. 7 ha large integrative urban development area in the 23rd district of Vienna and aims to be the first realized building plot of the ensemble with 133 apartments [12]. The plot shapes the southern part of the masterplan area and is located adjacent to the public ‘Bruno-Morpurgo-Park’ in the south of the area, which also brings climatically benefits for the building plot (see **Figure 3**).

Figure 3. *Localization of the GREENPASS® case study ‘FLAIR in the City’ in the south of Vienna*

The co-creative multi-year development process inclusive public participation started 2014 with the zoning map. 2015 ‘FLAIR’ developer provided the building plot for an urban gardening initiative, called ‘Freiluftsupermarkt’, as temporary use. The GREENPASS® certification was applied in the detail planning phase in December 2015, in cooperation with ‘FLAIR’ developer and the Municipality Department of Vienna for Environmental Protection (MA22). The progressive planning and optimization process together with the developer and architectural team was finalized in September 2016. The ground-breaking ceremony took place in August 2018, while the building project is actual still under construction and will be finalized expected in 2020 (see **Figure 4**).

Figure 4. *‘FLAIR in the City’ planning and construction process timeline*

3.1. Data processing

For the generation of a digital simulation model for microclimate simulation, respective data is needed. Beside an architectural model (see **Figure 5**), the team from “uma architects” provided the data in .dwg and .pdf formats. The plans were edited in the respective data layer structure with containing information’s, based on GREENPASS® data specifications.

Figure 5. Architectural model of the draft version of the residential building complex 'FLAIR in the City' in concept design phase from 'uma architects'

Based on the project plans the rule-based reference scenarios have been elaborated. For every scenario a digital simulation model with a horizontal cell resolution of 2 m was generated (see **Figure 7**). The models have a size of 150 x 300 m inclusive surrounding buildings and park adjacent to the building plot.

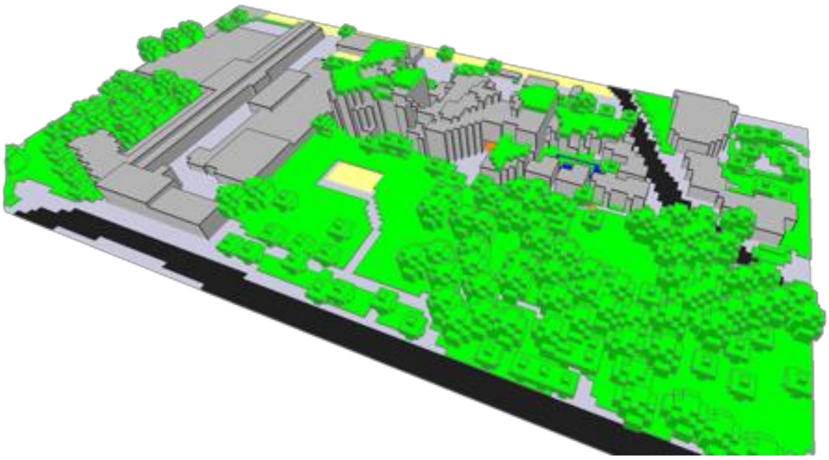

Figure 6. Digital simulation model for ENVI-met®, based on the architecture draft version inclusive surroundings: Scenario Planning

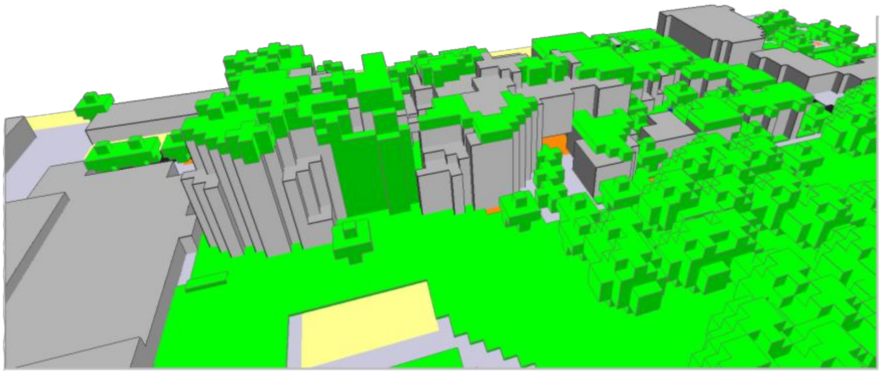

Figure 7. Digital simulation model for ENVI-met®, based on the architecture draft version inclusive surroundings: Scenario Planning optimized

3.2. *GREENPASS® results*

The microclimate simulation input is generated by ENVI-met® [1][19], one of the worldwide most famous and validated software for microclimate simulations. The following figures show exemplary results of the evaluation and optimization process for 'FLAIR in the City' – in form of the Key Performance Indicator (KPI) - Thermal Performance (PET).

- KPI - Thermal Performance - PET (physiological equivalent temperature) on 21st July at 3 pm and 1.8m height for scenario planning and planning optimized (see **Figure 8** and **Figure 9**)

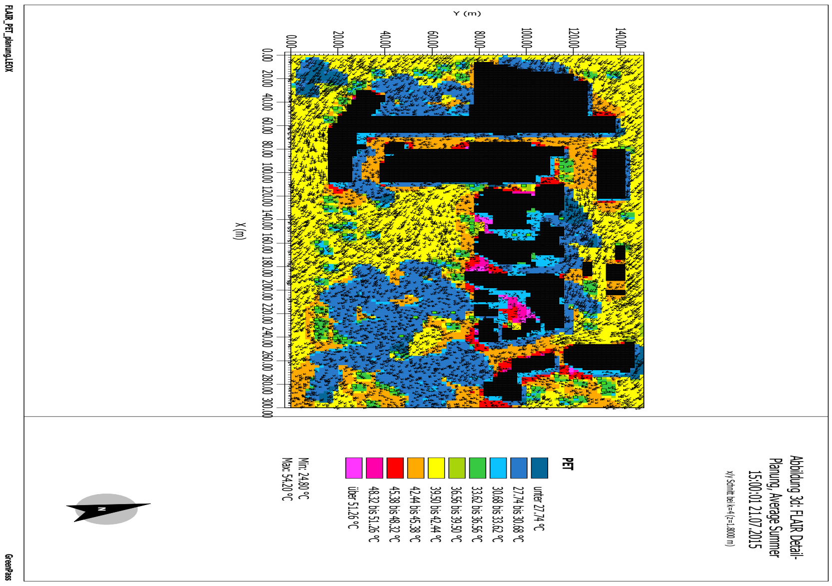

Figure 8. GREENPASS® KPI - Thermal Performance (PET) for 'FLAIR in the City' on a hot summer day (21st July) at 3pm and 1.8m height - for the scenario planning

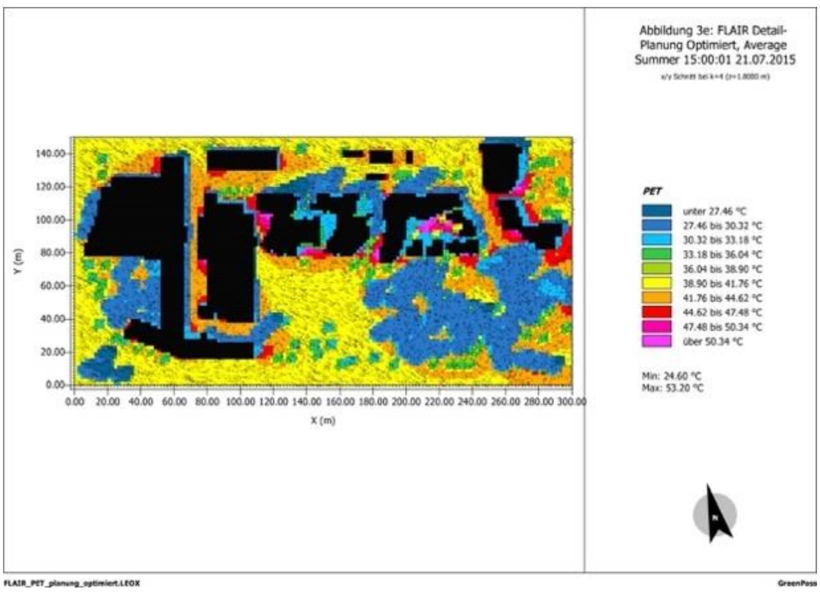

Figure 9. GREENPASS® KPI - Thermal Performance (PET) for 'FLAIR in the City' on a hot summer day (21st July) at 3pm and 1.8m height - for the scenario planning optimized

3.3. *Optimization process*

The project optimization was performed in close cooperation with the architectural team and the developer in an iterative process. **Figure 7** shows the design amendments via Green Infrastructure leading to an improved thermal comfort (PET) as well as Thermal Comfort Score for the optimized planning, in comparison to the former planning scenario (see **Figure 10** and **Figure 11**).

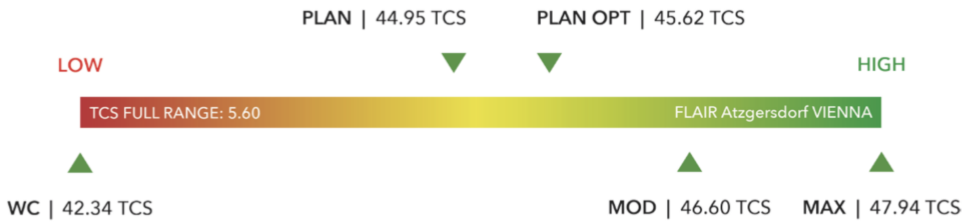

Figure 10. GREENPASS® TCS bar for different scenarios of 'FLAIR in the City'showing the performance ratio

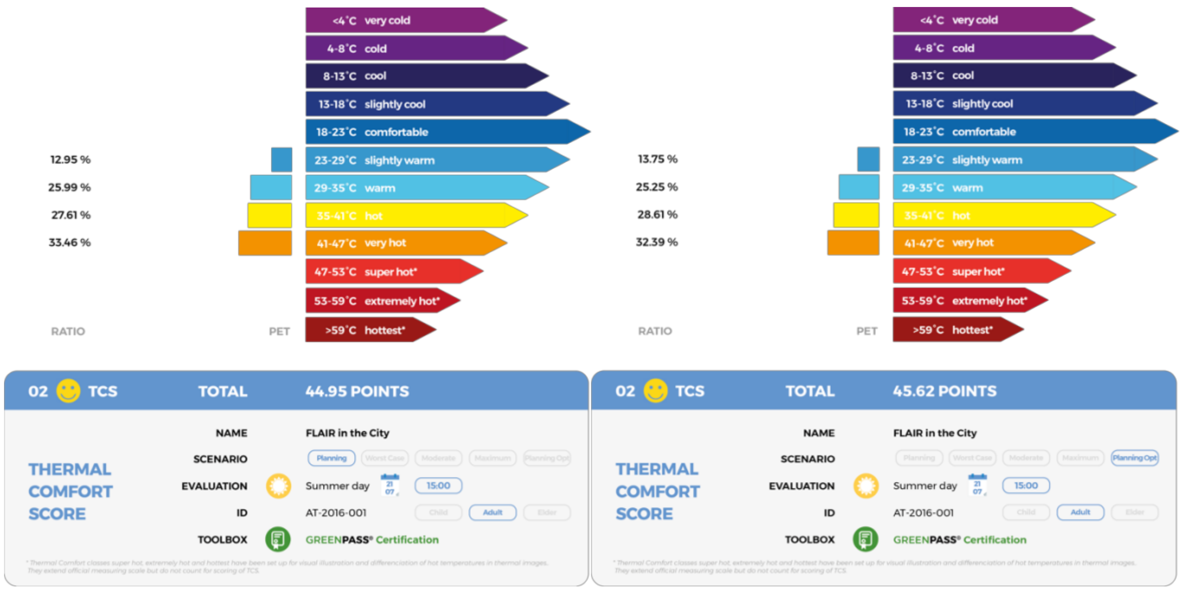

Figure 11. GREENPASS® KPI - TCS – Thermal Comfort Score for 'FLAIR in the City' Planning and Planning optimized

3.4. *Certification results*

The overall results of the GREENPASS® certification show that the planning area has been optimized with regard to climate resilience and the use of green and blue infrastructure and their multiple effects. A cost/benefit analysis enabled the most cost-efficient and resource-efficient solution to be found. The original 'FLAIR in the City' planning design had the performance of a total degree of fulfillment of 67 % (see **Figure 12**).

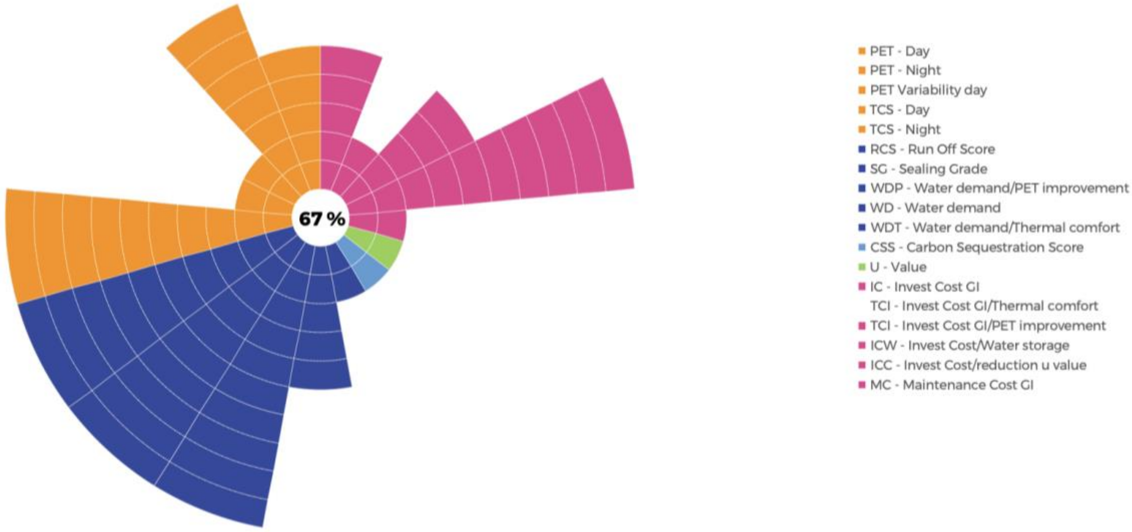

Figure 12. GREENPASS® Assessment Flower - 'FLAIR in the City' Planning – 67 % total degree of fulfilment

The optimized planning for 'FLAIR in the City' reaches with 79 % total degree of fulfillment finally the worldwide first GREENPASS® Gold certificate. The results are presented in form of a comprehensive and detailed report (app. 100+ pages) and summarized in a project factsheet including project details, evaluation results and performance facts. The results per indicator and urban challenge are further shown in form of an assessment flower graphic (see **Figure 13**).

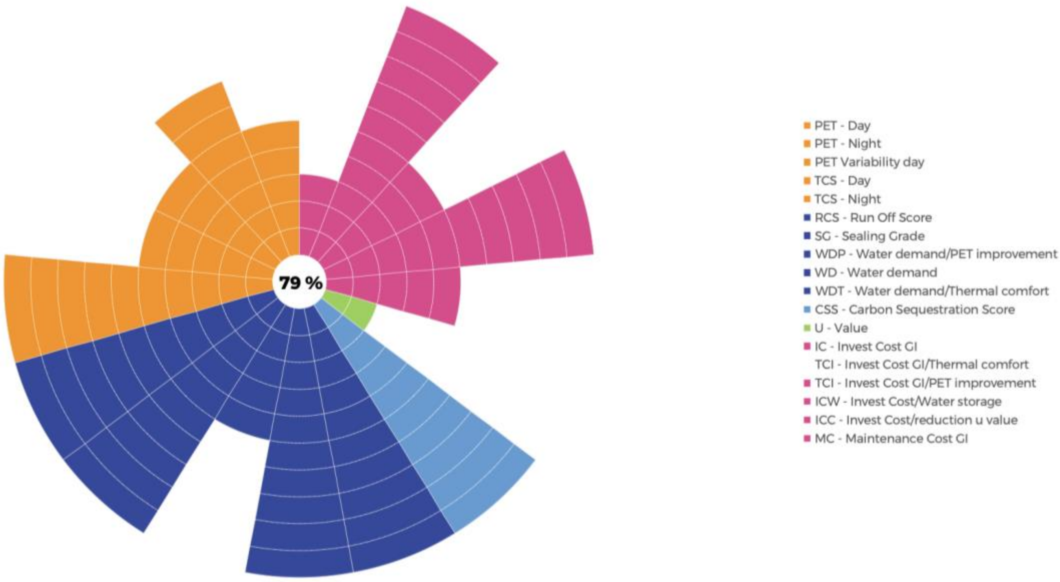

Figure 13. GREENPASS® Assessment Flower - 'FLAIR in the City' Planning optimized – 79% total degree of fulfilment

The performance facts show e.g., that the planned actions have a cooling performance of up to 1°C air temperature and 10°C PET (see **Figure 14**). Regarding the average run-off coefficient, 'FLAIR in the city' performs with an average of 0.2 again very well. For the performance, the plants have a need of 1.312 m^3 of water by same time saving 274 m^3 of water recurrently, depending on the intensity of rain fall events. And many more (see **Figure 14**).

Figure 14. GREENPASS® facts – 'FLAIR in the City' – 1st GREENPASS® Gold certified project

4. Discussion

For an effective climate change adaption of urban areas, the optimization of urban development projects is nowadays crucial. Therefore, every single urban development project should consider microclimate and urban climate related aspects, to optimize the quality of life for residents and citizens.

GREENPASS® has been successfully used for optimization purpose to improve the planning regarding climate-resilience, water retention and cost. A typical microclimate simulation provides only thermal maps (e.g. PET, PMV, UTCI, AT, …) and wind flow information. An optional evaluation of planning projects remains only on a descriptive level. A comparison of different designs and actions, as well as the interpretation and understanding of results is hardly possible and limited to urban climate experts.

Compared to classic microclimate simulations, GREENPASS® additionally delivers now a decision support for urban development planning and architecture, due to a standardized certification process, sophisticated Key performance indicators (KPIs), clearly defined reference scenarios and an easy understandable graphical presentation of results. In an iterative planning process, hot spots can be analysed, defined and optimized in cooperation with the developer, architects and other involved trades. Because the building structure was set already at this point of time, the applicable actions have been limited to specific improvement measures, like the additional integration of Green and Blue infrastructure.

5. Conclusion

The GREENPASS® approach has been successfully proven itself in practice, based on the Case Study 'FLAIR in the City' – the worldwide first GREENPASS® Gold certified project.

Figure 15. Visualization - 'FLAIR in the City' Planning optimized (FLAIR GmbH)

It is following recommended, to use GREENPASS® as standardized tool for climate-resilient urban planning processes, in parallel to the energy pass for buildings. This international award is further proof that not only costs can be saved with the right choice of building integrated greenery and targeted green space design, but also maximizing the thermal comfort for all residents. This result shows that the consideration of green and blue infrastructure ensures climate-resilient urban planning in a simple and cost-effective manner. The thermal comfort and the quality of life for residents in urban areas can thus be significantly increased. In addition, biodiversity and habitat quality can be promoted, too.

The worldwide applicable GREENPASS® technology has been already applied for more than 35 projects in Austria and the EU [3] and is summarized, an efficient planning approach and realization tool that provides profound decision-making ground. It helps to prevent urban heat islands and other urban challenges in times of climate change and to make our cities climate-resilient and livable.

Nevertheless, it's important to consider climate adaption aspects and the integration of innovative planning tools in urban design process as early as possible, due to a strong impact of the building structure and used materials to its surrounding and on humans and to be able to optimize the building structures, if necessary. Lesson learned is following, that climate adaptation in urban design processes should be considered from the very early beginning of the detailed planning process (or even in urban planning processes before) to get the best out of the project.

Abstract. Carbon emissions emanating from infrastructure construction projects are substantial and stem primarily from production of construction materials and use of energy for construction transport and site activities. In recent years, public infrastructure clients world-wide have begun to include carbon reduction goals in their procurement requirements. This is however a new and complex field where practices vary and are still developing. In this paper, we compare models for carbon reduction requirements in infrastructure construction projects based on case studies of large projects in Australia, USA, the Netherlands, Sweden and UK. We found that open, functional carbon reduction requirements were considered innovative but entailed costs for calculating baselines and risks for speculation. Also, high time pressure in projects limits contractors' opportunities to explore reduction opportunities. Thus, specific, prescriptive requirements may play an important role in client-led, long-term innovation processes. Organizational competence and resources on the buyer side are essential, and policies for carbon reduction should aim to increase client capacity. Further, procurement practices are developed in mutual interaction between clients and suppliers over longer periods of time, which limits possibilities to transfer procurement policies and requirements between contexts.

1. Introduction

The construction sector causes a substantial part of all carbon emissions, primarily carbon dioxide. Traditionally, the focus has been on improving the energy efficiency of buildings, while it is only recently that the considerable carbon emissions arising from the manufacturing of construction materials and components, and from construction processes and transport, have been acknowledged [1]. Consequently, the infrastructure construction sector is now recognized as a major source of carbon emissions and there is increasing awareness that these emissions need to be significantly reduced if the international and national carbon reduction targets are to be met. In the UK, the Green Construction Board has estimated that emissions from the construction, maintenance and operations of infrastructure assets account for 1/6 or 16 % of the nation's total carbon dioxide emissions.

In the European Union as well as in the OECD countries, the focus on public procurement as a policy instrument has increased in recent years [2]. In particular, ecological and social sustainability and innovation procurement have been promoted. Large public buyers are pointed out as key actors in driving development especially in sectors where they stand for a high share of total demand, such as construction [3]. This allows them to not only influence emissions stemming from their own purchasing, but also to create lead markets for new products and services.

In the infrastructure sector, large public buyers such as road and railroad administrations, state-owned companies, municipalities and county councils represent a large proportion of the total demand. Their procurement models and requirements not only define the assets constructed but also the incentives and motivation of contractors, designing engineers and material manufacturers to develop competencies and new innovative solutions [4] also in the field of sustainability [5]. In recent years initiatives have been taken world-wide to include sustainability criteria in infrastructure construction procurement. Sustainability assessment schemes (CEEQUAL, BREEAM Infrastructure, the IS rating system, Envision), sustainability frameworks (SUNRA) and carbon management frameworks (PAS 2080, CO2 Performance Ladder) have been developed. Recent guidelines such as those by UK Green Building Council [6] and IISD and i24c [7] address the role of public procurement in this field and provide best practice examples.

Still, it is not evident how to design and implement procurement models and incentives that efficiently contribute to carbon emissions reductions in infrastructure construction projects. The measures to achieve reductions in the infrastructure projects are multifaceted: they involve new construction materials, optimizing designs to use less materials and energy over the life cycle, coordinating use of masses within and between projects, minimizing emissions from transport and site operation, as well as documentation, reporting and verification of requirements [8, 9]. Thus, similar to green public procurement in the construction sector in general, a wide range of project functions and supply chain partners are affected [10].

This research project provides a cross-country overview of how public infrastructure clients use procurement requirements to support carbon reduction goals in large construction projects. This paper describes the different types of procurement requirements used and briefly discusses experiences, developments over time and policy context. The countries covered are Australia (New South Wales), The Netherlands, Sweden, the UK and the US (California).

2. Previous research

2.1. Research on green and sustainable procurement

There are few research-based studies on carbon requirements in infrastructure projects and the number of studies on green public procurement (GPP) or Sustainable Public Procurement (SPP) in construction is also limited. However, the body of literature on GPP and SPP often covers wider areas which also may include construction. More generally, Cheng, Appolloni, D'Amato and Zhu [11] showed that GPP is a growing research field with 50 % of the articles published between 2013 and 2016. Low carbon procurement emerged as a subset of GPP around 2010. Often, the ambition is to map practices, drivers and obstacles. For example, Brammer and Walker [12] report results of a survey of GPP/SPP practices in all sustainability dimensions and in all sectors in 20 countries. They found that procurement policy and practices vary significantly between regions, and that the national policy context has a high influence on the use of SPP as well as on focus areas and measures [12]. Such cross-country studies are however rare and repeatedly called for [8, 12].

Studies focusing on public procurement for innovation show that change processes are complex and dependent on mutual interaction between demand-side requirements and supply-side development over longer periods of time [12, 13]. The need for organizational awareness, competence and capacity on the buyer side to craft and implement successful policy measures is emphasized [13-17]. Collaboration between the purchasing department and environmental units is another success factor [16], and many studies find that individuals are important [18]. Front-runner suppliers play a key role since a lack of green products and services on the market is one of the main obstacles to innovation-oriented green public procurement [10, 12, 14].

2.2. Green procurement and procurement requirements in construction

Research has shown that green requirements are becoming increasingly common but there are only few studies on how criteria are formulated and developed [15, 19]. Further, there are different types of requirements. First, sustainability may be used in the tendering process, as pre-qualification or award (MEAT) criteria [5, 20]. Other requirements regard the product or asset to be built and these may be project-specific specifications or embedded in standards or rating systems. There are also requirements that specify processes, documentation and competence. In construction, award criteria and style of specifications are strongly related to the chosen delivery model. Prescriptive requirements and price-based selection are associated with traditional, or design-bid-build, models, where the client specifies the design. Design-build contracts are based on performance requirements, and place more of the design responsibility on contractors. The general trend is towards design-build contracts [21]. In many countries there is also increased use of integrated strategies where contractors are involved earlier in the process and collaborate with the client and the design consultants to jointly define the design [22].

In our case study descriptions and discussions, we classify requirements using the following four categories:

- Selection and award criteria (qualification and MEAT criteria)
- Technical specifications and other requirements pertaining to the finished asset, the production process or organizational and individual competence. An important distinction is between prescriptive/specific/closed and functional/performance/outcome specifications.
- Rating systems/Sustainability Assessment Schemes, where the infrastructure asset may receive a certification or label provided that certain product and/or process criteria are fulfilled.
- Carbon reduction requirements, which specify or reward percentage reductions of emissions in relation to a baseline. Such requirements are sometimes referred to as “functional” or “performance”, since they leave it open to contractors how to achieve the reduction goals.

3. Method

The study has been designed and conducted in collaboration between partners from academia and industry. Interviews were performed with client representatives as well as with other parties in the supply and value chains, primarily contractor and consultant representatives but also manufacturers of construction materials. Interviewees were selected with the aid of local WSP and SKANSKA connections who were involved in the projects. Depending on project phase and availability, different combinations of roles were interviewed in different projects. In general, interviews lasted for 2-3 hours. Most interviews included more than one interviewee. The Swedish case study was coordinated with a project to follow-up the experiences from a new model to incentivize carbon reduction in construction supply chains, and there was a higher number of interviews. All interviews were voice-recorded under permission of the interviewees, and transcribed.

For a summary of interviews see Table 1. The interview guideline questions were organized under six headings aiming to capture information about procurement requirements used in the case study projects as well as personal experiences and views. The headings were:

1. Sustainability procurement requirements for reduction of carbon emissions in the project
2. Basis for/origin of requirements, such as policies, standards or certifications
3. Organization and processes for implementing and following up requirements
4. Mechanisms for learning and improvement
5. Results

6. Perceived key success factors and barriers

Case summaries were developed and fed back to interviewees for fact-checking and comments. As a basis for the analysis, a description of the policy context of each case was developed based on literature and input from local representatives.

Table 1. Cases and interviewees

Country	Project	Actors interviewed (no of individuals in parenthesis)	Number of interviews
Australia	Sydney Metro Northwest	Client (3), Contractor (1), Designer (2), Steel Supplier (1)	4
Australia	Newcastle Light Rail	Client (1), Contractor (1), Designer (4)	2
The Netherlands	A6 Almere	Client (2), Contractor (1)	1
Sweden	3 projects and other interviews	3 project interviews + interviews with clients (23), consultants (16), contractors (22) and suppliers (15).	17
UK	Anglian Water, Grafham WTW Resilience and Dalton Piercy WTW	Client (2), Contractor (1), Designer (1), other (1)	1
UK	HS2	Client (3), Contractor (1)	2
USA	California High-Speed Rail	Client (4), Contractor (1), Designer (1), Supervisor (1), Steel supplier (1)	5
USA	SFO AirTrain Extension	Client (1), Contractor (2), Designer (2)	3

4. Results

This section gives an overview of policies, procurement requirements and experiences.

4.1. Policy context

The general policy structures for the procurement requirements for carbon reduction were influenced by the national culture for policy development. Fundamental differences concerned the governance structure: Australia and the US both have a state level with high power while in the Netherlands, UK and Sweden the national level is the most important. Further, some countries and organizations (Australia/NSW, NL, UK) have a longer tradition of carbon management in infrastructure construction while in others (Sweden, US/California) such ambitions are more recent.

Some clients and projects have implemented a national policy while others have taken a role to push policy and practice forward. For very large mega-projects such as CHSR in California and HS2 in the UK, the client management teams perceive an obligation to align project ambitions with higher national and international goals despite that explicit directives to clients or projects were in fact vague or lacking. In the UK, the water company Anglian Water has served as a role model for the whole industry, demonstrating that it is possible to achieve a 50% reduction in capital carbon and also that carbon reduction is often associated with cost reductions. In the CHSR project, the explicit ambition was to use its volume and drive market development. In several cases, such as Sydney Metro, CHSR and Anglian Water, individual champions have played key roles in raising ambitions. In the Netherlands, HS2 and Sweden, the development is more policy-driven. We can also see that governments, clients, projects and industry networks take different roles in driving development. In Sweden there is a relatively clear top down approach by the Swedish Transport Administration whereas in the two US cases it is more up to the clients and projects to drive development. In New South Wales in Australia, clients have been the primary change agents, while in the UK and the Netherlands industry collaborations and partnerships with active support by government have also been important. Suppliers as well may act as front runners and set more ambitious goals than those of the client. In Sweden, some large contractors have been ahead of the client in implementing carbon reduction measures.

4.2. Procurement requirements

A summary of the types of procurement requirements with relevance to carbon reduction identified in the cases is provided in Table 2.

Table 2. Types of requirements and examples in the cases

Type of requirement	Examples in cases
Selection and award criteria	Tender discount based on organizational capabilities (NL: CO2 Performance Ladder) Tender discount based on carbon footprint calculation/reduction (NL: DuboCalc, see also under reduction req. below) Organizational environmental competence based on staff CVs Organizational competence evaluated based exemplar low carbon designs (UK: HS2) (Award criterion)
Technical specifications and other specific requirements	Requirements for competence, roles and processes: - req. for carbon manager, carbon management plans - carbon footprint calculations and documentation - PAS 2080 compatible (UK), SUNRA (SW) Carbon performance and documentation requirements: - Carbon performance for selected products/material - Renewable fuels/energy - EPDs Technical requirements: - Cement clinker replacement, Recycled ballast - Steel production req. - Asphalt, LED lightning
Rating systems/Sustainability assessment schemes (SAS)	LEED, BREEAM, Green Star (buildings) BREEAM, ISCA, CEEQUAL, Envision (Infra)
Carbon reduction requirements	Reduction in embodied or capital carbon in relation to baselines calculated for reference designs (AU, NL, SW, UK) or in relation to business as usual (US).

Following the general trend in construction procurement towards performance specifications, the case studies show that there is a preference in several countries (UK, NL SW) for open requirements that do not specify in detail which measures should be employed by contractors to reduce carbon emissions. The ambitions are to provide incentives for carbon reduction and reward contractors that invest in carbon reduction competence. Two types of requirements are used for such purposes: MEAT award criteria and requirements for carbon reduction in relation to a baseline. The UK cases have set ambitious goals of 50% reduction levels and emphasize collaboration within the supply chain: Anglian Water uses a long-term alliance contract while HS2 uses a two-stage Early Contractor Involvement contract. The Swedish Transport Administration has recently begun to include carbon reduction requirements in all projects above 5 MEUR, starting with targets around 15% which are to be raised over time. In the Netherlands, the DuboCalc tool has been developed to calculate environmental impact of construction projects, including carbon. In large projects, DuboCalc is used as an award criterion in combination with the Competitive Dialogue process. In New South Wales in Australia, reduction requirements are included in the ISCA Rating System, which is compulsory for projects of a defined size and significance. Requirements for conformance with rating schemes are applied also in the UK. In the Netherlands, the certification system CO2 Performance Ladder for carbon management is used in tender evaluation.

4.2.1. Experiences

As for MEAT award criteria, several interviewees said that the main difficulty was that there are many aspects to consider when procuring a contractor and that each area will account for a small share of the total score. In several cases studied, award criteria were used not so much to produce sharp incentives but as a means to raise awareness of the importance of carbon reduction activities and ensure that contractors include staff with high carbon competence in their teams.

Regarding reduction requirements, setting a baseline was seen as a fundamental challenge. The main points were:

1. Uncertainty in defining the reference case: on what design should the baseline be based (what project stage and on worst-case or state-of-the-art design)?
2. Uncertainty as to when the baseline should be updated, as well as which changes should be counted as savings (or increases) in relation to the baseline and what should be counted as a scope change leading to adjustment of the baseline.
3. Calculating and re-calculating baselines is costly and competes for personnel resources and management attention with actual activities to reduce carbon emissions.
4. There is a risk that incentives for carbon reduction either do not influence behavior or produce speculation and a focus on creative calculation.
5. There is limited time in a construction project to involve sub-contractors and material suppliers in low carbon design activities.
6. The development and testing of new products and materials require a longer time and need to be managed with a long-term perspective that stretches over several projects.

To some extent, these uncertainties are related to inexperience: certainty as to how to set baselines is expected to increase as standard practices develop. However, setting relevant reduction levels calls for high client competence and market knowledge, and sharp incentives may increase transaction costs for both clients and contractors. More collaborative models carry a higher potential for knowledge integration and innovation [23], but the UK experiences show that strong client leadership and commitment is essential both to legitimize collaborative contracting models and to achieve more fundamental behavioral change within such schemes. Rating systems as well are only used in the more mature contexts. In general, client carbon competence and active engagement is seen as important success factors. To speed up innovation processes and reach out in the supply chain, clients in Australia and NL use specific requirements while in the UK, innovation and learning between projects is addressed by national initiatives.

5. Discussion and conclusions

There is a high belief on the policy level in procurement as a driver of change and innovation, especially in a highly government-dominated and outsourced industry such as infrastructure construction. This study points at the complexity involved in designing and implementing procurement requirements for carbon reduction in this context. In general, it is not just a question of including certain requirements and incentives in the tendering documents, but a lengthy process that includes development of industry competence and institutions as well as clients with a long-term perspective and deep understanding of how innovation may be driven in this complex, project-based industry. Goals and measures for carbon reduction are new to many actors, and both clients and industry partners need time to adjust and develop new competencies [14].

Regarding style of requirements, specific/prescriptive requirements are often associated with conservatism while performance/functional requirements and MEAT award criteria are believed to encourage innovation. In practice, however, it is more complicated. Any single award criterion will hardly achieve enough weight to be a strong driver, and both time and resources for developing and evaluating tenders are limited. Carbon emissions in construction have many sources, and all of them are not possible to consider at the tendering stage. Functional carbon reduction requirements in relation to a baseline were used in all countries except the US. However, these were found to entail numerous implementation issues, including time and costs for calculating baselines, risks to produce a work-to-rule speculative mindset and need for independent institutions. Moreover, high time pressure limits contractors' opportunities to explore reduction opportunities during the design stage, especially if suppliers need to be involved [24]. This implies that functional requirements are less useful to leverage innovation in a project-based context than in sectors with more continuous demand and production. In effect, the case studies show that specific, prescriptive requirements may play an important role in long-term innovation processes by transferring new knowledge between projects. However, such processes have to be led by competent clients and require effective collaboration between their environmental and technical experts, procurement functions and project managers. Thus, in line with previous studies [14-17], this study emphasizes the importance of organizational awareness, competence and capacity on the buyer side.

Implications for policy-makers and client top management are that policies for carbon reduction should encompass measures to increase client capacity and incentives to drive innovation, including development of transparent systems for updating standards. Further, in countries with a longer history in carbon management, development of procurement strategies and requirements has been aligned with information and training initiatives, tool kits and guidelines for the entire supply chain. Since there is a close relationship in infrastructure construction between carbon reduction and cost reduction, and because so many project processes and participants need to be involved, policies should address the general competence of public clients to procure and manage infrastructure projects, including collaborative delivery models and strategic alliances.

Altogether, the results demonstrate that opportunities to transfer procurement policies and requirements between contexts are limited. Procurement requirements are developed in mutual interaction between clients and suppliers over longer periods of time [12, 13, 16]. Thus, policy and procurement strategy taken out of context will seldom work in a new setting that differs from the original one.

Implementing climate impacts in road infrastructure in the design phase by combining BIM with LCA

Slobodchikov R, Lohne Bakke K, Ragnar Svennevig P, O'Born R

University of Agder, Jon Lilletuns vei 9, 4879 Grimstad, Norway

reyn.oborn@uia.no

Abstract. Building information modelling (BIM) software is increasingly being used in as a visual road design tool and offers real-time information on material demands as designs change. Life cycle assessment (LCA) is a tool that is used to measure the lifetime environmental impacts of systems, materials and processes. LCA data sets are organized according to process or product, which is ideal for implementation as a parameter in BIM. This paper seeks to explore how BIM and LCA can be used together in road design by analysing existing literature, creating a Norwegian test case on a road designed in a BIM model and adding LCA data to the model before comparing to a standard LCA study of the same road. Challenges such as including machinery emissions, uncertainty, data availability, and other insights gained will be discussed. The goal of this paper is to present a path forward for road builders to combine LCA and BIM to promote simplified LCA calculations.

1. Introduction

1.1. Background

Materials extraction and their associated processes contribute up to 50% of the global greenhouse gas (GHG) emissions and new infrastructure has outsized role in this growth [1]. Construction of infrastructure, and especially road infrastructure, is estimated to be a significant contributor to global GHG emissions [2]. As a road is designed and built, the most important decisions are made in the early design phase, which can have significant impacts on the overall GHG emissions of a project [3], [4]. The use of tools, such as life cycle assessment (LCA), can help determine environmental impacts in the early design phase, but use of such tools are often hindered due to lack of data, poor interface between road designs and LCA tools, and poor understanding of LCA as methodology [5]. This has been partially addressed by simplifying LCA for use in early decision making through tools such as CO_2CONSTRUCT, LICCER, CHANGER and JOULESAVE [6]–[9]. These models still require users to input data from one model (the road design) into a separate LCA model, requiring additional time, effort and expertise [10]. As the design of road infrastructure increasingly takes place within digital design tools as they become more sophisticated, integrating LCA with tools such as Builiding Information Modelling is becoming more attractive, although the use of Building Information Modelling (BIM) in road design is not widespread [11], [12]. BIM has several advantages over traditional modelling software and paper designs, namely that changes are shown visually in real-time [13], [14]. There have been several studies that have successfully integrated BIM and LCA in the construction sector [15]–[18] but still more work needs to be done for wider use. There have been few studies on integrating BIM with LCA for road construction but there has been some work on using spatial visualization and adopting BIM for road infrastructure projects [12], [19]. As road builders are increasingly forced to consider LCA and are increasingly moving towards digital tools for road design, it will be natural to combine BIM and LCA. This paper will show how it is possible for road planners to integrate BIM and LCA together for use in road planning and design.

1.2. Case study

The Norwegian government has set targets for greenhouse gas (GHG) emissions reductions in new road transport infrastructure in accordance with the signing of Paris Climate Agreement. The Norwegian government must reduce GHG emissions in new built transport infrastructure by 50% by the year 2030 [20]. This has meant that road planners, road builders, material producers and researchers have been forced to cooperate on developing strategies for reducing emissions in order to meet these targets [21]. The Norwegian Public Roads Administration (NPRA) is slowly mandating that LCA be used in assessing road projects and have their own simplified model for calculating emissions based on basic volumetric calculations and material requirements [22]. This model, like all LCA studies and models used in road construction, is not directly connected to the design process and requires users to input data from the road design model into an additional LCA model. The University of Agder and engineering consultant firm Sweco have been developing a BIM and LCA tool for road builders in Norway so that the design process and the LCA model are directly connected. The model is currently unnamed but can be called the BIM-LCA-ROAD (BLR) model for this paper.

The BLR model was developed and tested using a real-world road design model from Sweco's design for a highway stretch on the European Highway 6 (E6) between Arnkern and Moelv in Norway as shown in Figure 1. Sweco chose this route for testing as there was an interest on determining GHG emissions in the project and because they had a design already built in a 3D BIM model. The model was designed in Trimble Novapoint according to Norwegian road standards and exported into the file format LandXML so that it be possible to import the models into Autodesk Civil 3D for further work.

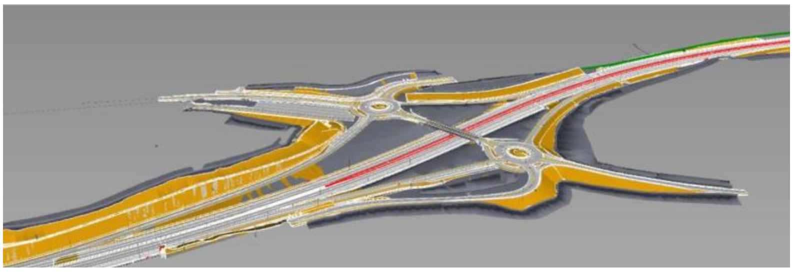

Figure 1. Sweco's Trimble Novapoint design for E6 route Arnkern-Moelv

2. Methods

2.1. Life cycle assessment

According to ISO 14040, a life cycle assessment study comprises of four main phases[23]:

1. Goal and scope definition
2. Inventory analysis
3. Impact assessment
4. Interpretation

The *goal and scope definition* phase includes the definition of the system boundaries and processes covered, the functional unit, the impact categories to be included and a declaration on who the LCA study is for. The BLR model is intended to be used by road designers and has a functional unit of one road. The BLR model is a cradle-to-gate model and has system boundaries that include the material production, construction machinery and transportation of materials to the construction site. Road operation, maintenance, traffic and end-of-life are not included in the BLR model and currently only global warming potential (GWP) and cumulative energy demand (CED) are included, although the model framework can be expanded to include costs (in Norwegian Kroner) and other LCA impact categories. The *inventory analysis* phase involves the collection of data on resource and energy demand for each process and emissions from each process within the system boundary and calculated according to the functional unit. The data collected for the testing of the BLR model comes from the material requirements calculated in the BIM model while transport distances are from real world calculations from Sweco. The test analysis used in this paper only analyzed the road base layers and driving surface and associated material production, construction and transport processes. Fuel usage in machinery comes from the Norwegian EFFEKT model version 6.6 [22]. Additional material requirements come from an additional Norwegian case study and EcoInvent 3 [21], [24]. The *impact assessment* phase uses the results from the inventory analysis phase to present the environmental impacts of the system. This is accomplished by organizing emissions into impact categories and calculating their potential impact through characterized emissions factors. The emissions factors used in this version of the model also come from the EFFEKT model version 6.6. The BLR model calculates GWP using ReCiPe 2016 midpoint indicators [25] and expresses emissions in CO_2-equivalents. Finally, the *interpretation* phase presents the results of an LCA study and recommendations. There is often also a validation process for these results, usually via comparison to other studies found in literature or through data analysis, such as a sensitivity analysis on important model parameters. This paper presents the results of the BLR model for the case and compares it to the same calculations carried out in LCA software SimaPro. This comparative analysis was also performed to determine where the most uncertainty in the model occurs and to see where model improvements need to be made.

2.2. Programming and calculation procedure in BLR model

The programming of the BLR model took place using .NET framework with C# as the programming language in Microsoft Visual Studio. This code was then implemented in Autodesk Civil 3D to carry out calculations in the form of an add-on application. Autodesk Civil 3D is one of the two main programs for digital road design used in Norway (the other being Trimble Novapoint). Autodesk 3D has an advantage over Novapoint in that add-on applications can be implemented and that external programs can easily communicate with these applications. The BLR model use Dynamic Link Library (DLL) files to import external coding into Autodesk Civil 3D to the application programming interface (API), or application. In essence, the BLR model is actually an add-on application in Autodesk Civil 3D but is designed in the same way as a conventional LCA tool. The basic inventory analysis and emissions data were imported from an Excel file into the application. The BLR model has an additional module that shows the results in real-time color coding on the actual modelled road (See Figure 6). The code used in this model is currently has not been made public. The full calculation procedures for the BLR model are shown in Figures 2 and 3.

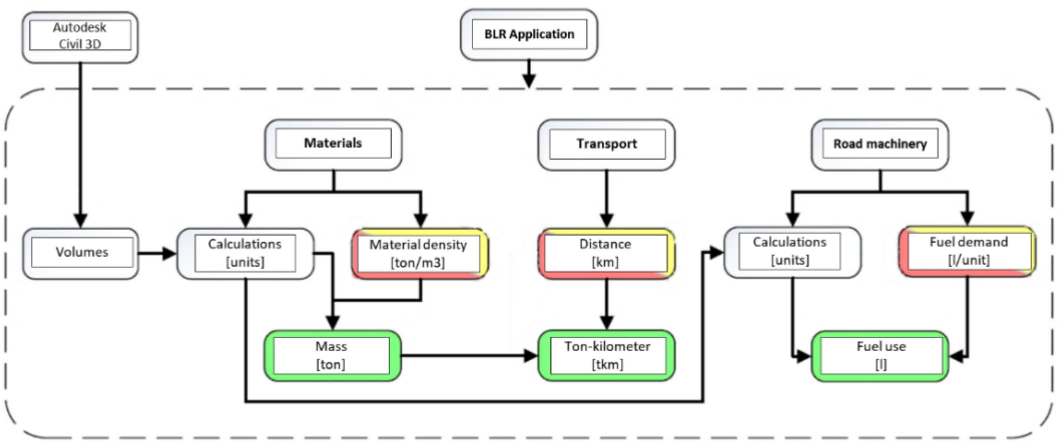

Figure 2. Calculation procedure for materials, transport and fuel in BLR model

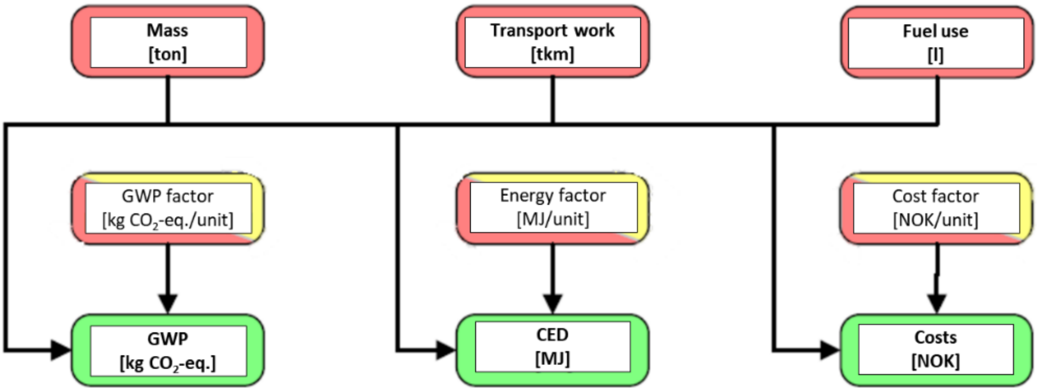

Figure 3. Calculation procedure for total GWP, CED and costs in BLR model

The BLR model calculates volumes according to the geometric volumes in the BIM model which are then converted into mass based on material density. The transport distance takes the mass calculations to calculate the overall transport work in ton-kilometers (tkm) which are used for calculating transport fuel demand. Road machinery processes also calculate based on volumetric mass calculations for earthworks and are combined with the transport fuel demand to determine the overall fuel demand in the road project. Once the fuel, mass and transport work are known, these are multiplied by GWP, Energy and Cost factors to determine the overall impact of the project. In Figures 2 and 3, the red boxes show which areas where the model does not allow for any changes in calculation parameters while the yellow boxes show where project-specific inputs can be added if the user so chooses, while the green boxes show the final calculated results.

3. Results

3.1. Life cycle inventory results

The two cases were calculated with Autodesk Civil 3D to determine the overall material requirements for each road base. Case 1 is a theoretical road crossing made in Trimble Novapoint and exported to Autodesk Civil 3D while Case 2 is a real-world example of a 4-lane highway design.

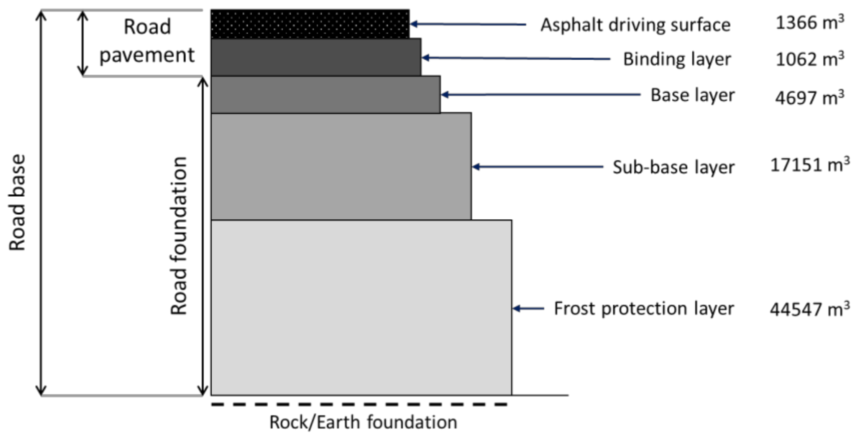

Figure 4. Material requirements for the test case

Figure 4 shows the volumetric material requirements for each component of the road base as modelled. These were calculated directly in Autodesk Civil 3D. The asphalt driving surface is a mix of gravel and bitumen while the other layers are layers of gravel and aggregates of various dimensions.

3.2. Life cycle global warming potential results

This case study is limited in that it only evaluates the GWP of the case and is used as an illustration of what is possible with a BIM model. Nevertheless, the aim of the BLR model is to calculate emissions as equally well as a standard LCA model thus the results were compared with an LCA model constructed in SimaPro. The model in SimaPro used the same impact factors and material demands as the initial BIM model. Figure 5 shows the relative emissions for each construction process and for material production for both the SimaPro LCA model and the BLR model while Table 1 shows the aggregated emissions for each of the main processes.

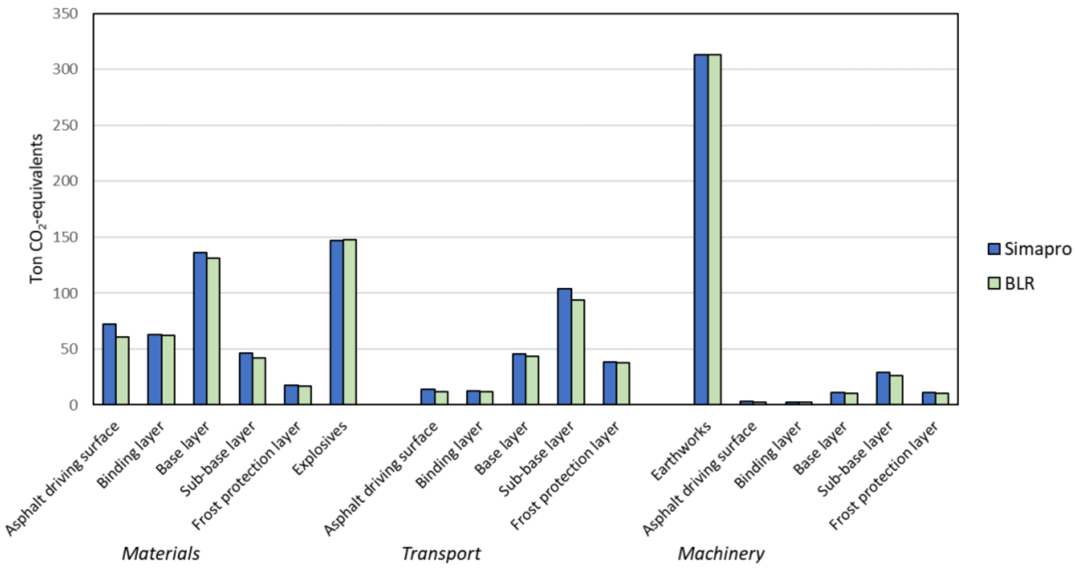

Figure 5. GWP life cycle impact assessment results (in tons CO_2-equivalents)

Figure 5 shows the emissions for each of the different road layers according to the material production, transport of materials and construction machinery. The largest single impact for both versions of the model was emissions from earthworks machinery (primarily cutting and filling, digging of trenches and drainage), which amounted 313 tons CO_2-eq. for each analysis. Other high impacts were explosives (147 to 148 tons CO_2-equivalents), material production for gravel in the base layer (which require more crushing) and transport of materials for the sub-base layer (which have the greatest total mass of all materials produced). The frost protection layer is generally lower emissions for both production and transport as emissions from the production of these materials are included in cutting and filling, which are reflected in the earthworks emissions. Overall, there is a small difference for many of the processes in the SimaPro model versus the BLR model, where the SimaPro model in general has slightly higher emissions. Table 1 summarizes the differences between the three main processes of material production, material transport and construction machinery.

Table 1. GWP results based on SimaPro and BLR analysis

Item	SimaPro	BLR	Unit	Difference
Materials	482.24	461.53	Tons CO_2-eq	4.3 %
Transport	213.93	199.15	Tons CO_2-eq	6.9 %
Machinery	370.36	366.46	Tons CO_2-eq	1.1 %
Total	1066.53	1027.14	Tons CO_2-eq	3.7 %

The BLR model underestimates emissions by 3.7% compared to the SimaPro model. Most of this is due to material production emissions being underestimated although the highest uncertainty comes from transport of materials. This is largely due to calculation differences between the original Trimble

Novapoint design and the re-imported version in Autodesk Civil 3D. This variation issue can be solved by adding coordinates directly from the LandXML file, although this has not been implemented in the BLR model at this time.

3.3. Model results and model functionality

This section outlines the functionality of the model beyond the LCA results. The BLR model was developed in this study is designed so that the user has the ability to comprehensively calculate environmental impacts in real-time during the design process. This is useful for users who are familiar with designing roads in BIM but lack the time or expertise to do a separate LCA analysis. The calculations are shown both in numerical form as tables and visually on a color-coded scalar plot as shown in Figure 6.

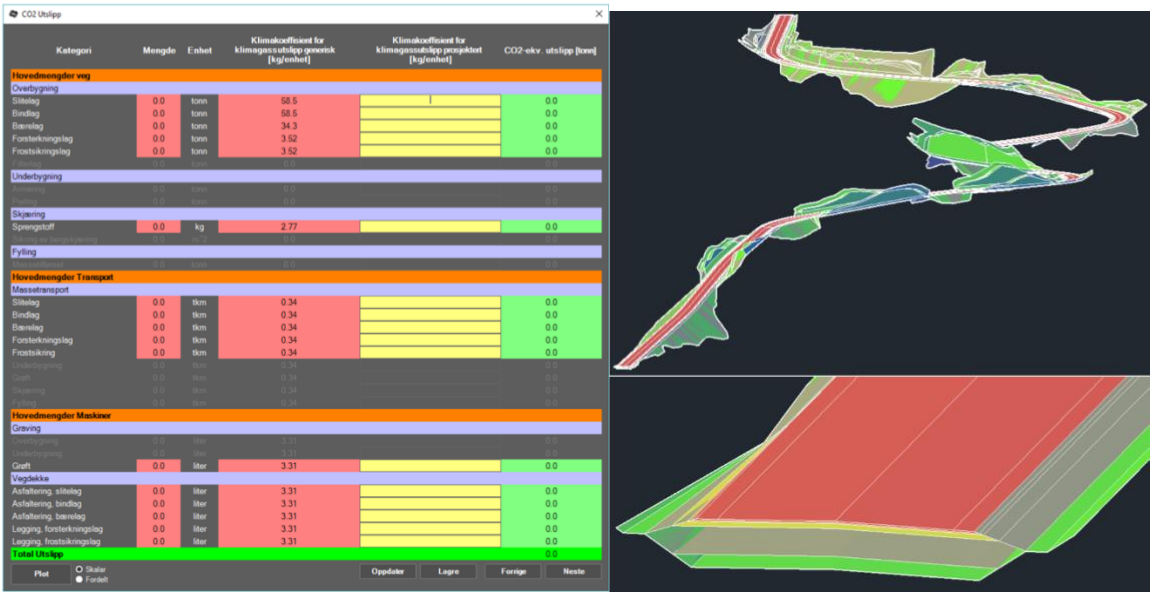

Figure 6. Example of GWP results presentation in BLR model

The table shows the calculated amounts for each material/process in the second column and the emissions factors (GWP per unit in this figure) for each material/process in the fourth column. The fifth yellow column allows for the user to add a project specific emissions factor if they choose while the sixth green column shows the total calculated emissions. The scalar plot on the right shows the overall project emissions color coded, where red has the highest emission and green has the lowest emissions. Grey colors signify elements that are not included in the current BLR model. The user can also zoom in or out on the project in the same way as any other BIM model shown Autodesk Civil 3D.

4. Discussion

Researchers have been working for many years to try and develop models that combine LCA with road project designs as customers and road authorities demand emissions reductions in new infrastructure. The overall goal of the development of BLR was to make LCA calculations as simple as possible while also being robust enough to compare well with more standard LCA road models. BLR differs from existing LCA models in that the road design and impact calculations are carried out simultaneously within the same model while other models typically require information from finished road designs as inputs. The BLR model is advantageous for road builders and designers as they can evaluate emissions and make decisions to reduce emissions in real-time. The visual aspects of the BLR model also help to easily see which sections of the road require efforts to reduce emissions.

The BLR model is a proof of concept showing that it is possible to include emissions in BIM for road designs but the model has several shortcomings in its current form and in relation to traditional

LCA models and methods. The first major shortcoming is that the scope of the model is extremely limited compared to other LCA studies as only CED and GWP are included. Other LCA studies and even Environmental Product Declarations (EPDs) have far more impact categories included. As the BLR model was only designed as a proof of concept, these impacts were not included but space for additional impact categories has been included as road authorities prioritize GHG reduction over all other impact categories [26]. Other impact categories such as eutrophication, acidification, and photochemical oxidation that are usually included in road LCA studies should be prioritized [27], [28]. The BLR model is also limited in that it does not include the full depth and breadth of materials and construction processes used in road construction in its current form. As the model continues to be developed, more information will be added to it which will improve the model quality and LCA results and could be expanded to included maintenance and end-of-life processes in the future. This will require better data inputs, which could be improved by linking up to existing LCA inventories for roads in Norway, by implementing EPDs and by using project specific data when available [29], [30].

5. Conclusion

This paper presented an integrated BIM and LCA model for road design and tested the model through the use of a case study in Norway. The results of the testing showed that it was indeed possible to combine emissions calculations in a BIM model through the use of C# to develop an Autodesk Civil 3D application. Future work should improve the robustness of the model by adding emissions factors for more construction processes and materials, by expanding the model to include more impact categories and additional life cycle phases, and by linking the BLR model to existing LCA datasets.

Abstract. In order to achieve the climate goals, the implementation of sustainable construction is becoming more and more topical in the construction sector. Due to very long service lifes especially in railway projects, the consideration of life-cycle aspects into the early design process is of great importance. Regarding the assessment of the economic pillar of sustainability, life-cycle costing has become an established method. This study presents the application of life-cycle cost analysis (LCCA) for decision aiding in railway construction. The two tunnel tubes of the project Koralmtunnel (KAT) are connected with approximately 70 cross-passages (CPs) at intervals of around 500 m. These CPs serve as escape-ways and additionally host utility rooms for technical equipment (telecomunication, power supply and remote control). First thermal simulations revealed indoor temperatures up to 80 °C due to the heat release of the technical equipment without implementation of technical cooling systems in operation phase. This is caused by the limited heat transfer with the surrounding rock and with the adjacent running tubes. Therefore, the implementation of a cooling system is necessary. It is stated that higher indoor temperatures lead to reduced service lifes of the installed telecommunication systems. By the application of Arrhenius equation, the influence of several indoor target temperatures on the expected life time of the installed telecommunication systems has been determined. In order to meet target temperature requirements appropriate scenarios including different cooling scenarios have been designed. Finally, LCCA by application of the net-present value-method (NPV-method) was conducted in order to determine the most economical solution regarding CPs cooling systems based on selected target-temperatures.

1. Introduction

Large railway projects place manifold requirements on the design, the construction, the equipment, the commissioning as well as on the later operational management. In order to reconcile all these areas, which in some cases need to be assessed very differently, far-reaching considerations are required in advance. Long railway tunnel projects, increased demands on tunnel safety and the exploitation of existing technical possibilities are reasons why a massive increase in technical equipment can be observed. This trend needs to be monitored very carefully and critically so that it does not lead to increased maintenance cost, reductions in system availability, capacity constraints and quality of

operations management. Sustainable construction occupies a special place in the construction industry due to the centuries-long life-cycles of construction projects. Therefore, the construction sector plays a key role in this context and has enormous potential to reduce the human impact on our environment. From a economic persepective, private stakeholders often only focus on maximum profit and on short-term yielding. To implement sustainable construction, the three dimensions of sustainability (ecology, economy, sociality) must be considered throughout the lifecycle of a construction project. For the consideration of the economic pillar over the entire life span of construction projects LCCA represents a suitable instrument. Especially, public railway projects usually have very long lifetimes. Due to the long-term cost implications of operating cost and the maintenance of their technical equipment, a life-cycle-oriented approach is indispensable.
The so called southern corridor (the Austrian part) is part of the Baltic Adriatic corridor of the Trans-European Network Transport (TENT-T) [1, 2, 3, 4]. Core of this southern corridor are the Semmering Base Tunnel (SBT) with a length of 28 km and the Koralmtunnel (KAT) with a length of 33 km.

The two railway projects SBT and KAT will be operated as high-speed track. According to the distance reduction between Graz and Klagenfurt (230 km to 130 km), the travel time will be reduced for more than 2 hours [3, 4]. Today the KAT is the sixth longest railway tunnel in the world. The KAT consists of 2 tunnel tubes, which are connected with approximately 70 CPs, every 500 m. The CPs (see figure 1) serve as escape-ways and as utility rooms which contain the technical equipment for operation.

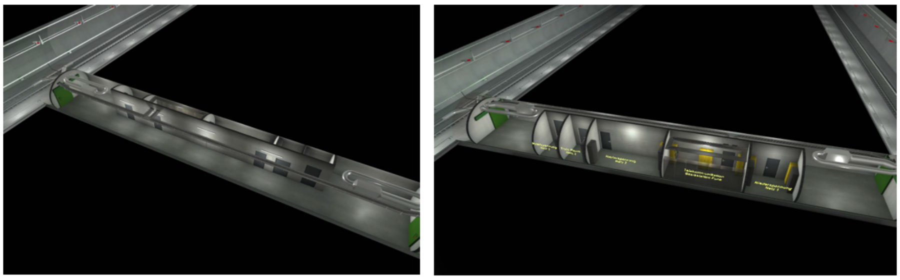

Figure 1. Schematic of a cross-passage - escape-way (left), utility rooms (right)

Thinking the entire life-cycle in the construction phase leads to different implementation scenarios due to limited service life of telecommunication systems. Due to the limited possibilities of dissipating the heat through the rock or through the adjacent running tubes, utility room temperatures of up to 80 °C occur during operation without cooling activities. These high temperatures mean that the telecommunication systems has to be replaced in shorter cycles. Based on the Arrhenius equation, the service life of the telecommunication systems can be determined as a function of the temperature. To increase the service life of the telecommunication systems, the utility room temperatures must be cooled. The cooling of the utility rooms requires additional construction cost of air- conditioning systems and/or ventilation systems in the construction phase as well as higher energy requirements for cooling in the use phase. On the other hand there are longer replacement cycles of the telecommunication systems in the use phase. In the sense of sustainable implementation, the decision-making problem arises for the investor between low initial construction cost with high usage cost or higher initial construction cost with lower usage cost.

2. Applied methodology

We illustrate how to use a NPV-method for decision-aiding in the design stage of railway projects under consideration of different thermal conditions.

2.1. Thermal conditions of long railway tunnels

The requirements for the thermal conditions inside a tunnel differ between construction phase and tunnel operation. During construction phase, the main constraint is the maximum allowable air temperature at the working areas, which must not be exceeded. While operation, the thermal conditions in the tunnel are important because tunnel air often is used for cooling technical equipment, which usually is located in utility rooms or zones within the CPs between the two tunnel tubes. To guarantee that the acceptable temperatures limits for the single utility rooms will be kept, a cooling process by the usage of tunnel air is required. Due to cost efficiency a simple mechanical ventilation system shall be installed in as many CPs as possible. In case this simple cooling process is not sufficient, air-conditioning systems are required.

As soon as outside air gets into the tunnel, the outside air temperature is one of the influencing parameters for the tunnel air temperature. For the current simulations the weather data (outside air temperature) from the region for the years 2010-2016 [5, 6] was processed. It turned out, that in 2013 summer short-term outside air temperatures, which represent the worst case for compliance with the temperature specifications, were maximum.

The rock temperature is one of the major parameters for the tunnel air temperature while construction and operation. The rock temperature curve was measured and monitored during the excavation phase and represents the start condition for the simulation of the time dependent evolution of tunnel-wall temperatures along the tunnel.

The most important heat sources during operation are the trains themselves. The impact of trains depends on the speed, the geometry of the trains as well as of the tubes. The piston effect of the trains generates an air flow in the tubes, which is essential for the thermal conditions along the tunnel. Hence the interval between the trains as well as their driving direction are further essential parameters. Depending on the slope of the track the convective heat release by breaks has to be considered too. The highpoint of the KAT is a few kilometers west from the emergency stop station. On both sides of the tunnel is a regular train station, so trains will have to stop and breaking energy will be released already in the tunnel.

In general, the fresh air-requirement is the major parameter for the tunnel air conditions. The higher the fresh air volume flow the bigger the influence of the outside air temperature.

Since tunnel air is used for cooling the utility rooms inside the CPs, the released heat from technical equipment such as the telecommunication units or the power supply units, have to be considered. In all of the 70 CPs technical equipment is installed. The released heat varies between 3 kW and 25 kW, depending on the type of equipment installed. A single CP would not have a big impact to the thermal conditions, but the sum of transported heat can lead to remarkable changes in thermal conditions within the tunnel. Due to redundancy reasons both cooling systems (ventilation and air-conditioning) are capable for re-cooling in both tubes. Depending on the tunnel air temperature in front of the CPs, re-cooling will take place in the tube with lower air temperature. If one tube is closed for maintenance, the second one is still in operation and due to the trains, an air flow and therefore a heat transport is granted. In the maintained tube the airflow depends on meteorology and if required on the maintenance ventilation. Simulations were performed, for identifying tunnel regions where tunnel air is cool enough to fulfill the thermal requirements. In figure 2 the simulation of thermal conditions within the utility rooms along the Koralmtunnel is shown.

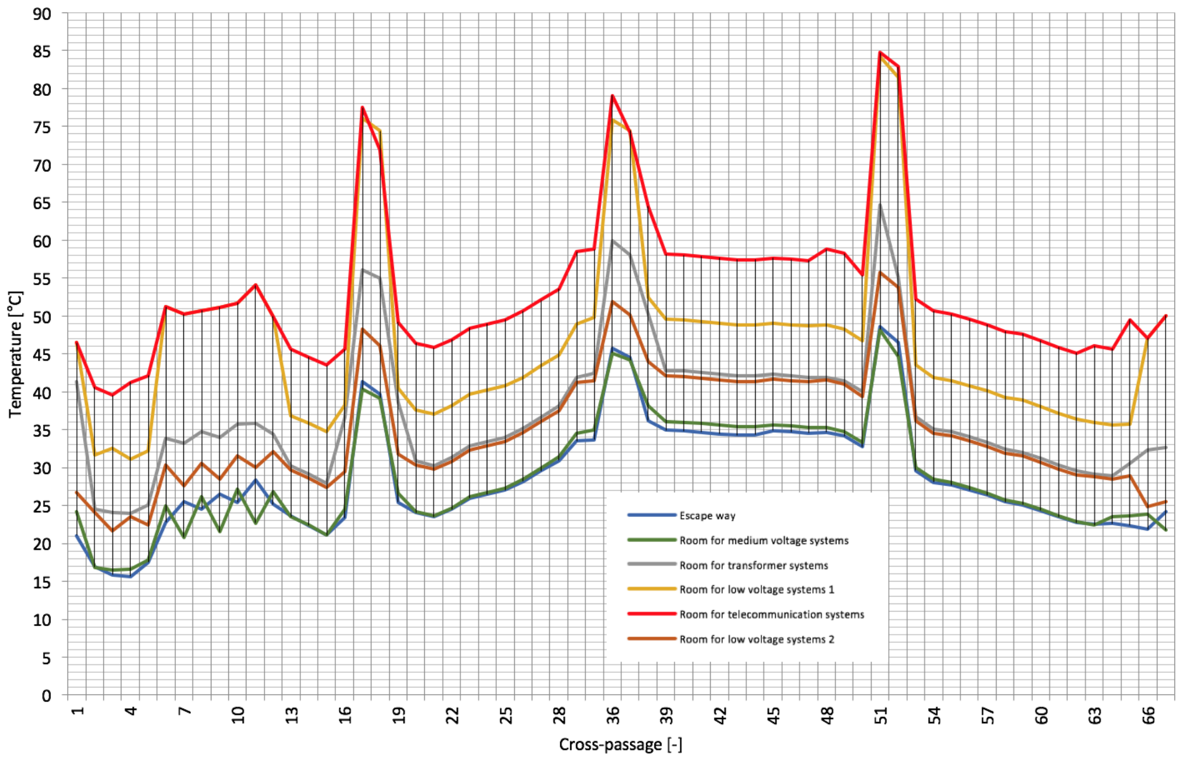

Figure 2. Simulation of thermal conditions within the utility rooms along the Koralmtunnel

The technical equipment includes power units for low voltage, medium voltage, transformer systems and telecommunication systems. Due to the high temperature sensitivity of the telecommunication systems and its effects on their service lifes, only utility rooms with located telecommuncation systems are considered. The increased room temperature in the CPs in figure 2 is the result of the installed telecommunications systems with base stations, which produce increased waste heat.

2.2. Service life of telecommunication systems - Arrhenius equation

The Arrhenius equation, named after Svante Arrhenius (1859 - 1927), describes approximately a quantitative temperature dependence in physical and chemical processes in which an activation energy has to be overcome at the molecular level [7, 8]. The Arrhenius equation is related to the Eyring equation, which represents a connection of the microscopic interpretation.

$$t_E = t_Q * e^{\frac{E_A}{R} * \left(\frac{1}{T_E} - \frac{1}{T_Q}\right)} \qquad (1)$$

where:

t_E = qualified life at absolute operating temperature T_E
t_Q = test or qualification duration at absolute test or qualification temperature T_Q
E_A = activation energy (the aging reaction)
R = gas constant

Based on the Arrhenius equation, the service life of the telecommunication systems were calculated as a function of the utility room temperatures. Table 1 shows the service life and the replacement cycles of the telecommunication systems over a 50 year period.

Table 1. Service life of telecommunication systems at different utility room temperatures

Utility room temperature	Service life	Replacement cycle
22°C	16 years	3
25°C	13 years	3
30°C	9 years	5
35°C	6 years	8
40°C	4 years	12
45°C	3 years	16

2.3. Life-cycle cost analysis

The framework for assessing the economic performance of construction projects is defined on international level in ISO 15686-5 [9]. In the course of a life-cycle cost analysis, different cost types that occur during the life-cycle of a construction project can be taken into account. In addition to different cost types, different calculation methods can be used. In general, a distinction is made between static and dynamic methods [10]. This study uses the NPV-method for the life-cycle cost analysis. With the NPV method it is possible to estimate the difference between the present value of cash inflows and the present value of cash outflows over a period of time [11].

$$NPV = \sum_{t=0}^{N} \frac{R_t}{(1+i)^t} \tag{2}$$

where:

R_t = net cash inflow-outflows during a single period t
i = discount rate or return that could be earned in alternative investments
t = number of time periods

In particular, the usage cost and the assumed calculation parameters are of great importance for the results of LCCA [10]. In addition due to the uncertainties in assumed calculation parameters, the uncertainty of LCCA results is increased with increasing reference study period. Dominance analyzes, sensitivity analyzes and risk analyzes were performed to estimate the uncertainty of results. Dominance analysis is an appropriate analytic technique to identify the relative importance of predictors of an outcome [13, 14].

According to the ISO 15686-5 sensitivity analysis is defined as the test of the outcome of an analysis by altering one or more paramaters from initial value(s). A sensitivity analysis can reveal how precise the calculation is, and how it affects the calculation if the inputs were different. Sensitivity analysis helps to identify input data with the highest impact on the LCCA results and the robustness of the final decision. Finally, for evaluating the opportunity and risk potential of the results Monte-Carlo simulations are applied. Monte-Carlo simulation is a numerical method that runs simulation with random numbers. Within the Monte-Carlo simulation, it is possible to determine probability distribution functions based on defined calculation rules [15].

3. Case study - Koralmtunnel

In the course of LCCA, two calculation runs were carried out. In the first calculation run, the classification of CPs made at the beginning was compared with an extreme value scenario (cooling of all CPs with air-conditioning systems). It turned out that the high energy requirement for cooling to low target temperatures with air-conditioning systems was the driving cost factor. Based on the first results the extreme value variant was excluded after the first calculation run. Furthermore, scenarios with target temperatures in the utility rooms above 35 °C were excluded for reasons of occupational safety during maintenance and repair. The adapted classification of CPs (four scenarios) is shown in figure 3.

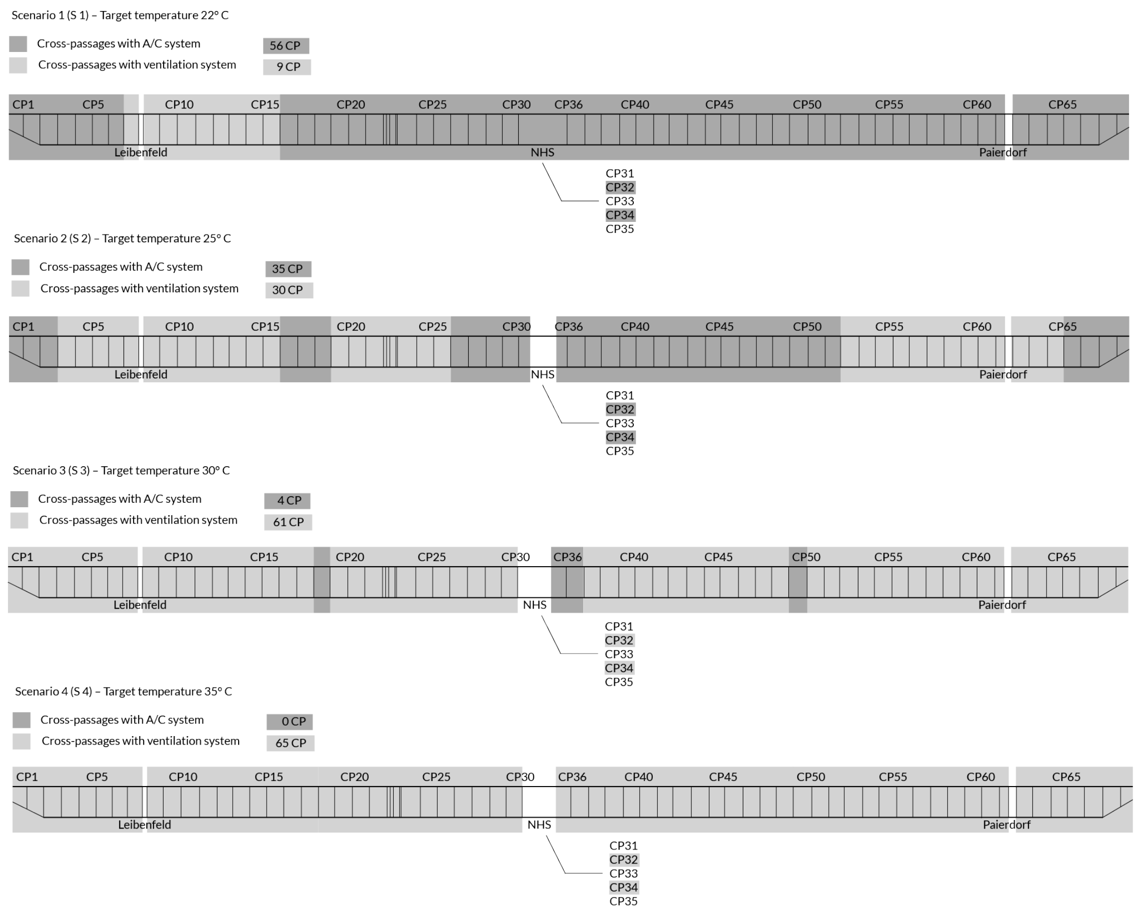

Figure 3. Classification of CPs depending on different target temperatures

The darkgray areas represent the CPs with air-conditioning systems and the lightgray areas the CPs with ventilation system. In all target temperature scenarios the CPs without utility rooms for technical equipment (CP 31, CP 33, bypasses and fire brigade accesses) are not considered.

The required input parameter for the application of the LCCA is shown in table 2. The values were given on the basis of literature research and from the experience of the project partners.

Table 2. Initial input parameter LCCA - Scenario 3 (target temperature 30 °C)

Input parameter	Value
Reference year	2025
Interest rate	4.0 %
Rate of price increase	2.5 %
Rate of energy price increase	2.75 %
Energy price	0.125 €
Initial construction cost air-conditioning systems	211377 €
Initial construction cost ventilation system	89094 €
Initial construction cost telecommunication systems for standard CPs	178265 €
Initial construction cost telecommunication systems for CPs with base station	385516 €
Adaption, refurbishment and repair cost air-conditioning systems	3 % of CC/year
Adaption, refurbishment and repair cost ventilation system	6 % of CC/year
Adaption, refurbishment and repair cost telecommunication systems for standard CPs	11.3 % of CC/year
Adaption, refurbishment and repair cost telecommunication systems for CPs with base station	11.3 % of CC/year
service life air-conditioning systems	10 years
service life ventilation systems	20 years
service life telecommunication systems for standard CPs	9 years
service life telecommunication systems for base station CPs	9 years
Operating hours air-conditioning systems	8760 h/a
Operating load scenario air-conditioning systems (Year 1 to 4)	25 %
Operating load scenario air-conditioning systems (Year 5 to 9)	28 %
Operating load scenario air-conditioning systems (Year 10 to 24)	29 %
Operating load scenario air-conditioning systems (Year 25)	31 %
Operating load scenario air-conditioning systems (Year 26 to 44)	31 %
Operating load scenario air-conditioning systems (Year 45 to 50)	33 %
Operating hours ventilation systems (Year 1 to 4)	2600 h/a
Operating hours ventilation systems (Year 5 to 9)	2700 h/a
Operating hours ventilation systems (Year 10 to 24)	2750 h/a
Operating hours vventilation systems (Year 25)	3200 h/a
Operating hours ventilation systems (Year 26 to 44)	3256 h/a
Operating hours ventilation systems (Year 45 to 50)	3500 h/a
CPs with air-conditioning systems	4
CPs with CS	61
Standard CPs	57
Base station CPs	8

For the NPV-method, all input parameters were compounded to the reference year 2025. Dynamic energy consumptions were determined for a realistic picture of the temperature development due to climate change. This is why an increasing energy consumption is emerging in the cooling of the utility rooms over the years. As a result, higher operating hours of the ventilation systems and higher operting load scenarios of the air-conditioning systems are required.

4. Results

This section presents the decision aiding process based on the results of the LCCA. To deal with the uncertainties in the assumptions, the results of dominance analysis, sensitivity analysis and risk analysis are also presented.

4.1. Comparison of scenarios

In figure 4 the results of the four CPs classifications (S1, S2, S3 and S4) are shown.

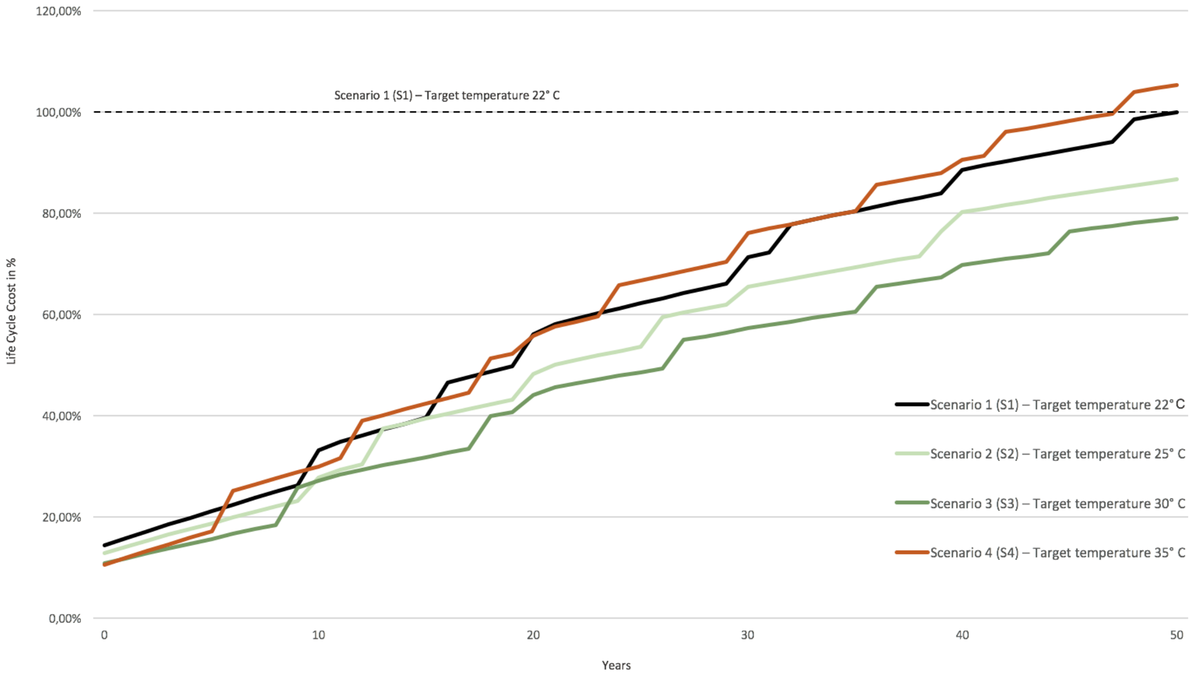

Figure 4. LCCA comparision of scenarios

As shown in the illustration, scenario 3 (darkgreen line) has the lowest life-cycle cost after 50 years. Based on this scenario, the course of jumps and slopes over the considered life-cycle are explained.

In the construction phase, the initial construction cost of air-conditioning systems, ventilation systems and telecommunication systems are incurred. The initial construction cost for scenario 3 involves the cost of 4 air-conditioned CPs and 61 ventilated CPs. All 65 CPs will be equipped with telecommunication systems (8 of them with telecommunication systems for base stations). The slope up to the year 9 results from the annual cost for the energy consumption for the cooling as well as from the annual adaption, refurbishment and replair cost for air-conditioning systems , ventilation systems and telecommunication systems. The jump in year 9 results from the first replacement cycle of telecommunication systems. The next jump in year 10 results from the first replacement cycle of the air-conditioning systems. Based on dynamic energy consumption, the slope between jumps is always a bit steeper over the years. Further jumps occur in the years 18 (second replacement cycle of telecommunication systems), in the year 20 (second replacement cycle of the air-conditioning systems and first replacement cycle of ventilation systems), in the year 27 (third replacement cycle of telecommunication systems), in the year 30 (third replacement cycle of the air-conditioning systems), in year 36 (fourth replacement cycle of telecommunication systems), in year 40 (fourth replacement cycle of the air-conditioning systems and second replacement cycle of ventilation systems) and in year 45 (fifth replacement cycle of the telecommunication systems).

Compared with sceantio 1 (black line in figure 4), which was adopted as a reference scenario (100 % after 50 years), scneario 3 reduces life-cycle cost by up to 20 %.

4.2. Dominance analysis

In the course of the dominance analysis, the most influencing factors on the overall result. were identified. Figure 5 shows the influence of the different cost categories in a sankey diagram. The considered cost categories are assigned to the technical systems (air-conditioning systems, ventilation systems and telecommunication systems) on the right side of the sankey diagram. Telecommunication systems of standard CPs and telecommunication systems of CPs with base stations were merged in this illustration.

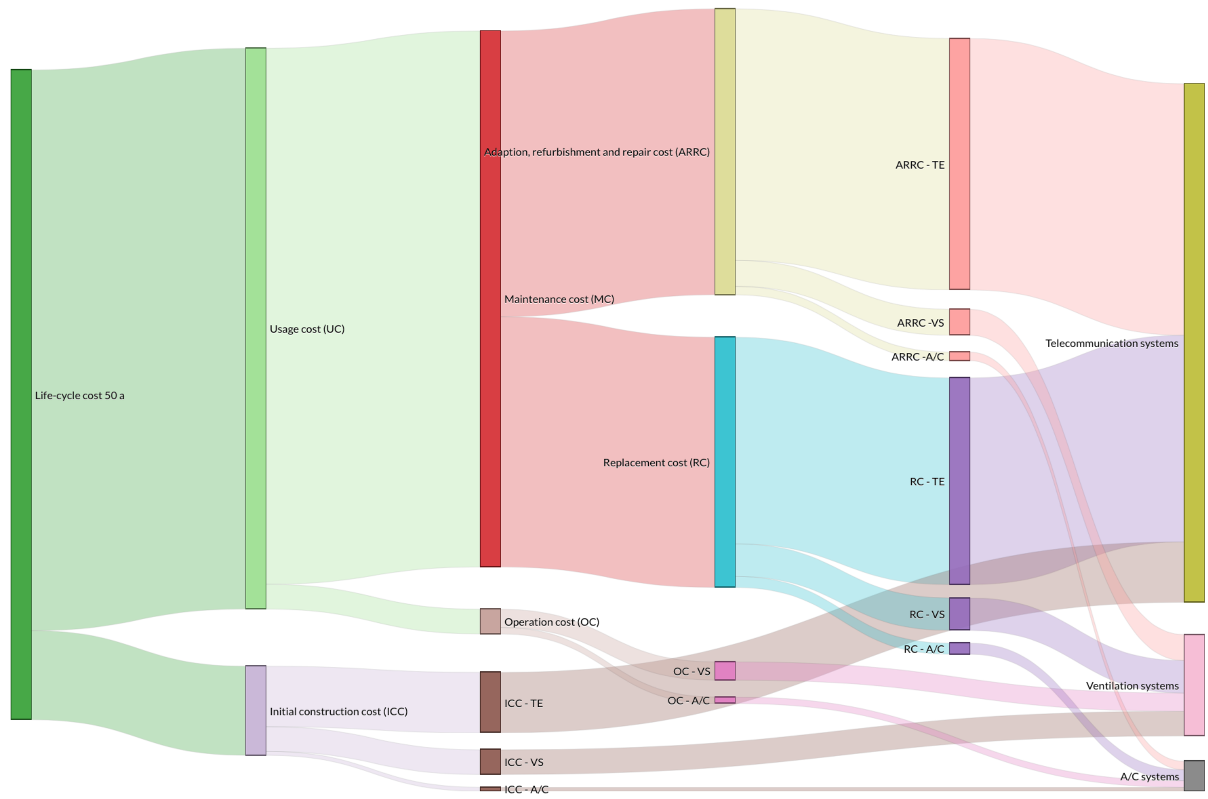

Figure 5. Sankey diagram for scenario 3 (target temperature 30 °C)

The life-cycle cost after 50 years are initially divided into approx. 86 % on usage cost and approx. 14 % on initial construction cost. A closer look at initial construction cost shows that the air-conditioning systems have a very small influence on the initial construction cost, followed by the initial construction cost of ventilation systems and telecommunication systems. The usage cost are divided into maintanencance cost and operation cost. 73% of operation cost come from the energy consumption of the ventilation systems and 27 % from the energy consumption of the air-conditioning systems. The maintanencance cost are divided according to ISO 15686-5 in adaption, refurbishment and repair cost and replacement cost. The adaption, refurbishment and repair cost has a share of 53 % and the replacement cost a share of 47 %. Most of the adaption, refurbishment and repair cost comes from the telecommunication systems. These make up the decisive contribution with a share of 88 %. The second largest share is the adaption, refurbishment and repair cost of ventilation systems with 9 %. The remaining 3 % is provided by adaption, refurbishment and repair cost of air-conditioning systems. Even in the replacement cost the decisive stem from replacements of the telecommunication systems (replacement cycle every 9 years) with 83 %. Followed by the replacements of the ventilation systems with 13 % and the replacements of the air-conditioning systems with 4 %. In the right part of the sankey diagram, all cost categories are transferred to the technical systems. It can be clearly seen that the telecommunication systems account for the largest share of life-cycle cost (80 %.). The contribution of the ventilation system to the overall life-cycle cost is 17 %. Due to the low active cooled cross-passages (only 4 CPs with air-conditioning systems), the share of air-conditioning systems is only 3 %.

4.3. Sensitivity analysis

In the first step of the sensitivity analysis, based on the assumed initial input parameters (table 2), the parameters are changed individually and the effect on the life-cycle cost after 50 years was analysed. This procedure identifies the most sensitive parameters for influencing the overall life-cycle cost after 50 years.

Table 3. Sensitivity analysis for scenario 3 (target temperature 30 °C)

Initial input parameter	Minimum threshold	Input parameter	Maximum threshold
Interest rate	3.0 %	4.0 %	5.0 %
Rate of price incease	1.5 %	2.5 %	3.5 %
Rate of energy price increase	1.75 %	2.75 %	3.75%
Energy price	0.0625 €	0.125 €	0.1875 €
ARRC[1] ventilation systems	0 % of ICC[2] /year	3 % of ICC/year	8 % of ICC/year
ARRC air-conditioning systems	1 % of ICC/year	6 % of ICC/year	11 % of ICC/year
ARRC telecommunication systems	6.3 % of ICC/year	11.3 % of ICC/year	16.3 % of ICC/year
Service life ventilation systems	15 years	20 years	25 years
Service life air-conditioning systems	5 years	10 years	15 years
Service life telecommunication systems	4 years	9 years	14 years
Operating hours air-conditioning systems	3760 h/a	8760 h/a	13760 h/a
Operating load scenario air-conditioning systems	11 %	31 %	51 %
Operating hours ventilation systems	1200 h/a	3200 h/a	5200 h/a

1 Adaption, refurbishment and repair cost

2 Initial construction cost

In figure 6 the fluctuation of the considered input parameters after 50 years is shown. Accordingly, the economically positive effects are shown with the dark gray bars (below 100 %) and the negative effects are shown with the light gray bars (more than 100 %). The 100 % line represents the life-cycle cost after 50 years with unchanged input parameters (initial input parameters in table 2). The most sensitive screw within the life-cycle cost analysis is the service life of the telecommunication systems. If this information differs by 5 years (from 9 years to 14 years), the total life-cycle cost would increase by more than 45 %. The second and third most important parameters are the interest rate and the rate of price increase. With a fluctuation of the interest rate and the rate of price increase by plus/minus 1 % the life-cycle cost would increase by more than 20 %.

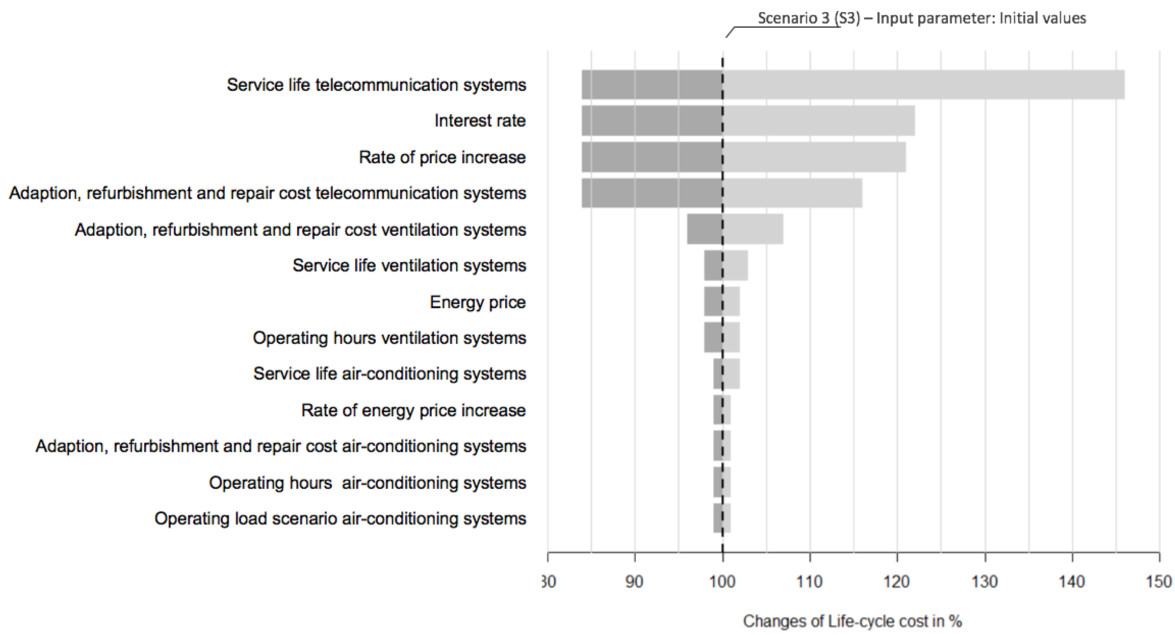

Figure 6. Sensitivity analysis of input parameters of scenario 3 based on the minimum and maximum thresholds (see table 3)

As shown in figure 6, the adaption, refurbishment and repair cost of the telecommunication systems - increasing life-cycle cost by more than 15 % at 5 % higher adaption, refurbishment and repair cost of the telecommunication systems - and the adaption, refurbishment and repair cost of the ventilation systems - increasing life-cycle costs by more than 6 % at 5 % higher adaption, refurbishment and repair cost of the ventilation systems - are also decisive parameters.

4.4. Risk analysis

In the course of the risk analysis it is examined with which probability the economically best scenario (S3 - target temperature 30°C) with fluctuating input parameters also remains the best scenario. For this purpose, the input parameters (interest rate, rate of price increase, rate of energy price increase and energy price) are stored within their bandwidths (see table 3) with a probability of occurrence. For the calculations, it was assumed for the parameters considered that the probability of occurrence between the lower and upper thresholds was 68.27 % (which corresponds to a standard deviation of sigma). Within these bandwidths random numbers were determined by Monte-Carlo simulation.

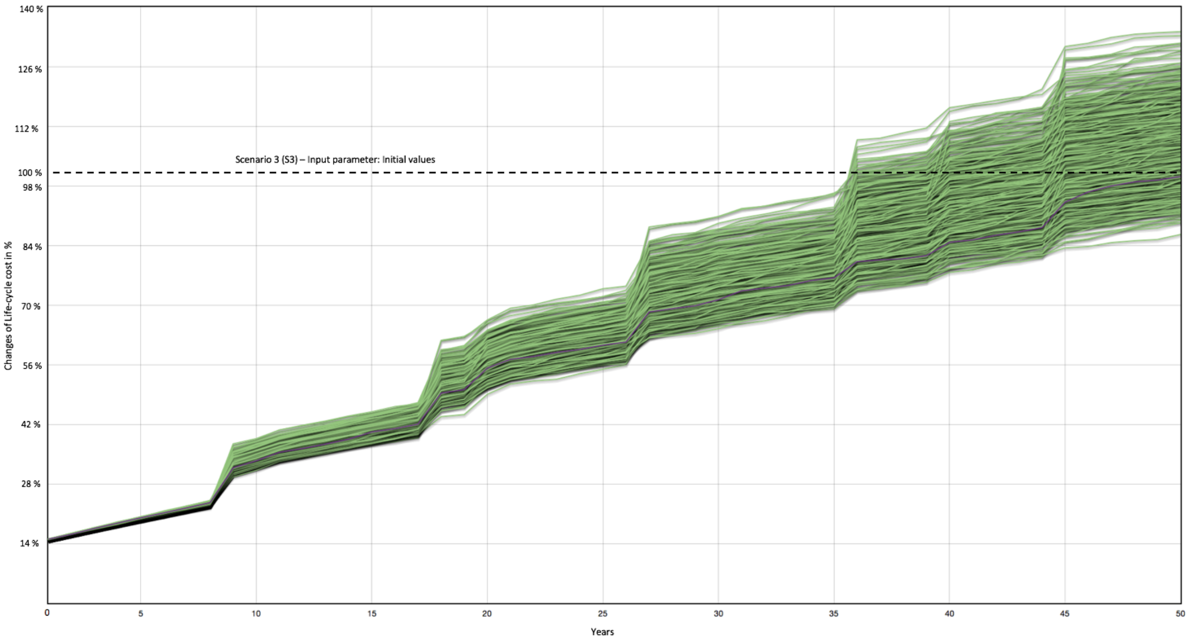

Figure 7. Risk analysis scenario 3

Figure 7 shows the range of life-cycle cost for scenario 3. As already mentioned, a large amount of uncertainty arises as the reference study period increases. In the year 50, due to fluctuations in the parameters, in best case up to 15 % lower and, in worst case, up to 30 % higher life-cycle cost could occur. A comparison of all 4 scenarios in a risk analysis is not required. A different fluctuation of the input parameters in different scenarios can not occur.

5. Discussion

The first calculation run has shown that the decisive input parameters are the required cooling energy for air-conditioning systems and ventilation systems. This required energy input is significantly influenced by the classification of the cross-passages (cooling with air-conditioning systems or ventilation systems). From these findings, the extreme value scenario (all CPs equipped with air-conditioning systems) was discarded after the first calculation run and the focus was placed on the reduction of the required energy demands. The most obvious optimization measure with regard to the reduction of the life-cycle cost was the change of the cross-passages classification. With higher target temperatures, it is possible to equip less cross-passages with air-conditioning systems and thus reduce the energy consumption.

After completion of the second calculation run, it was found that, the cross-passage classification for the target temperature 30 °C (scenario 3) is the most economical scenario over a period of 50 years,.

Allowed target temperatures of 35 °C (scenario 4) exceed the life-cycle cost of scenario 3. The reason for this is that at 35 °C target temperatures the decisive parameter is the replacement cycle of the telecommunication systems (every 3 years). This huge cost factor can not be compensated with the reduced energy demand in scenario 4 (no CPs equipped with air-conditioning systems).

In the dominance analysis, it can be seen that the cost drivers for the most economic scenario are the maintenance cost of the telecommunication systems. This finding is also confirmed by the sensitivity analysis carried out. The uncertainties in the service life of the telecommunication systems would most affect the overall life-cycle cost. The final risk analysis repeatedly emphasizes that life-cycle cost analyzes are always subject to uncertainties. Future developments of interest rates or price increase rates can not be predicted and can therefore only be taken into account with scenario analyses.

6. Conclusion

In the course of the study, it has emerged that an accompanying life-cycle cost analysis has a medium to long-term economic advantage in the construction of railway projects. The life-cycle cost can be considerably reduced, if the results of the LCCA are incorporated into the planning of cross-passage classification iteratively. Due to the great influence of energy consumption, the location of technical equipment (power units for low voltage, medium voltage, transformer systems and telecommunication systems) should be determined early in order to calculate the resulting waste heat in detail. Therefore, the design of the utility rooms should be tailored to the technical equipment in an early design stage.

Abstract. Solving the problems of high energy consumption and high emissions generated by the urban road systems is of great importance for the construction of low-carbon cities. Several tools have been developed to establish a method to evaluate the carbon emission related to the life cycle of road pavements. However, the lack of key basic data such as energy consumption, pollutants and carbon emissions, and accurate management policies have hindered the transition of urban roads to clean, low-carbon systems. The HERMES project aims to compile long-term dynamic inventory of urban road energy consumption and environmental emissions and build a life cycle model. The Data Envelopment Analysis model will be used to predict the energy saving and emission reduction potential of urban roads depending on the technological solution, establish a multi-criteria evaluation system that includes energy, environment, and economic parameters, identify the best available technological solution in different cities, and propose a more targeted and effective clean low-carbon management policies. The study will provide an accurate understanding of the environmental impact of urban roads in China and Europe, evaluate the potential for energy saving and emission reduction, and provide theoretical data and decision-making reference for a clean, low-carbon transition.

1. Introduction

More than 275 million tons of asphalt are produced every year in Europe alone for maintenance and rehabilitation of roads (1). This consumes large amounts of resources and contributes to the emission of greenhouse gases (GHG). This equals approximately 30 million tons of CO_{2eq} emissions from the production of asphalt for maintenance and rehabilitation alone (EPD Norway). However, roads are heterogeneous in their design and construction; the global warming potential (GWP) associated to these operations shows a large variation, depending on the material composition, procedures and maintenance. Typical values vary from almost neglectable to 60 000 tons of CO_{2eq} per lane km over a 50 year time

period (2). In order to reduce the negative impact related to maintenance and rehabilitation of urban roads, the goal of HERMES project is to provide a methodology enabling the selection of the best available technology and strategy with the lowest cost for the environment and society.
The final output of the project would therefore be a matrix usable by road owners and contractors to define, based on the local conditions, regulations, restrictions and technology availability the best solution for the construction or maintenance of the road in terms of environmental factors, financial investment and local boundary conditions.

2. Objectives and targets

Targets for a greener future are being set worldwide. To achieve these goals, a shift towards more sustainable technologies is required in all fields including road construction, maintenance and rehabilitation. Better asphalt mixtures and technologies have a great potential to contribute to the reduction of greenhouse gases, pollution and energy consumption (3). The introduction of a procurement system based on sustainability criteria could encourage the development of more efficient and durable solutions. Several methodologies (LICCER, CEREAL, EDGAR (4, 5)) have already been developed and EPDs are becoming a standard procedure: the general trend highlights the shift towards more environmentally friendly technologies. The limited success, in terms of direct use by others, of the previous projects was due to several factors such as the extend of the life cycle considered, the flexibility in considering additional new technologies, the possibility to adapt the tool to local conditions and requirements and most important user friendliness and practicality. It has therefore been of crucial importance to consider all those factors already from the conception of the project.

A suitable tool to analyse the operations connected to road construction, maintenance and dismantlement thoroughly is represented by Life Cycle Assessment (LCA) . Previous researches have highlighted the most important inputs, system boundaries, functional units and limitations connected to the LCA of pavement infrastructure (6, 7); furthermore, LCA is a holistic tool that can be used to assess the impact of using both traditional and alternative materials (8). LCA is a data-intensive methodology strongly dependent a variety of inputs connected to various scientific fields; acknowledging the deficiencies of the LCA conducted so far can allow HERMES study to define a more transparent assessment framework, thus contributing in synergistic fashion the literature and previous researches (9, 10).

The overall objective of the HERMES project is to establish a long-term dynamic inventory of carbon emissions deriving from the analysis of a variety of urban roads, based on best practices is Europe and China. The main research tasks are connected to the following areas:

1. Energy consumption and emission patterns throughout the life cycle,
2. Best available technologies for road pavements,
3. Clean and low-carbon construction and maintenance operations.

The project aims to improve emission reduction management policies that can be adopted to promote the sustainable development of urban road systems in China and Europe. Currently there is no cross-national comprehensive comparison regarding the different road design methods and their environmental impacts on the service-life in different urban settings and climate zones.

The development of HERMES project will be based on the following criteria:

- User-friendly and global
- Comprehensive
- Sustainability oriented
- Performance oriented
- Tested in collaboration third parties.

To achieve the main objective, the following targets have been identified (refer to figure 1 for short work package (WP) description):

1. Review of the available methodologies and technologies for the assessment of green asphalt (and other construction materials) (WP3)

2. Analyse the procurement processes including a sustainability assessment (WP3)
3. Broaden and improve the data inventory by including information about pavement life time prediction (WP3 and 4).
4. Assess the effects of maintenance schedule on emissions (WP5).
5. Test the validity and usability of the HERMES tool (WP6)
6. Establish the bases for further implementation and cooperation (WP2, 3 and 6).

In order to avoid a strictly national approach, the project acknowledges that road construction operations are influenced by climate mitigation policies that contribute to different SDGs (Sustainable Development Goals). Thus, a more integrated approach can allow for a broader understanding of mutual dependencies in the development of road construction. This will provide a more detailed insight into the actual design and operating of road constructions.

Moreover, the project is especially aimed at creating a management system able to take into account the pavement life cycle, environmental, social and economic issues. Special emphasis is put on how the management and monitoring operations are performed when it comes to evaluate climate change policies. For a better mutual understanding and implementation, the methodologies will be applied in trial road sections in both Europe and China.

The project involves trans-national cooperation between Norway, Austria and China, and is meaningful for both research institutes and stakeholders of road construction projects. The collaboration also addresses how road constructions in Norway, Austria and China approach sustainability assessment in their strategies. Therefore, HERMES project entails the exchange of knowledge, analysis of policy making strategies and identification of differences in planning frameworks at an international level.

The LCAs connected to HERMES project take the first steps considering the limited amount of literature currently available regarding pavement infrastructure. These investigations have been carried out on countries that are geographically close to the nations involved in the HERMES project: Sweden (11), Finland (12), Switzerland (13), South Korea (14) and Taiwan (15).

The project contributes to ongoing scientific discussion by adopting different interdisciplinary insights. On one hand, the project provides a more practice-oriented research perspective to sustainability assessments, at road constructions which enables to discuss how the context of urban processes and subsystems is conceptualized in these assessment methodologies. Rather, this project aims at developing ways to contextualize assessment methodologies from the perspective of stakeholders' practices. On the other hand, the project provides a more assessment-oriented research perspective to practice and transition studies in relation to sustainable development.

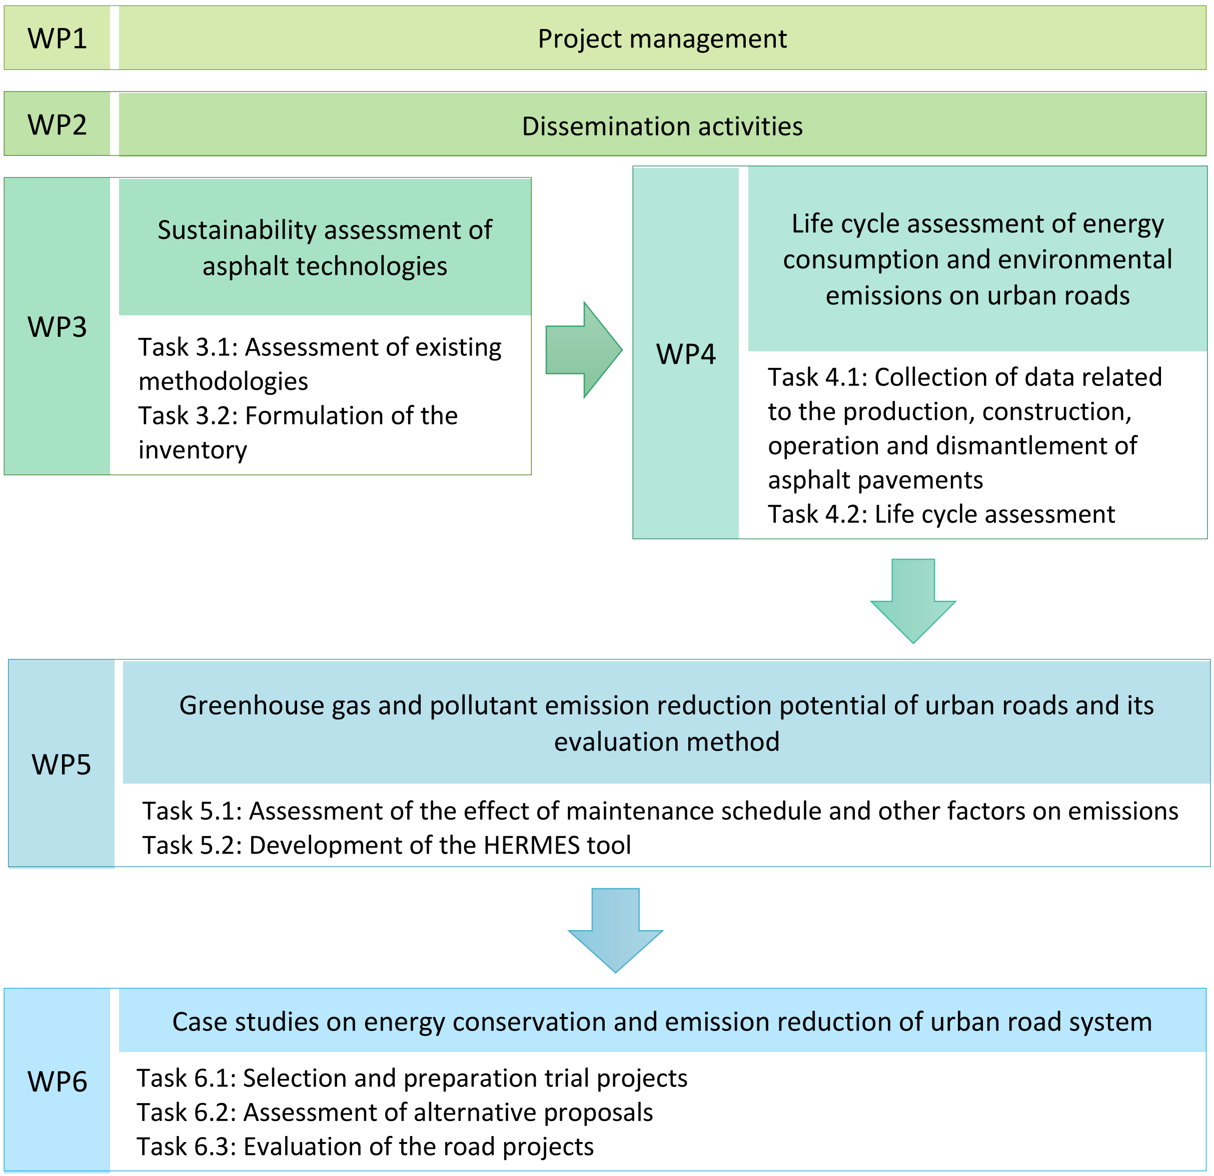

Figure 1: Work package description

3. Key activities

The overall objective of the project is to create a tool able to help both stakeholders and contractors reducing the impact of pavement maintenance and rehabilitation on the urban environment in terms of both energy consumption, emission and pollution production, efficiency and cost-effectiveness through a more efficient and effective planning. At the end of the project, the existing gaps will be filled, and a functional methodology will be available, rising the technology readiness level from 5 to 8. Therefore, the project will start from an analysis of previously developed tools and procurement processes based on sustainability criteria leading to the formulation on the basic framework of the HERMES project (WP3). At the same time a high resolution dynamic inventory of emissions from urban roads construction and maintenance will be created (WP3).

Once the energy consumption and emission sources have been identified and analysed, an appropriate life cycle analysis method (Simapro and Ecobalance) will be used to quantify the effects of urban road systems on resources, energy and environment in both the Chinese and European case (WP4). Great importance will be put in the uncertainty/variability assessment of the different indices used in the analysis.

The next step (WP5) is focused on the development on the HERMES tool based on considerations on how other factors, such as pavement service life, maintenance schedule, and innovative technologies influence the computation of the technical indices. In this step it will be important to emphasize user-friendliness and flexibility of the tool. The tool shall be able to integrate the evolution of energy saving and emission reduction potential with management strategies for the urban road systems. Collaboration and cooperation between the partners and dialogue between the work-packages will be central enabling factors to facilitate and make the success of the project possible.

While the other work packages will progress towards the development of the HERMES tool, the WP6, centred on its utilization, will start its activities in large advance to guarantee a smooth cooperation with the local stakeholders and contractors during the preparation of the procurement tender and contract documents. The extended period of time will also allow the contractors to gather data and information to calculate the technical indices to be considered in the procurement process. Once the alternative proposals will be assessed, the partners will evaluate the case studies and how stakeholder and contractors interacted with the HERMES tool.

4. Expected impacts

The expected outcome of the HERMES project is to analyse effective ways of assessing environmental impact of both present and future urban road systems. The project interdisciplinary approach enables a meaningful connection between stakeholders of road construction projects, policy maker practices and sustainability assessments.

A major challenge of the project is to ensure a proper holistic integration of the many perspectives and interests of the involved parties. The non-hierarchical structure of management should facilitate the execution of such an interdisciplinary project.

The potential users of research project are mainly stakeholders of road construction projects, policy makers in municipalities and similar organizations that are responsible for developing strategic plans and project concerning climate mitigation solutions. The project is also intended to challenge the national and international policy making systems (like that of the European Union), since these often play an important role in defining the planning framework for the development and access to strategic plans. There is a general need to recognize the difficulty of bridging between the local complexity of specific plans and projects, and the abstract methodological complexity of sustainability assessments. This challenge can only be addressed through a more thorough understanding how these issues intersect in the practices of policy makers.

Since the project entails a tight Sino-European collaboration, the differences in creating policies are important to be taken into account. Generally, when a study is carried out at a purely national level, the specific social, technical, geographical and organizational norms of the country are often neglected or overlooked. A trans-national project will ensure that these critical differences between different countries involved in the project are surfaced and addressed. Such a trans-national perspective will also contribute to help to address the scaling challenges more specifically, since it will become clear that the three countries operate within similar global contexts, but within different national and local conditions.

5. Expertise of the consortium

The project brings together a unique combination of research knowledge and expertise to underpin the development of the HERMES tool at international level. The consortium is formed by five research institutions (SINTEF, Graz University of Technology – TUG, Norwegian University of Science and Technology – NTNU, Wuhan University of Technology – WUT and Shangdong University) with key knowledge in the project's topics and an enterprise (Zement+Beton Handels- und W. GmbH (Z+B)) who has already widely contributed to the development of sustainable solutions for concrete roads with the implementation of tools and regulation for their construction and maintenance.

This consortium combines environmental, technical and social research competences, hereby representing a truly interdisciplinary consortium that analyses quantitative sustainability assessments and social dynamics of change and practices in relation to technical infrastructures and networks in an urban context. This provides a more holistic basis for developing assessments tools and methods to be more effectively adopted to achieve reductions in GHG emissions through climate mitigation policy making. The partners have a well-recognized leadership, expertise and skill in the following crucial areas for the project:

- Management and coordination: SINTEF
- Greenhouse gas and pollutant emission: NTNU, TUG, Shangdong University and WUT, Z+B
- Energy consumption: TUG, Shangdong University
- Life cycle analysis: NTNU, TUG, Shangdong University, Z+B
- Road materials: SINTEF, NTNU, WUT
- Life cycle cost assessment: SINTEF, NTNU, Shangdong University, Z+B
- Road pavement construction, maintenance and rehabilitation: SINTEF, NTNU, WUT,
- Z+B
- Communication, dissemination and exploitation of results: SINTEF, NTNU, TUG,
- WUT, Shangdong University, Z+B

For the assessment of existing methodologies, a large effort is expected by all partners. The internationality of the group allows to gather information about projects and procurement processes using sustainability indicators to evaluate road pavements around the globe, giving the opportunity to finally extend the analysis to the Asian context that because of language and cultural barriers has always been difficult to approach. The involvement of other research groups and local stakeholders will be necessary.

Shangdong University and WUT, together with TUG, Z+B and NTNU will also have an extremely important role in the assessment of both emissions (including greenhouse gas and VOCs) and energy consumption due to pavement construction and maintenance. During this phase the partners will gather information also through direct contact with local contractors.

SINTEF, NTNU and WUT are nationally and internationally known for their expertise in pavement design, maintenance and rehabilitation. Their knowledge, previous research projects and local contacts will be used to assess the service life of different pavement technologies. Their impact on emissions and energy consumption will then be assessed by TUG, Shangdong University and Z+B.

A common effort will be put in the development of the HERMES tool and in the case studies.

Acknowledgments

This project is supported by the Research Council of Norway (NFR), National Natural Science Foundation of China (NFSC) and Austrian Research Promotion Agency (FFG).

Abstract. Phosphogypsum (PG) is the most abundant by-product generated by the phosphate fertilizer industry. Formed during the production of phosphoric acid from natural phosphate rock, PG is mostly disposed in stacks or released into coastal regions' waters. Due to the expected increase in the world PG production – currently estimated to be around 250 Mt per year – and the environmental impacts of actual waste management scenarios, there is a call for a paradigm shift, by considering PG not as a waste but as a resource. About 15% of the total PG production is nowadays used as fertilizer, retarder, road base material or building material. The load of radionucleids and heavy metals contained in PG however questions the sustainability of such valorization routes. This paper aims to compare the environmental impacts of different PG valorization scenarios through life cycle assessment. Based on Moroccan conditions for phosphoric acid production, it discusses the key parameters influencing the assessment as well as assumptions regarding the allocation of emissions and resource use over PG and phosphoric acid.

1. Introduction: Phosphogypsum: waste or resource?

Phosphogypsum (PG) is the most abundant by-product generated by the phosphate fertilizer industry. It is formed during the wet production process of phosphoric acid, after digestion of natural phosphate rock with sulpuric acid (eq. 1). On average, the production of 1 ton of phosphoric acid (as P_2O_5) generates 5 tons of dry PG [13].

$$Ca_5F(PO_4)_3 + 5H_2SO_4 + 10H_2O \rightarrow 3H_3PO_4 + 5CaSO_4{\cdot}2H_2O + HF \qquad \text{(eq. 1)}$$

PG is mainly composed of gypsum but also contains impurities such heavy metals (Pb, Cd, As...) and radionucleids (Uranium-238, Thorium-232 and their daughter elements such as Ra-226), naturally occuring in the phosphate ore [3],[7]. Because of its low radioactivity, PG has been considered as a waste and is mostly stored indefinitely in open stacks (Florida, China) or discharged into the sea close to coastal regions (Morocco, Tunisia, South Africa...). Both PG disposal routes have environmental impacts and costs [20]; [4];[10];[17].

In 2013, the International Atomic Energy Agency concluded that "[a]ll evidence suggests that the doses received as a result of the use of PG in agriculture, road construction, marine application and in landfill are sufficiently low that no restrictions on such uses are necessary.” [11]. As a consequence, there is a call for a paradigm shift, by considering PG not as a waste but as a resource [12],[5].

Due to the increasing demand in phosphate fertilizers at global scale, PG production – currently estimated to be around 250 Mt per year [19] – is expected to increase, as well as the environmental impacts of actual waste management scenarios. About 15% of the total PG production is nowadays used as fertilizer, retarder, road base or building material [6]. The sustainability and environmental suitability of such valorization routes are however to be investigated.

The objective of this paper is to assess the environmental impacts of PG valorization as road base material throughout its life cycle. It aims at 1) comparing environmental burdens of “conventional” versus alternative road base materials, respectively granulate and PG mixtures; 2) assessing the potential displacement of environmental impacts from a life cycle stage to another; and 3) discussing the influence of allocation approaches on the assessment. It presents preliminary results of a study conducted at the Ecole des Ponts ParisTech in collaboration with the OCP group. Based on Moroccan conditions for phosphoric acid production, it discusses the key parameters influencing the assessment, and assumptions regarding the allocation of emissions and resource use among PG and phosphoric acid.

2. Goal and scope definition

2.1 Goal

The main objective of this study is to compare the potential environmental impacts of formulations used as base layer containing different proportions of PG.

2.2. Functional unit (FU)

The functional unit (FU) considered in this case study is an experimental road pavement structure of 200 m length, with a width of 7 m. The PAP is 25 years. The average annual daily traffic (AADT) is considered to be equal to 15 heavy duty vehicles (HDV)/day. The FU is defined as a “unit of pavement that can safely and efficiently carry the same traffic over the same PAP” [15].

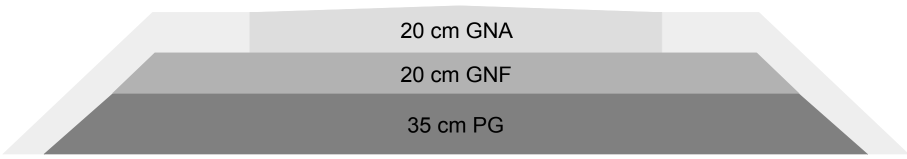

Figure 1 – Experimental road pavement cross section, modified from [14]

The pavement structure (Figure 1) is composed of 20 cm bank-run gravel type A (GNA), 20 cm bank-run gravel type B (GNB), and 35 cm phosphogypsum mixture (PG) as base layer, the latter being under scrutiny. Table 1 presents the formulations of the PG mixture used for the base layer, as described in [14]. The baseline scenario is a base layer composed of 100% granulate. The 4 phosphogypsum mixture scenarios have different proportions of PG and waste rock, and a constant 7% dry mass binder material, as cement 42.5. All materials are produced in Morroco, in less than 100 km radius from the road pavement construction site. As a first approach, it is assumed that the total dry weight of material required for the FU is equivalent for all scenarios (1200 t/UF). This assumption should be further discussed.

Table 1 – Formulation of the phosphogypsum mixture used for the base layer (%dry mass equivalent)

	Baseline	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Granulate	100	0	0	28	0
Cement	0	7	7	7	7

Phosphogypsum	0	57	65	65	93
Waste rock	0	36	28	0	0

2.3 System boundaries

The system boundaries of this study (Figure 2) include the extraction and production of road base material such as granulate, cement and PG; the material transportation from the production site to the road pavement construction site; the on-site laying of the base layer; and its use over the PAP. The PG formulation is assumed to have no influence on the lifespan and maintenance of the road structure. Therefore, extraction and manufacturing of materials for upper layers GNA and GNB are not accounted for, as well as road maintenance processes and the end-of-life (see below). Waste rock generation during phosphate rock washing (see below) is also excluded from the system.

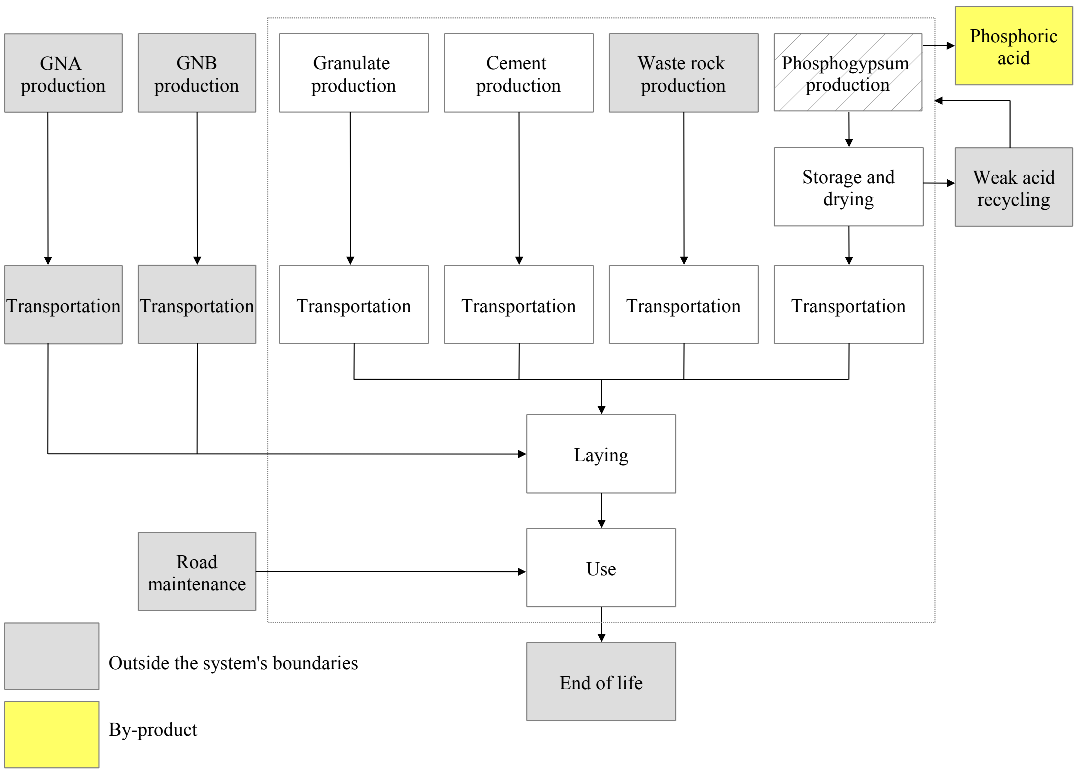

Figure 2 – Flowchart of major processes in the life cycle of a road pavement structure

In order to match Morrocan conditions, manufacturing of virgin materials (granulate and cement 42.5) are adapted from French processes, described respectively in [18] and [2]. Since no electricity mix exists for Morroco, Greek electricity mix from ecoinvent, "*electricity, medium voltage | market for electricity, medium voltage – GR*" is chosen for its proximity with the Morrocan mix (23% coal, 61% oil, 5% gas, 7% biomass, 2% renewable, 2% import, no nuclear energy, ref). It replaces the French electricity mix used in the processes where nuclear energy predominates.

PG production is adapted from the ecoinvent process for phosphoric acid production in Morroco, "*phosphoric acid production, dihydrate process | phosphoric acid, fertiliser grade, without water, in 70% solution state, MA*", described in [1]. After extraction, phosphate rock is beneficiated through screening, washing and flotation. The beneficiation process does not involve adjunction of chemicals. Reaction between beneficiated phosphate rock and sulphuric acid produces phosphoric acid and PG. Substances reported in the original ecoinvent process and emitted during disposal of PG into the ocean are allocated among the use and end-of-life stages, where 100% of heavy metals and radionuclides are leached into groundwater. Emissions, raw material extraction and environmental impacts generated by this multifunctional system are partitioned between the two co-products based on the “cut-off” approach, meaning that environmental burdens are attributed to phosphoric acid alone [16], as a first step. The influence of allocation methods is discussed below.

After attack of phosphate rock with sulphuric acid, the generated PG slurry (30% water content) is conveyed, stored in open tailings ponds and air-dried. Acidic pond water is partially recovered (about 15% of the total volume) and reinjected in the phosphoric acid production process, before adjunction of sulphuric acid [8]. Although this is common practice for Morrocan conditions, the recycling of weak phosphoric acid and the benefits associated with avoided sulphuric acid production are not included in the system. Air-dried PG (15% water content) is recovered for further use. PG recovery thus avoids waste management where PG slurry is diluted in the Atlantic ocean (see above).

Distances and vehicle types for road base materials transportation are taken from [14].

The on-site laying process is assumed to be the same for all formulations, i.e 30 minutes mixing, except for the baseline scenario where no mixing is required [14].

During the use phase, only direct leaching to groundwater of water soluble substances contained in PG is taken into account. While all substances particularly trace elements and radionuclides contained in PG are directly emitted into sea water when disposed into the ocean (avoided waste management scenario), addition of cement to the PG mixture has an inerting effect [9]. Contaminants are trapped in a solidified matrix and only a part is leached with precipitation water. The crucial point is to determine the flows of pollutant potentially tranfered into groundwater. Since no data are currently satisfactory to estimate transfer coefficients, assumptions about the inerting effect of cement are made. It is assumed that 100% of the impurities are emitted into groundwater (no interting effect: worst case scenario), based on the transfer coefficients into sea water estimated in ecoinvent [1]. This assumption will not be discussed in this paper.

Exposure to radioactive substances resulting from airborne particle emissions are usually carefully considered [1]. In our case, phosphogypsum mixtures are used for road subgrade layer construction, the emission of airborne particules from abrasion during the use phase is considered inexistant.

For the end-of-life, it is assumed that the road pavement structure is rehabilitated after the end of the PAP, i.e. after 25 years. Rehabilitation of the road pavement implies scraping the surface course, excavating the base layers GNA, GNB and PG which are mixed together, compacting the road foundation, applying the mixture as base layer and renewing upper layers. As a consequence, the rehabilitated road pavement structure is raised 10-15 cm. The effective lifespan of the road is not known. Since it is assumed that the PG mixture does not influence the rehabilitation frequency and lifespan of the pavement structure, the only discussion is about the long term fate of contaminants and how to allocate pollutants release between the use and the end-of-life. Too many uncertainties are attached with the fate of such structure, the end-of-life is then excluded from the system.

3. Results and discussion

The OpenLCA software version 1.7.4 is used for the modelling of the scenarios and calculation of environmental impacts scores. The chosen impact assessment method is RECIPE (H), at midpoint level.

3.1 Impact assessment

The LCIA scores for the road pavement scenarios are calculated by applying the RECIPE midpoint (H) method. Environmental impact scores are calculated considering that first burdens related to phosphate rock processing is totally attributed to phosphoric production (cut-off approach: Schrivers et al (2016)), second no substitution related to the avoided waste management of PG (disposal into the ocean) is taken into account and third 100% of the heavy metals and radionucleids contained in PG are released into groundwater during the use stage of the road (worst case scenario).

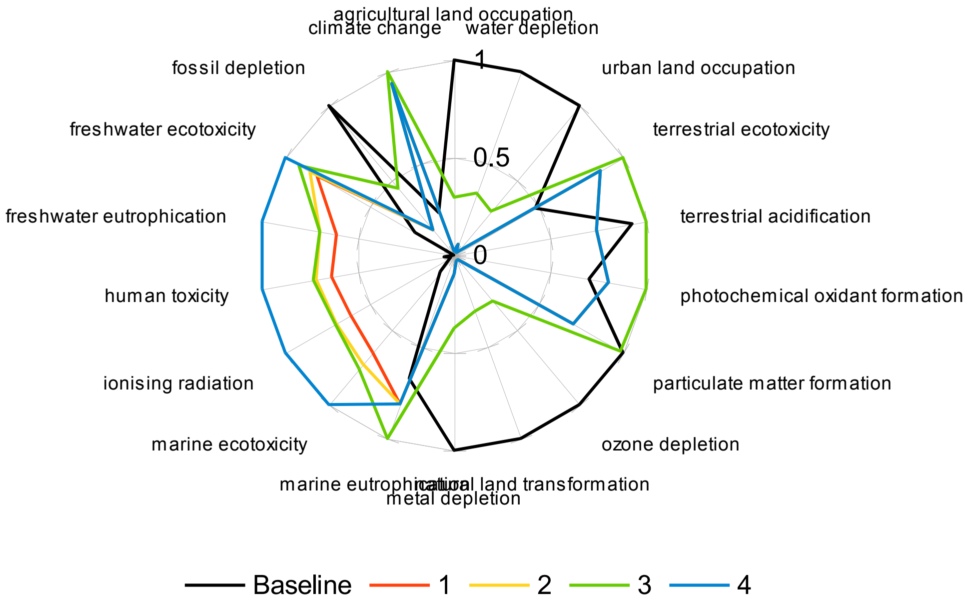

Figure 3 – Relative LCIA results for the road pavement scenarios, calculated with RECIPE midpoint (H), cut-off approach, 100% transfer to groundwater, without substitution

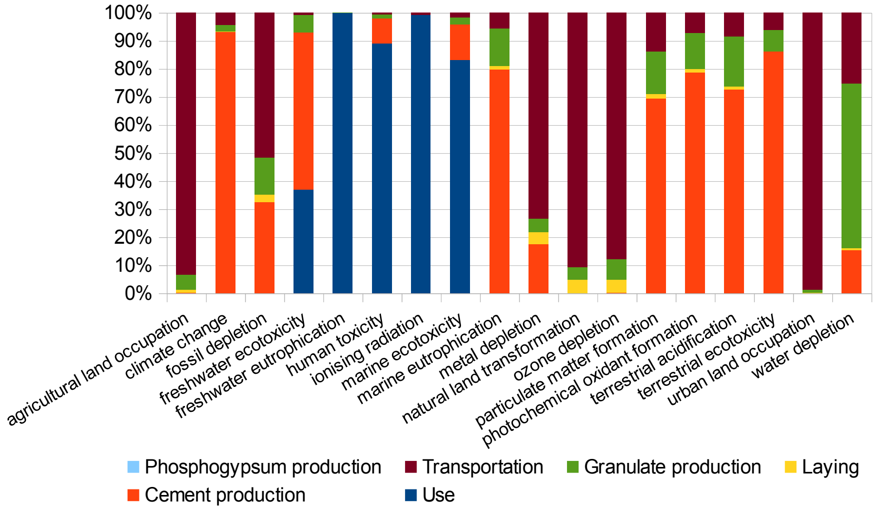
The results presented in Figure 3 show that phosphogypsum mixtures scenarios are improving the environmental performance of the road pavement for impact categories such as ozone depletion, metal depletion and fossil depletion, compared with the baseline scenario (hight impact related to transportation).



(a)

(b)

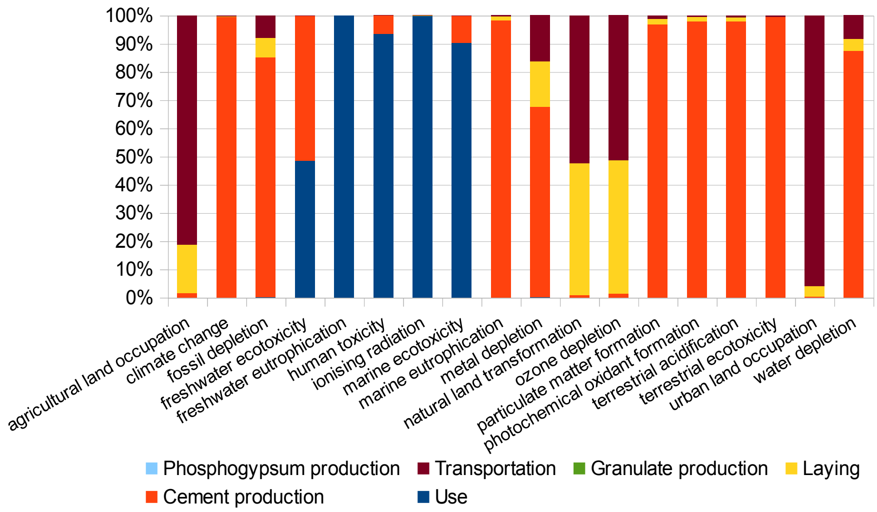


Figure 4 - Relative impacts for a) road pavement scenario 3 and b) road pavement scenario 4, life cycle stages, cut-off approach, 100% transfer to groundwater, without substitution, ReCiPe Midpoint (H)

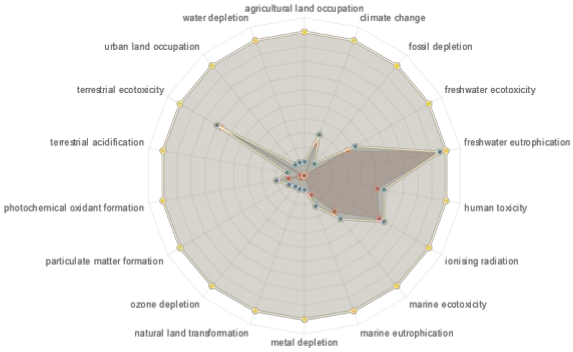
Scenario 4 presents the highest impact scores for freshwater ecotoxicity, freshwater eutrophication, human toxicity, ionising radiation and marine ecotoxicity because of heavy metals and radionuclides transfered to groundwater (Figure 4). Scenario 3 shows the higher scores for impact categories such as terrestrial ecotoxicity, terrestrial acidification, photochemical oxidant formation and climate change. Effects on climate change are related to the production of cement as binder in the phosphogypsum mixtures, as production of cement induces decarbonation.

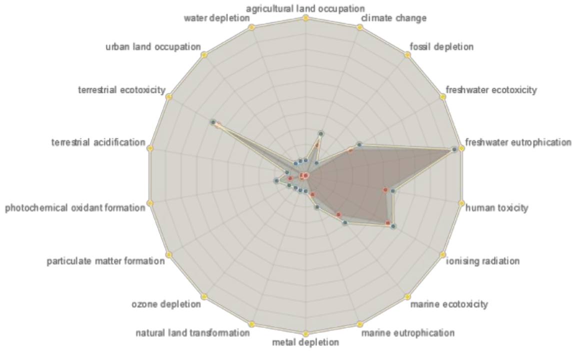
3.2 Sensitivity analysis: influence of allocation methods

PG is generated during the production of phosphoric acid. Previously, emissions, extractions and related impacts have been allocated between the two co-products based on the cut-off approach (Schrivers et al 2016). According to this approach, environmental impacts of phosphate rock extraction and processing are attributed to phosphoric acid alone. The choice of allocation methods however influences significantly the impact scores. Figure 5 compares the relative impacts of scenario 1 to 4 calculated based on the cut-off approach and two other partitioning methods (based on mass and market price of substituted material). With mass allocation, since 1 kg P2O5 in acid and 4.83 kg PG are produced during the processing of phosphate rock, 82.8% of the environmental burdens are attributed to PG. With economic partitioning, it is assumed that 1 t of PG substitutes 1 t of granulate (30 €/t); and 1 t P2O5 in acid worths 350 €/t. Therefore, about 8% of total impacts are attributed to PG.

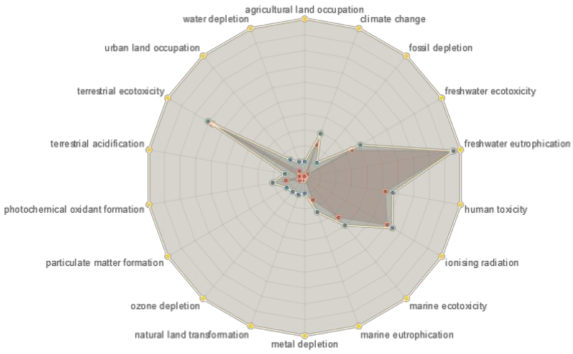
Considering that 100% of the environmental burdens associated with the extraction and processing of phosphate rock are attributed to PG has a significant influence on the calculated impact scores. According to the mass allocation approach, the PG production stage generates the greater impact for almost all categories.



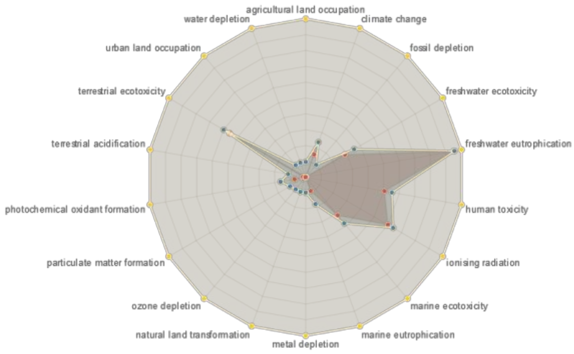
(Scenario 1)



(Scenario 2)



(Scenario 3)



(Scenario 4)

Figure 5 – Relative impacts for road pavement scenarios, according to different allocation approaches (orange: mass allocation; red: cut-off; blue: economic partitioning). 100% transfer to groundwater, without substitution, ReCiPe Midpoint (H)

4. Conclusion

Preliminary results show that, with 100% transfer of heavy metals and radionuclides into groundwater, direct emissions during the use stage of the road pavement structure are responsible for major impacts on human health and ecosystem quality. This assumption however ignores the inerting effect of cement. It is then necessary to specify transfer coefficients from phosphogypsum mixture to groundwater and to take into account the temporality of such transfer. Allocating the effects of heavy metals and radionuclides leaching between the PAP and the long term (end-of-life) has to be discussed as well.

The impact of cement consumption in the PG mixtures predominates for climate change, particulate matter formation and photochemical oxidant formation. Decreasing the proportion of cement in the PG mixture should be investigated parallel to its inerting effect.

Preliminary results are based on the hypothesis of no abrasion during the use phase, because PG is used in the base layer mixture and not in upper layers. Scenarios taking into account abrasion processes and particulate dissemination in different environments (with low to high population density, for example rural and urban areas) are to be discussed for longer PAP.

The impact assessment shows the influence of several parameters. The choice of the electricity mix is important, especially regarding ionizing radiations. There is no ecoinvent electrictity mix for Morocco and the available African electricity mix is not suitable. The allocation method has a great influence on the results. By allocating emissions and extractions based on mass, PG production is the life cycle stage with the higher impact score for most categories.

Finally, substitutions related to the replacement of virgin material (granulate) by phosphogypsum mixtures and the avoided waste management scenario (PG disposal into the ocean) are not taken into account. This should be further investigated.

Towards housing sustainability: a framework for the decision-making process of tenants

Pagani A, Binder C R

Laboratory for Human-Environment Relations in Urban Systems (HERUS), École Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne, Switzerland

anna.pagani@epfl.ch

Abstract. The mismatch between the supply and demand of rental apartments in Switzerland represents an obstacle to the transition towards a more sustainable society. The difficulty for the housing providers to accommodate the fast societal change of the demand brings about an increase in vacancies and, to minimize investment risks, a resistance to innovation in the building sector. In this context, understanding the determinants of tenants' residential mobility and location choice becomes key to designing and promoting sustainable housing. In this paper we present a new interdisciplinary framework for the decision-making process of tenants. To do so, we elucidate the main parameters of the decisions to move and where to move, based on literature review and a group discussion in the Swiss canton of Vaud with the tenants of the two housing providers SCHL and Swiss Mobiliar. We find that the desired housing *function* determines the tenants' housing selection. We observe that this desired function changes according to the type of trigger that pushes tenants to move. Additionally, we elicit the potential sustainability implications of the housing functions in the Swiss context. We conclude that the framework can serve as a starting point for rethinking sustainable interventions in the housing sector.

1. Introduction

Considering that nearly a third of the global final energy use and CO_2 emissions comes from buildings, and that 75% of these are residential [1], the transition towards sustainable housing is crucial. The ways to implement this transition are, however, still unclear. In fact, housing is a central and interconnected part of an urban system, whose complexity makes both the system understanding and its sustainability assessment a difficult endeavor [2]. As a consequence, and despite the many attempts to conceptualize it, housing 'sustainability' remains an ambiguous notion that is rarely regarded – as proposed by the 2015 UN Geneva Charter on Sustainable Housing [3] – in its environmental, economic, social and cultural components. Furthermore, each of these components is often weighted very differently [4] by each of the actors in the housing value chain, whose requirements and expectations do not always coincide [5]. This mismatch manifests itself in the rental housing market, where discrepancies occur between the needs and strategies of the housing providers (e.g., apartments layout, location, features) and the ones of the increasingly fast changing demand (e.g., ageing population, high divorce rate, trend towards single living).

Currently, in Switzerland, the mismatch between the residential preferences of the tenants and the offer of the housing providers is resulting in increasing vacancies [6], which often involve new constructions: in June 2017, 1 in 6 vacant apartments (ownership and rent) was newly-built [6,7].

Therefore, an increase in the number of new low-carbon and zero-energy housing solutions cannot support alone the transition towards sustainability: for these solutions to be effective, dwellings need to be rented. However, this is not possible if buildings and related measures negatively impact users' quality of life e.g., by layout restrictions, occupancy rules, or the need to move to a different home if their circumstances change [8]. In fact, when the buildings cannot accommodate users' needs, these move to adjust their housing disequilibrium [9]. On these premises it becomes clear that ensuring *acceptability* and *acceptance* of housing sustainable solutions is crucial for determining their success, and overcoming the 'innovation resistance' of the building sector.

To understand the factors governing the success of sustainable housing solutions, the identification of the driving factors determining people's decisions has been proven to be key [10]. In the context of residential mobility and location choices, these factors have been studied by a multitude of disciplines [9,11,12]. They can be grouped into the two following categories:

- *The triggers: the determinants of the decision to move*. Triggers are situational or 'push' factors'[11] – such as opportunities (e.g., new job), problems (e.g., noise), changes in family structure – that affect the stress threshold of the household. When this threshold is overcome, the household moves to adjust its housing disequilibrium [9].
- *The determinants for the selection of a new dwelling*. The household perceives its housing environment in terms of characteristics [9], defining both the dwelling (balcony, view, materials) and its context (the location and neighborhood). The characteristics that play a role in the selection of a new dwelling are divided in 'non-substitutable' (must be there) and 'substitutable' (interchangeable) [11].

Concerning the triggers, previous research shows (1) that the determinants of the decision to move are not equally influential and effective in exceeding the household's stress threshold and (2) that these determinants have unequal correlations with the level of satisfaction of the household [9]. Therefore, greater study of the interrelationships between the triggers, the level of satisfaction of households with their dwelling, and the final decision to move is needed. With regard to the determinants for the selection of a new dwelling, studies have prioritized the role played in the decision by the characteristics of dwelling, location and neighborhood, which, grouped in categories, have long defined the building *typologies* used by practitioners (e.g., 'Multi-family residential'), or researchers (e.g. for the sustainability assessment in the construction sector [13]). However, households may not necessarily group the characteristics into categories as theorized by economic publications [9].

Therefore, it becomes clear that, in the context of rental housing, the study of the decision-making process of tenants needs a systemic understanding. To acquire system knowledge and explore the interrelationships between the decision components, we address the following research questions (RQ):

- **RQ1:** Which determinants prevail in the decision for the selection of a new dwelling?
- **RQ2:** How do the triggers influence the decision to move?
- **RQ3:** Is there a relationship between the triggers and the determinants for the selection of a new dwelling?

In this paper we propose an interdisciplinary framework, which links the elements playing a role in the decision-making process of tenants. The framework displays the interaction between supply and demand, advancing the hypothesis that, being the determinant of the system's dynamics, the *function* of housing plays a central role in the housing decisions of tenants. Furthermore, investigating how this desired housing functions can hinder sustainable housing strategies allows us to question how sustainable interventions are currently designed or promoted.

We structure the paper as follows. First, we introduce the methods for identifying the determinants of the decisions to move and to choose a new dwelling. Subsequently, we display the framework obtained, the functions and their validation, and explore the determinants of the decision to move based on the analysis of the qualitative group discussion in the Swiss canton of Vaud. Lastly, we critically review the methods adopted, the results, and our contribution to the practice, and conclude with an overview of the next steps of the research.

2. Methods

2.1. Project Partners

This research was carried out in collaboration with two of the largest housing cooperatives in Switzerland, ABZ and SCHL, and a large insurance company and institutional property owner, Swiss Mobiliar. SCHL (Société Coopérative d'Habitation Lausanne) owns over 2'100 dwellings in and near Lausanne and ABZ (Allgemeine Baugenossenschaft Zürich) about 5'000 in or near Zurich. Swiss Mobiliar, an institutional property owner, owns 3'500 dwellings located all around Switzerland.

2.2. Framework Development

To acquire system knowledge, we first developed a systematic conceptual framework by conducting interdisciplinary literature review. Theoretical frameworks are fundamental in interdisciplinary contexts, where their use allows for the integration of disciplines [14]. To develop the framework, we scanned literature by discipline and subject and defined the boundaries of the system studied. Following this step, theories were identified and combined in a first conceptual representation displaying the relationship between variables. Furthermore, literature review supported the identification of the different functions fulfilled by housing, which were then represented in a table structured in line with the system elements (Table 1).

2.3. Qualitative Group Discussion

To assess whether the theories and assumptions of the framework were *credible* (or to ensure the *internal validity*) [15], we organized a group discussion. The group discussion allowed us to validate the functions, and to further explore their relationship with the trigger. The structure of the group discussion was based on the *Pilot Study* proposed by Ajzen [16], where behavioral outcomes, normative referents and control factors are elicited from a small sample of individuals.

2.3.1. Sampling. The group discussion took place in November 2018 in the École Polytechnique Fédérale de Lausanne, Switzerland. The location made it possible to gather the tenants of two project partners, SCHL and Mobiliar. After defining the sample universe, we adopted two different sampling strategies: the purposeful sampling first, followed by convenience sampling [17]. We then sourced the samples accordingly [18]. To contact the tenants, agreement on the data to collect was established with our partners, their technical administrations, and the Human Research Ethics Committee of EPFL (HREC). The final sampling resembled the original structure of the stratified purposeful sampling, involving 10 participants: 5 tenants of the SCHL and 5 of Swiss Mobiliar, among which 5 women and 5 men, 4 living alone and 6 in larger households. The total duration of the group discussion was about 2h, and the language used in the session was French.

2.3.2. Analysis. The group discussion was organized in 5 different phases. It investigated the tenants' reasons for moving as presented in the framework (*Phase 1*), the relevance of each housing function in the decision process (*Phase 2*), the 'non-substitutable' characteristics of their former and present dwelling (*Phase 3*), the determinants for the selection of a new apartment (*Phase 4*), and the lessons learnt during the discussion (*Phase 5*).

The material collected at the end of the group discussion was in form of drawings, post-its, questionnaires, and recordings. Data were then extracted, condensed and summarized. Code construction was followed by the design of qualitative tables for the analysis. The systematic presentation of information in the data displays allowed for comparisons and pattern recognition, and was used to draw descriptive conclusions [19]. Two matrices were found to be useful for data display: the checklist matrix and the thematic conceptual matrix. The first was used to display the diversity of determinants of the decisions to move and to choose a new dwelling; the second (Table 2) resulted from blending inferences drawn from the first and was used to analyze and display the relationship between the determinants of the decisions (to move, to select), the housing function and the level of satisfaction.

Furthermore, to validate the functions proposed, word counting was performed. Finally, from the data display, a summary set of analytic comments was laid down.

3. Results

3.1. The framework

Nested in the system of interactions between the social structure, with its rules and resources, and the natural and technical environment, the housing system is defined by supply and demand constraints [9]. The supply is the dwelling itself, with its characteristics (design, location, neighborhood) and the values, standards, regulations shaping it, while the demand is the result of the tenants' decisions. In order to investigate these interrelationships, we propose a conceptual framework for tenants' residential choices (Figure 1). The framework combines Binder's work [20], which is based on the Structuration Theory of Giddens [21], and the Theory of Planned Behavior [22].

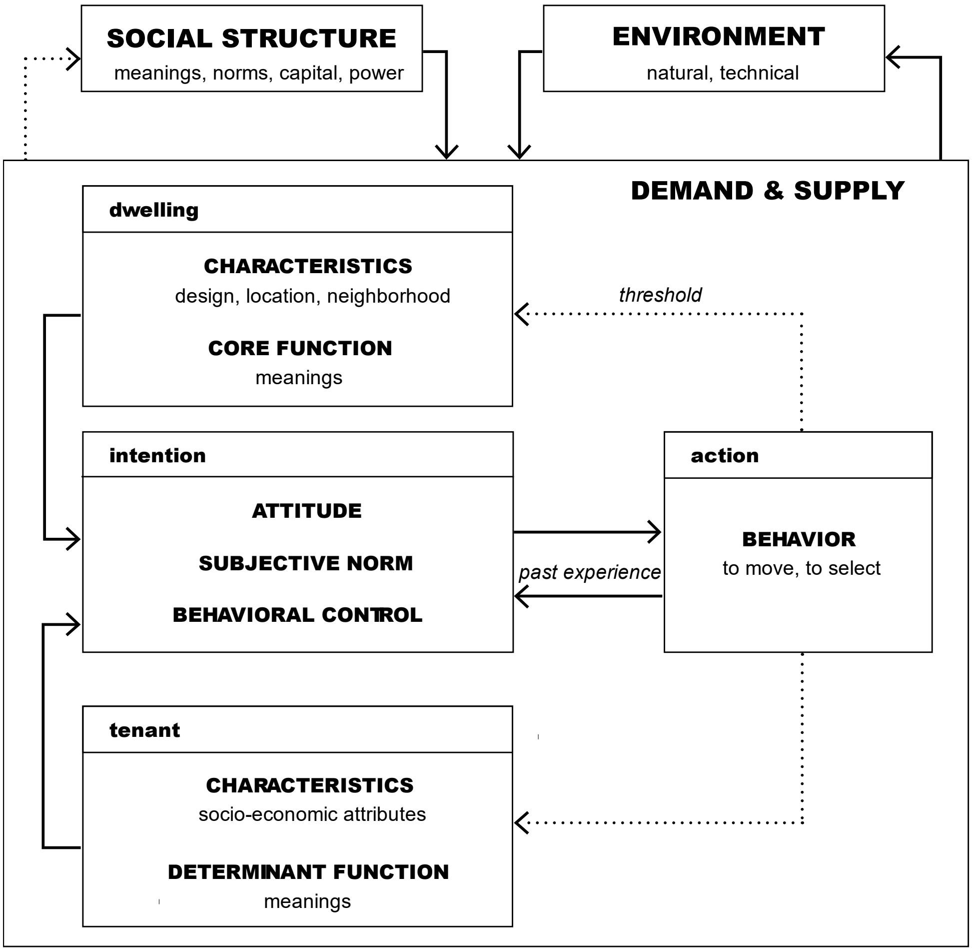

Figure 1. A new framework for tenants' residential mobility and location choice. The interaction between environment, social structure, and action is from Binder [20]; the intention and related factors are from Ajzen [22].

Binder's framework displays the interaction and feedback between social structure (e.g., legislation, culture, and economic system), human action (agent) and the environment [20]. More specifically, it displays that, when making decisions, agents consider external factors (i.e. the existing social structure conditions) as well as internal factors (i.e. their personal motivations and individual environmental awareness). At the scale of the agents, the work of Ajzen [22] provides insights for predicting and understanding tenants' decisions, determined jointly by the *perceived behavioral control* (or the ease or difficulty of performing the behavior of interest), the *attitude towards the behavior* (the favorable or unfavorable evaluation or appraisal of the behavior in question) and the *subjective norms* (the perceived social pressure to perform or not to perform the behavior). The framework considers the housing *function* as the determinant of the residential mobility and location choice of tenants. According to Meadows [23], the *function* of a system is the most crucial determinant of the system's behavior. Applied to the housing system, the housing function can be considered as determining the system's dynamics. Therefore, being nested in the larger housing system, the decision-making process of tenants is also affected by the housing function, which determines tenants' intention and final behavior. More precisely, this function originates in the social structure, which manifests itself through the sociocultural values [24] and collective meanings, later translated into material forms. The core function of the dwelling has to match the function that the tenant desires the dwelling to have, in line with the individual meaning it attributes to housing. This hypothesis makes it possible to overcome the heterogeneity and incompatibility of the research outcomes that have focused on housing characteristics as determinants of the household's decisions. Additionally, in the framework it can be seen how actions (to select a dwelling) provide diachronic (dotted lines) and synchronic (full lines) feedbacks to tenants, dwellings, the environment and the social structure (e.g., if a dwelling is often vacant, after a certain time threshold and according to the owners' strategies, its rent can decrease, or it can be demolished).

The *credibility* (i.e., internal *validity*) of the framework was assessed positively by the tenants during the group discussion. Firstly, preliminary results confirmed the applicability of the Theory of Planned Behavior to the housing case: the tenants considered the questions asked during the group discussion as pertinent, and were able to describe each intention component (e.g., *subjective norm*) that had played a role in their decision to move and select their current dwelling. Secondly, concerning the role played by the social structure in the decision, we recorded differences in the intention components between e.g., the tenants from the housing cooperative SCHL and the private investor Swiss Mobiliar, and tenants moving from foreign countries (undergoing a political transition e.g., Brexit). Lastly, we also proved the environment to play a role in the decision, in terms of awareness of the *natural* and *technical* possibilities in Switzerland (e.g., importance of view, green spaces, housing quality).

3.2. The role of the function

Dwellings are not only physical structures, but also social ones. The functions that these structures have to fulfill range from the basic provision of shelter and protection [25], to ensuring domestic activities [26], permanence, security, control, status, sense of belonging [27]. These functions vary among social groups and across history [28].

Table 1. Extract of the functions ranked by the tenants among the three most and three least important in the group discussion.

STRUCTURE	PURPOSE	BEHAVIOR	BEHAVIOR	BEHAVIOR	SOURCE
Changing factors	**Functions**	**Physical implications**	**Social implications**	**Potential implications (CH)**	
Location S-E status	**SHELTER** *refuge, protection*	-Basic house providing shelter	-Dream of the suburban house	-Obstacle to shared living	[25–27]
Location S-E status	**SECURITY** *for family and very restricted friends*	-Undifferentiated homes -Specific room function	-Desire for privacy -Recreation outside of the house	-Obstacle to flexibility and adaptability	[5,25,27–29]
Place of the individual in the culture	**IMPERMANENCE** *liberation from tradition and history*	-Comfort as negotiable social construct	-Different ideal solutions for household groups	-Increase in housing mobility and redistribution	[11,26,27,30]
Place of the individual in the culture	**PERMANENCE** *continuity, belongingness*	-Universal archetype of house -Long-lasting structures	-Rigid customs, codes and regulations -Attachment, identity	-Unsophisticated building technologies -Resistance to innovation	[5,11,24,27,30]

Table 1 displays an extract of the 9 functions derived from literature, organized according to the components of a system such as the structure, purpose and behavior. Each of the 9 functions proposed was ranked by the tenants at least once among the three most important functions of their dwellings. The function *Shelter,* followed by *Security*, occupied in the largest amount of cases the first, second and third ranking. The function ranked the most often among the least important, instead, was housing as a 'permanent' place. This can be explained by the fact that participants were tenants (and renting is not a long term investment). It must also be taken into account that international work migrants represent 1 in 3 persons in employment working in Switzerland [31] and frequently do not plan to stay permanently [32]. *Impermanence* was also a function often ranked amongst the least important. In fact, *Permanence* and *Impermanence* are not mutually exclusive: an impermanent dwelling might reflect the tenant's life-stage, needs and desires regardless of the future ones, while encompassing a desire for permanence, and an attachment to tradition.

Lastly, in the table, we introduce the 'potential implications' of each function specific to the Swiss context (CH), as discerned by the authors. Together with the physical and social implications, potential implications are relevant when considering the role played by each function in determining the behavior of the larger housing system. For example, the function *Shelter* can represent an obstacle to the use of shared spaces, and therefore hinder, in a sustainability setting, the goal of reducing the floor area per person.

3.3. The trigger

From the literature, we know that some triggers (1) are more effective than others, and (2) have unequal correlations with the level of satisfaction of the household with their dwelling [9]. Furthermore, triggers are difficult to represent in the framework, since they can influence all its components, and originate in each of them (e.g., a new child changes the household's characteristics and can result in the search for a new dwelling function and characteristics: larger, closer to school).

Table 2 displays the relationship between the levels of satisfaction, the situational factors (triggers), and the determinants for the selection of a new dwelling (functions, characteristics), resulting from the qualitative analysis of the group discussion. It is important to underline that this analysis does not lead to the design of a bidirectional link: the matrix displays only the trigger *needed* for tenants to move as observed in the data, or the link leading from the satisfaction to the trigger and function, and not the opposite (e.g., if the people with high satisfaction need an imposed trigger to move, it does not mean that all the people moving because of an imposed trigger have a high level of satisfaction).

Table 2. Thematic Conceptual Matrix: Relationship between levels of satisfaction and the mobility and location choices of tenants.

Satisfaction	**Low**	**Medium**	**High**	**High**
Trigger type	Trigger needed: Any trigger (AT)	Trigger needed: Opportunity (OP)	Trigger imposed 1: Radical Change (RC)	Trigger imposed 2: Problem solving (PS)
Trigger	Work opportunity	Opening of a bar, construction of a new building	Household formation (divorce, new family), retirement	End of contract, new job location
Characteristics	Correspond to what was missing	Some same others improved	New	Same plus problem solving
Function change	No change	No change	Change	No change
Function	Shelter	Asset; Impermanence	Production / Consumption; Property; Self-representation	Shelter

Four main observations can be made. Firstly, there is a relationship between the level of satisfaction of tenants with their dwelling *prior to the trigger* and the type of trigger pushing them to move. Secondly, the level of satisfaction determines the function and characteristics needed in the new dwelling. Thirdly, according to the different triggers, the function of housing is more, or less, prone to change; conversely, the function of housing suggests whether the tenants will be more keen to move or not. Lastly, there is a relationship between the change in function and the change in characteristics.

In fact, data show that when the level of satisfaction is low any trigger (AT) can push the tenants to move. In this case, the desired characteristics for the new dwelling correspond to the ones missing in the former location, and the desired function, which was not fulfilled, doesn't change. When the level of satisfaction is 'medium', instead, specific triggers are needed for people to move: opportunities (OP) (e.g., the opening of a bar, the construction of a new building in front of the current one) easily become triggers, presenting themselves to the tenants as favorable circumstances to improve some of the housing characteristics, and get closer to the desired housing function. Tenants belonging to this group display desired functions such as *'Asset'* and *'Impermanence'*, which suggest a greater propensity to move. When the level of satisfaction is high, an imposed trigger is the only push factor that can lead to the move. A radical change (RC) in the current life cycle stage (e.g., household formation, retirement) results in a change of the desired function: e.g., when retiring, the dwelling is not used for activities in after-work hours anymore, but rather for inviting friends and spending the day. The functions the most common in this category are the '*Property*' and the '*Self representation*'. Furthermore, tenants with high satisfaction are often forced to move because of another type of imposed trigger: problem-solving (PS). Examples of problem-solving are the end of the contract, or a change in job. In this case, tenants look for a dwelling with the same characteristics, of which one necessarily has to change to solve the problem. However, we must take into account that housing choices are often compromises between the desires of each household component. Therefore, despite having high levels of satisfaction, small improvements in the characteristics can be recorded. This category of movers has been found to be related to the function '*Shelter*', whose inhabitants tend to move only when conditions are not met (low satisfaction), or when triggers are imposed.

4. Discussion

The goal of this paper was to provide a systemic understanding to the study of tenants' decision-making process, in order to inform the actors in the housing value chain about housing dynamics and eventually mitigate the current discrepancies in the Swiss rental housing market, which prevent the promotion of innovative and acceptable housing solutions. We therefore answered the questions concerning the determinants for the selection of a new dwelling (RQ1), the role played by the trigger in influencing the move (RQ2), and the interrelationship between the determinants of the decisions to move and to choose (RQ3). We found that the housing *function* is the key determinant of the decisions to move and select the new dwelling: on the one hand it influences the level of satisfaction with the current dwelling (function is or is not fulfilled), on the other hand it changes – together with the dwelling characteristics – according to the type of trigger leading to the move and the level of satisfaction prior to the move. Other studies have previously explored the type of trigger, level of satisfaction and housing characteristics [9,11,12]. We go beyond these studies by integrating each of these components in the housing system, by means of an interdisciplinary approach.

It is also relevant to state the limits of this study. We acknowledge that, in the process of validation, the risk of *accumulating positive cases,* or gaining further evidence for the pre-defined hypotheses [33] can occur. Furthermore, *illustrative display formats* can lead to 'superficially comparable' but 'intrinsically different' data [19].

This research also provides relevant contributions to the practice. Practitioners can benefit from the housing functions as *reading keys* or *design tools*. More specifically, to ensure the success of the project in the long term, dwellings should be designed in such a way that they integrate more than one function, and therefore accommodate the new needs deriving from different types of triggers (e.g., change in family size). Furthermore, the implications of each function (Table 1) would also need to be (i) acknowledged (for a better understanding of a project's failure), (ii) overcome (as the starting point for a design e.g., *shelter,* but *permeable*; *permanent*, but *innovative*), and (iii) adapted to specific locations (e.g., Switzerland).

Based on these considerations, this paper was a first step towards a greater knowledge on the strategies for housing sustainability transition. Additional research in this direction should firstly assess the degree of dependence to the context of the results obtained, which can be done by implementing a second group discussion with the tenants of ABZ and Swiss Mobiliar in the canton of Zurich. Secondly, it should explore the correlations between the type (and not only change in) housing characteristics and the function. Thirdly, it should quantify the relationship between trigger, satisfaction and function. Thereby we consider that a survey, conducted with 10'000 dwellings from our partners, will allow for the methodological triangulation and quantification of the conceptual elements and links of the framework.

5. Conclusion

In this paper we proposed an interdisciplinary framework representing the elements playing a role in the decision-making process of tenants, with the goal to increase the knowledge on the housing system and support the transition towards housing sustainability. More specifically, we focused on the housing function as the determinant of the system's behavior. By combining the theories of Giddens [21] and Ajzen [22], we identified the determinants prevailing in the decisions to move and select a new dwelling as subordinated to the intention, and influenced by the social structure and the environment. In a group discussion with the tenants of our project partners, we further explored these components and their links, and validated the housing functions proposed. We found that the trigger influences the choice of moving according to its type (e.g., radical change) and the level of satisfaction prior to it. Additionally, we found that the determinants for the selection of a new dwelling (the function, and the dwelling characteristics) depend on the type of trigger leading to the move.

The housing functions are a new design challenge. We recommend practitioners from the housing sector, such as architects, urban planners and housing providers, to use them as a starting point to design or promote sustainable housing strategies that meet the needs of the tenants in the long term.

Acknowledgments

This research is part of the project 'Shrinking Housing's Environmental Footprint (SHEF)', supported by the Swiss National Science Foundation (SNSF) within the framework of the National Research Programme "Sustainable Economy: resource-friendly, future-oriented, innovative" (NRP 73). The authors would like to acknowledge Swiss Mobiliar, project partner and funder of the chair Human-Environment Relations in Urban Systems (HERUS), its technical administration for the data provided, and the housing cooperative SCHL for their collaboration and continuous support.

Sustainable cities and communities – Best practices for structuring a SDG model

Neumann K
Scharbeutz, Germany

info@ilsa.de

Abstract. The UN's SDGs are powerful beacons to a better world yet some of their targets remain vague for the sake of special interest groups. They are sometimes synergetic and quite often ambivalent. On a concrete operative level it is therefore a challenge to plan for them fostering synergetic measures and minimizing trade-offs. Since many concrete projects that go for the SDGs are rather unique and need to consider many stakeholders, the systemic approach of a participatory explorative cause and effect modeling should be applied in order to tackle the underlying complexity of these projects. On the example of SDG 11 and with the use of the software iMODELER the approach is presented offering some best practice for structuring a SDG model, facilitating participatory stakeholder workshops, identifying levers for successful action, and establishing a culture of reflection. Although this approach has been applied successfully in Africa as well as in Germany it is also crucial to prevent typical hindrances. A kind of template for a model structure will be presented for both, a town in a developing country and a town in an industrialized country.

1. Sustainable cities and communities (SDG 11) – a complex challenge

Aiming for sustainable cities and communities should imply all three dimensions of sustainability – the social, the economic and the environmental. The United Nation's 17 Sustainable Development Goals (SDG) and their 169 targets represent these three dimensions of sustainability and only looking at their interconnections [14] reveals that some of them in practice could be contradictive resulting in necessary trade-offs while others might be synergetic at least in the long run.

Any strategic planning for sustainable cities and communities in general and following the SDGs in particular thus needs to consider this interplay of economic, social and environmental aspects. However, the prevailing practice seems to be economic aspects first followed by either social or environmental ones when regions seek for investors who aim for short term return on investment which often contradicts the provision of living space for low income families as well as the investment into green technology, better insulation, and the use of more expensive renewable materials. Environmental criteria could be set by regulation or demand. Social criteria are set only by regulation, or the lack of demand for the same space from higher income target groups that allow for higher margins for those who sell or lend space as well as for a higher tax income for the local government and higher revenues for local businesses.

All too often, thus, new buildings serve some short-term demand often in so-called pork cycles when many projects try to serve the same target group resulting in a delayed oversupply. Neither demographic change of more, less, or aging people, nor variations from demand driven prices and their long-term financing are considered. Also, if each plot seeks to maximize the utilized area and go for individual designs the region will lack green spaces and an attractive look from a common design denominator. So each region seeks to attract businesses and residents in order to provide jobs and tax income and its seems odd to argue for less short term economic gains for a greater benefit of society and long term economic opportunities as well.

The strategic planning becomes even more complex if we consider social aspects like the integration of different social milieus living in the same area (SDG target 11.A), visiting the same schools, and sharing leisure activities in order to increase variety for the greater benefit of society [9]. Adding to that a planning for intelligent mobility, public transportation, short distances, infrastructure for decentralized energy supply and optimized waste management for the long run becomes even more of a challenge since many planners are used to basing their assumptions on rather linear thinking and some sort of sovereignty of interpretation qua position.

This paper provides a tool - not a case study - to overcome this linear thinking and develop strategies that best fit the many SDG targets by revealing trade-offs and synergies. Therefore the aspects or examples mentioned are rather general, often trivial.

2. Reflecting on projects through explorative qualitative stakeholder modeling

Complex challenges in general are characterized by a large number of factors that need to be considered, by a large number of interconnections that form dynamics from so called feedback loops [18], [19], or by unpredictable behavior from elements in a system [7], [2], e.g. humans or the environment.

That means that unlike complicated challenges complex ones can never be fully predicted, yet there are tools for modeling that help us to overcome the limitations of our mind [6] to grasp the range of possible consequences from our decisions.

Modeling in general [19] means that we consider our challenge being a system that is defined by the interplay of its elements and that we need to define so-called system boundaries (time, space, detail), find a way to consider the crucial elements, and describe their interplay either qualitatively [12], [17] or quantitatively (through either System Dynamics, Agent Based Modeling or Neural Networks).

The next paragraphs will show a powerful way of qualitative modeling of a strategic plan to achieve the SDGs.

2.1. General approaches on modeling the SDGs

The number of approaches [1] to model the interplay of the SDGs is constantly rising. There are for example applications [8] of the iSDG by the Millennium Institute (www.millennium-institute.org) or the qualitative approach by the Stockholm Environment Institute [15]. And there is even an approach deriving causation from correlation of data from the target's indicators [16]. These approaches are obviously quite sophisticated and not easily applicable for concrete regions since only more or less predefined but no individual, potentially crucial aspects are included, and since the math and the use of the tools are typically expert's but not stakeholder's work.

2.2. Explorative modeling

As mentioned before it is crucial to consider the decisive elements – also called factors - of a system in order to grasp the underlying complexity. One way, of course, would be to already know what they are. In that case a model of their interplay would be descriptive. However, that seems very unlikely and therefore these kinds of challenges require what can be called explorative modeling.

Though there will never be a guarantee to have included the decisive factors there are ways to increase the likelihood of it. One way is to ask the stakeholders as described in the next sub-chapter. Another is to systematically ask the right questions for each factor within the model until the concrete measures and their dependencies are found. Established are the so-called four know-why questions from the know-why method [13].

They simply ask:

- What leads directly to more of a factor?
- What leads directly to less of a factor?
- What might lead directly to more in the future?
- What might lead directly to less in the future?

A facilitator of a workshop for example should then vary these questions and ask for organizational, financial, psychological, legal, etc. factors. The result is the visualization of arguments through factors that are connected with arrows either labeled with a "+" or a "-" meaning that more of one factor leads directly to more/less of the other factor. This way of presenting arguments can be seen as a kind of lingua franca that works in interdisciplinary professional settings as well as with kids in elementary school. Any project, strategy, paper, newspaper article or discussion can be visualized in this way [12].

2.3. Stakeholder modeling

There are two reasons for so called stakeholder modeling and some requirements to get it working. First, as already mentioned, we need to include the decisive factors and often there is information that isn't known to the decision makers or it gets underestimated in its potential consequences since it is not properly put into perspective.

The other reason is when you present your model containing hundreds of factors and the conclusion you draw from its analysis many people will reject what they don't take the time for to look into the details and of which they were no part of.

The requirements to get it working next to the ease of a lingua franca as described in the sub-chapter before are rather technical. The tool iMODELER (available as freeware, www.imodeler.info) that that was applied for this paper is constantly being improved for this kind of modeling, offering:

- a change of perspective from which one is looking at the model so that different groups can work on selected factors without getting overwhelmed by the spaghetti look of hundreds of other factors and connections.
- a collaborative modeling feature so that not just the facilitator is typing input but anyone from a group that brings a computer or smartphone. That way they grow ownership and navigate through the model by themselves looking for further crucial arguments.
- a repository of existing models to get proposals for further relevant factors from other cases, as given with www.know-why.net and the possibility to intelligently search all its factors right from a factor of one's own model. Stakeholder can then easily evaluate the need to include these proposals.
- a link directly to the model so it can be read and discussed beyond a stakeholder workshop.

The iMODELER has been applied for stakeholder - also called 'participatory' - modeling in various projects on SDGs [14] and regional development [10].

2.4. Qualitative modeling

The major reason to apply so called qualitative modeling probably lies in the effort it takes to build quantitative models and use data and formulas. Another often-named [11] reason for its use is its potential to translate fuzzy and qualitative arguments directly into a model, which is particularly important for participatory stakeholder modeling.

'Qualitative' means that an interconnection is defined simply by the already described arrows in iMODELER, and the modelers then later, once all influencing factors are connected, are able to decide whether this influence is weak, medium, or strong compared to other influences on the same factor. Also to be decided is whether these influences change from short- to medium- to long-term (figure 1).

From this rough, fuzzy differentiations as shown with the next subchapter some powerful conclusions can be drawn. It is important to note that stakeholders can easily agree on these rough weightings.

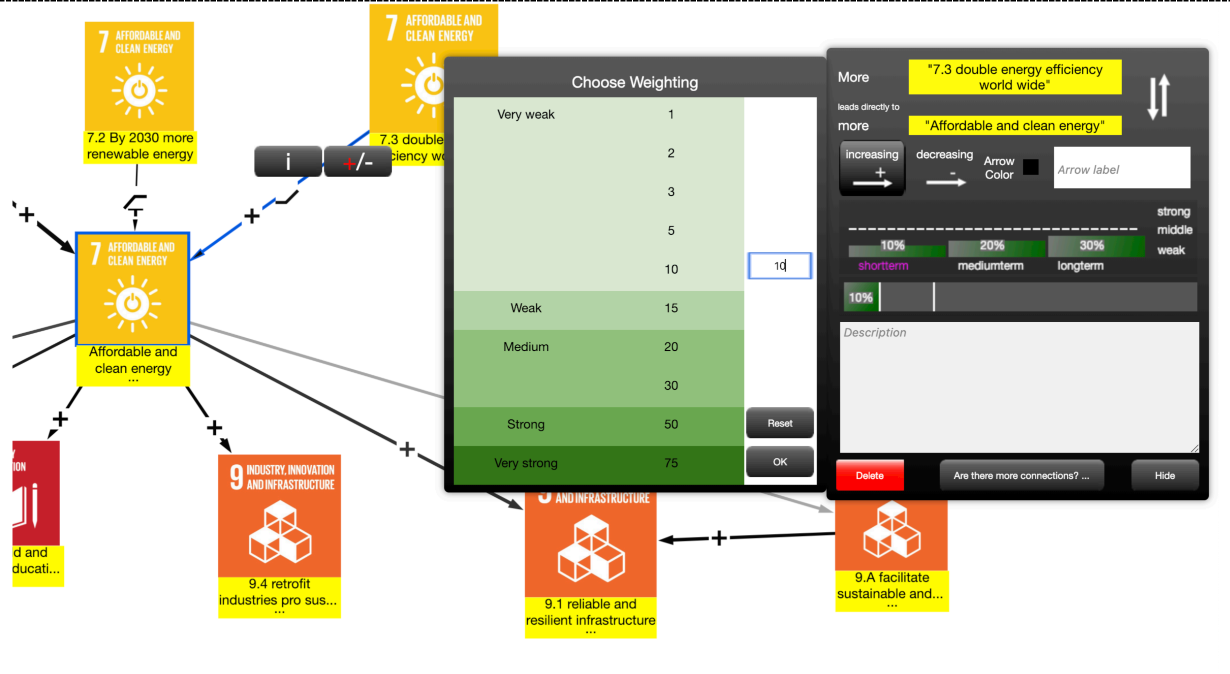

Figure 1. Weighting of connections within qualitative models.

2.5. Qualitative analysis featuring the Insight Matrix

Simulations of quantitative models show how, and with what likelihood something develops over time. A qualitative model can only compare impacts of factors within a system of interconnections, e.g. showing the potentially biggest risks or most promising action short-term, medium-term, and long-term with regard to a target factor of a model. Since these impacts stem from potentially various impact chains and interfering feedback loops that can be reinforcing or balancing it takes a computer to process the resulting effects [6]. The iMODELER offers an Insight Matrix [12] to compare the influences (horizontal x-axis) of factors and their change of impact over time (vertical y-axis) as shown in figure 2.

Reinforcing feedback loops could be both, virtuous or vicious cycles. For example more tax income from businesses could allow for more investments into public spaces that attract better-educated residents, thereby attracting more businesses. This dynamic can lead to both, an increasingly better region or an increasingly less attractive region.

An example of a balancing feedback loop could be that a dire situation causes pressure for political action and, once that action is taken and takes effect, leads to less pressure.

Modeling the SDG 11, Sustainable Cities and Communities, for a concrete region means that at least one factor is representing this goal. From its Insight Matrix the most important risks or hindrances as well as concrete actions should be derived. If one then continues to look at the Insight Matrices of these hindrances and actions, synergies and ambivalences or trade-offs can be identified that reveal crucial otherwise hidden aspects for successful strategies and projects [20].

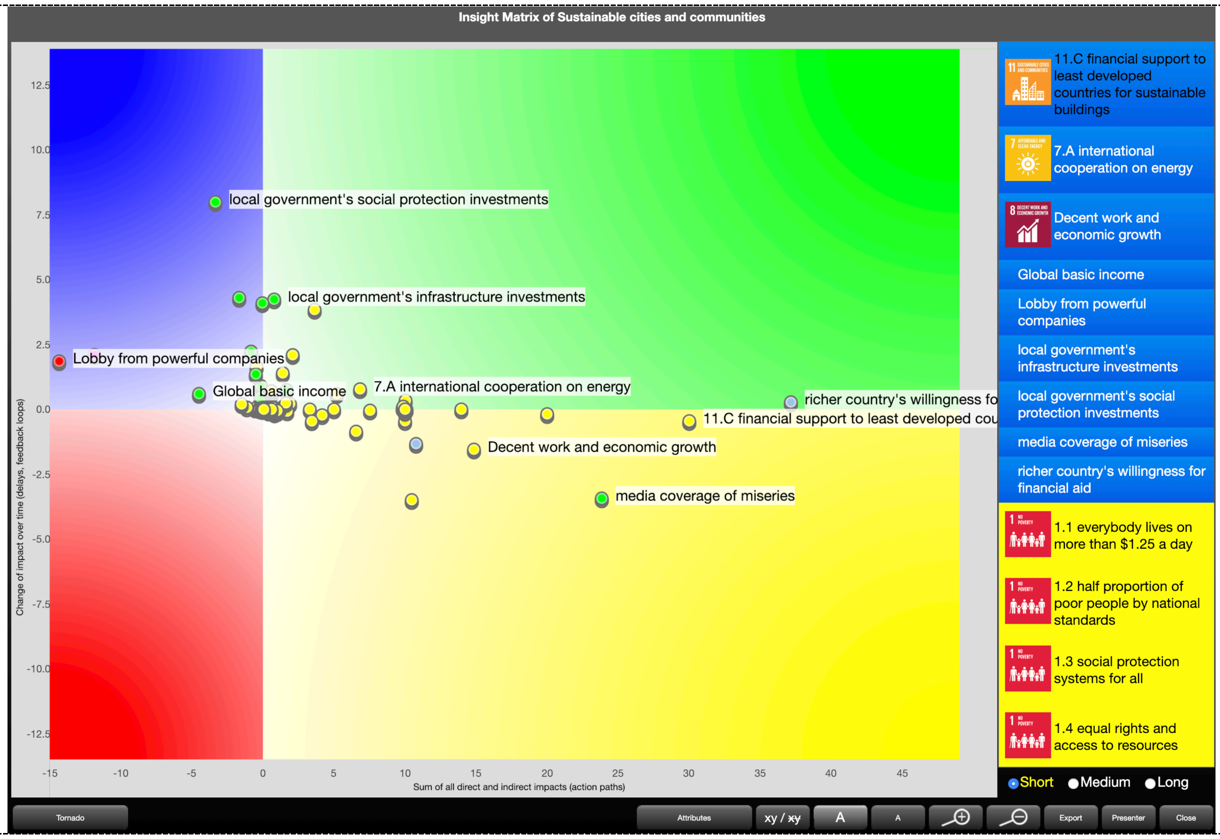

Figure 2. Insight Matrix to compare the influence of factors over time.

3. Templates to reflect on the creation of sustainable cities and communities

In principal one can start a model on the development of sustainable cities and communities from scratch by starting with that as a target factor and asking the aforementioned four know-why questions to explore the possible action and hindrances and their dynamics. But since the SDGs already feature sub targets for each goal and since they are meant to not been followed as isolated targets but rather synergetic it makes perfect sense to look at templates that have already connected the cause and effect relations between the targets and hence the goals.

One example that is publicly available and already featured in a published paper is the SDG model on know-why.net (https://www.know-why.net/model/CaLIsTKbVf7Yg5bm8yRXGyg) here shown with figure 3. It has more than 200 factors, more than 450 connections, and more than 13 million feedback loops.

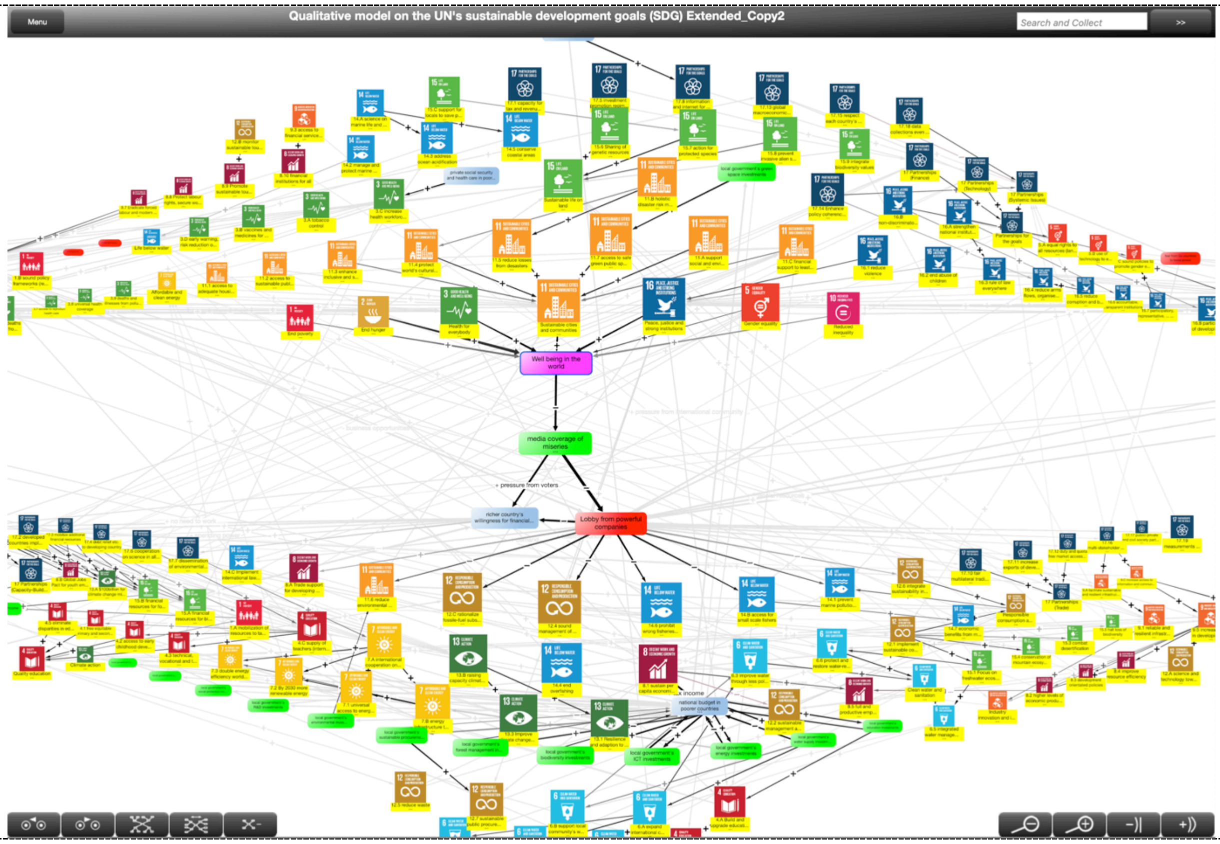

Figure 3. Screenshot of the general SDG cause and effect model from know-why.net.

Though it is a rather general model not focusing on a concrete region, it should be helpful to look for potential connections of each target with other targets. The model does not just connect the targets of the SDGs, it uses additional factors in order to explore and explain their interconnections.

Right at the beginning of the model an overall target called "well being in the world" was inserted and only 7 of the 17 SDGs directly influence this overall target while the rest are supporting these factors in some way.

Also between some of the targets the model features additional factors to show the interconnections. For example between SDG 8, Decent Work and Economic Growth, and many targets of SDG 17 on financing there are two factors, the "national budget in richer countries" and "richer countries' willingness for financial help", both influenced by further factors. This adds the possibility to explore the levers and hindrances for making a change actually happen.

It is crucial not to directly connect factors, for example each of the 169 targets with the overall target of well being in the world, if they are actually to be connected indirectly via other factors. The differentiated look at indirect connections, the so called cause chains and the feedback loops, is the added value of modeling. Drawing redundant direct connections [17] would make it impossible to draw conclusions from the model and its analysis.

Figure 4 shows the general model from the perspective of SDG 11:

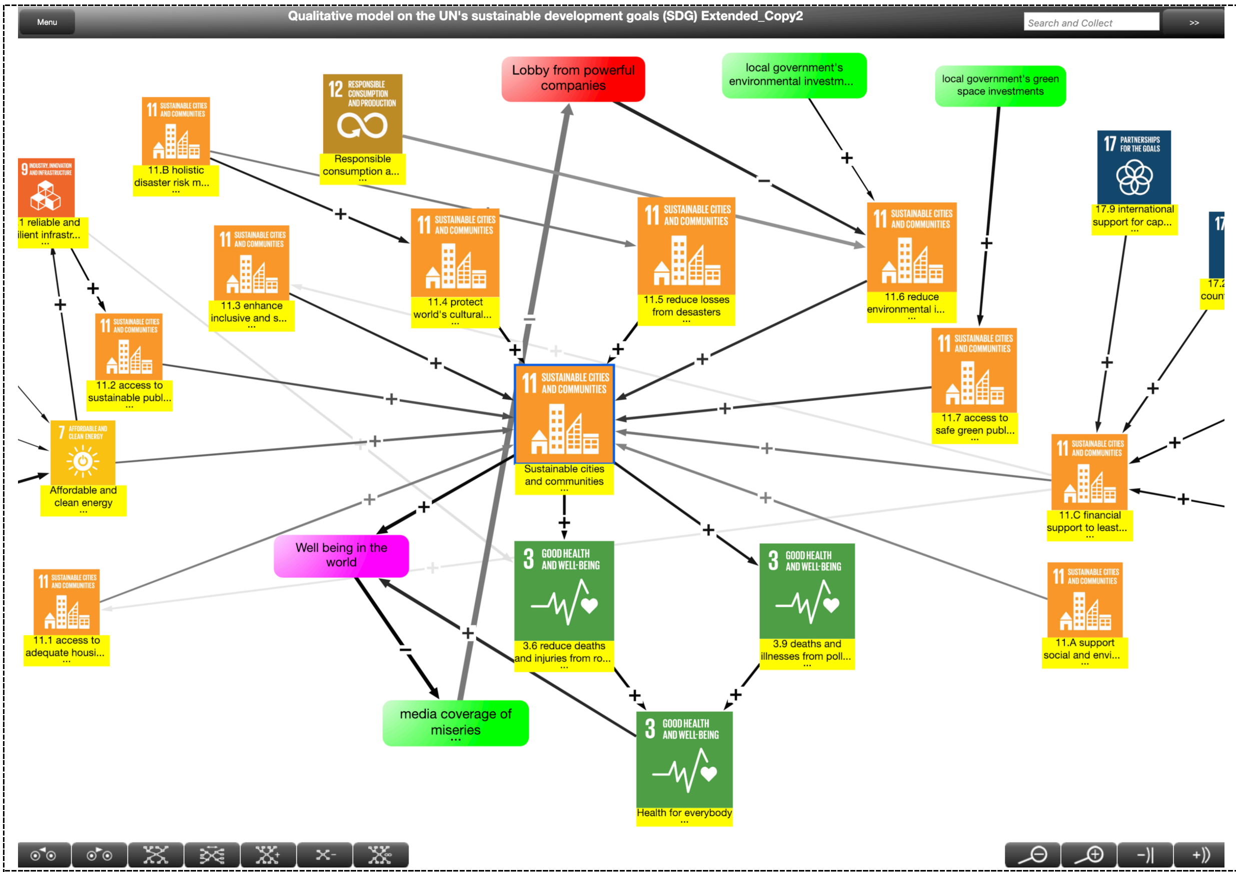

Figure 4. Screenshot from the general SDG model from the perspective of SDG 11.

Figure 5 shows the model from the perspective of SDG 7 and how this is connected to other sub targets and SDG 11 itself:

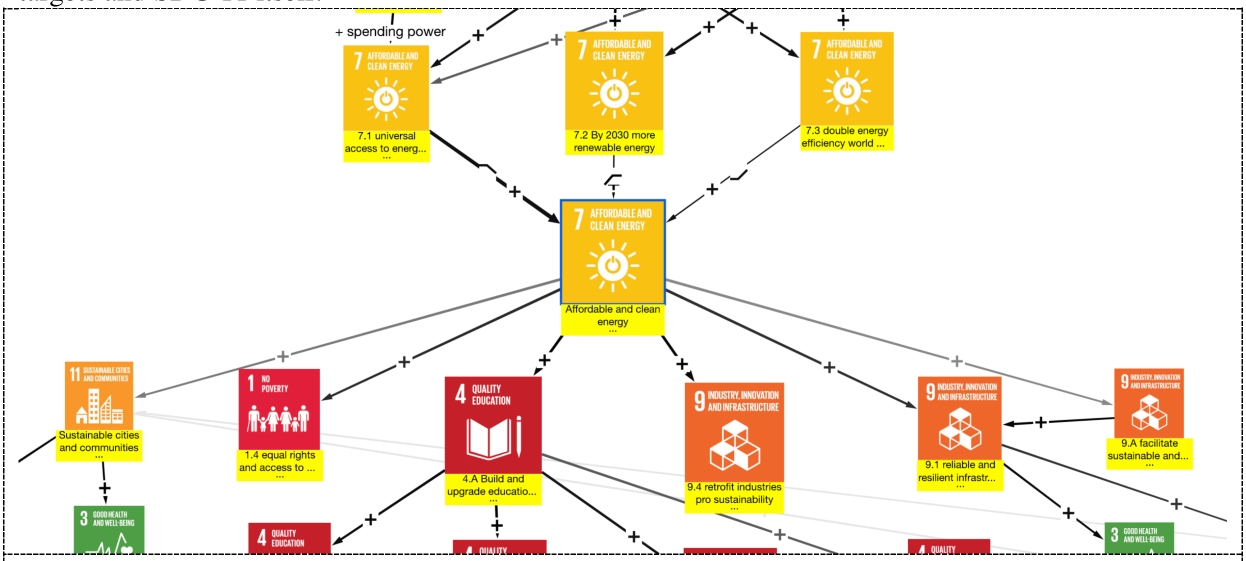

Figure 5. The general SDG model from the perspective of a sub target

Already the general model on SDGs reveals with its Insight Matrix of SDG 11 (figure 2) which targets from other SDGs are synergetic and which ones have the potential to be ambivalent. However, for a concrete region a facilitator can prepare a more concrete template.

3.1. Application for the "industrialized world"

The so-called industrialized world's population is not growing as fast as it is aging. Therefore younger people do not inherit property from their elders and need their own place to live in, which is why despite sometimes even shrinking populations there is a need for more housing. However, this implies a foreseeable decrease of need in the long run unless migration compensates for the low birth rates in those countries. A logical consequence is also the growing need for smaller and disabled friendly units. Some regions still face a rural exodus though this might change with growing numbers of home office workers and decentralized businesses [3].

Its infrastructure (e.g. SDG targets 9.1 and 11.2) features public transportation though road traffic from private cars dominates the need for space for roads and parking areas. Only recently some cities seek to provide more space for bicycle traffic. The trend to use cars to drive to outlet centers and to go for online shopping causes cities to lose businesses. The cities and their quarters thus need to plan for attractive, decentralized services that are accessible via public transportation.

Green spaces (SDG target 11.7), however, become rare since there is still a need for more housing coupled with an increase of real estate prices that could be derived from the low interest rates in the wake of the last financial crisis. And since the interest rates are low and prices are high there are widespread investment booms into new housing anywhere resulting in the pork cycle that was mentioned in the introduction. One challenge here is that today's standard will define the anthropogenic stock of resources (SDG target 8.4) and the need for energy (SDG target 7.3) for many decades to come.

Waste-water management (SDG 11.6), power supply (SDG 7), even communication cables are mostly established, yet infrastructure for the rise of e-mobility requires additional power lines and charging stations. As areas for photovoltaic panels rooftops and walls as well as pathways could be used. Rooftops also may serve as areas for urban gardening.

Active housing, that which supplies more power than it consumes, intergenerational living, short distances, access to public transportation and a lot more necessary for becoming more sustainable remains quite a challenge that requires reflection of its cause and impact relations. A model should always start defining the questions that it should help to answer! If it is the question "How to plan for a sustainable city and community?" the existing SDG model could be used as a starting point. Some targets, like '11.1 access to adequate housing and basic services', need to be either marginalized with a low weighing of their impact for a rich industrialized country, or they need to be differently interpreted e.g. as housing for all ages and income classes. Otherwise, they need to be referred to a partner city in a less developed country.

A factor like target '7.3 double energy efficiency world wide' is also interesting in its interpretation whether it means that the already high standards in industrialized countries should be increased or that they are allowed to point at higher possible margins of improvement in other areas of the world.

Starting from the given factors in the template one should continue with the four know-why questions until finally coming up with some concrete action and its required reflection. So, if for example, 'street lamps serving as charging station for e-cars' is the concrete action, one should ask how to finance it, what might cause problems, what might be a legal aspect, what is technically necessary, what might be the technology of the future, and so forth.

If it is a more detailed question that the model should answer, the model could start from scratch and use the SDG template only as a reference for inspiration. The four know-why questions should help develop a powerful explorative cause and effect model. In the context of buildings and infrastructure the questions should be varied and ask for financial, legal, organizational, social/cultural and technical levers and hindrances.

3.2. Application for the "developing world"

The so-called developing world has many more dynamics to consider when planning for its sustainable cities and communities. The worst way to develop would be the uncontrolled urbanization with all its problems of water supply, wastewater management, air pollution from road traffic, lack of standards to mitigate the effects from potential disasters (SDG target 11.4), and so forth. The second best way would be to copy the development of the industrialized world with its dominance of road traffic and the separation (neglecting SDG target 11. A) of privileged living areas from housing blocks or even slums for socially disadvantaged people. The best way would be to consider some leapfrogging to plan for cities that are more modern and sustainable than that of the industrialized world since many parts of them can almost be built from scratch.

In any case the developing parts of the world need investments. They could come from SDG target '11.C financial support to least developed countries for sustainable buildings', from investors that seek to profit from the domestic economy, from investors that seek to support the location of their business, or from investors that want to attract tourism. And, of course, there is still the possibility that a region does not strive for the typical western lifestyle with cars, petrochemical products and loads of luxury goods but instead embraces a more resilient, community centered way of living that could be based on a local bio-economy or sustainable tourism.

As for the template for a model for the industrialized world the questions that the model should answer are crucial. For rather general strategies and projects one could use the existing general SDG model. For more specific questions one might develop a completely new model using the explorative know-why questions again. One difference might be an increased emphasis on the questions what might lead to more or less in the future. For example, arguing for wider and more streets because of the increase of traffic jams that are bad for local business and investments, knowing that the future is emission free public transportation and even that of electric commercial vehicles, would be a typical shifting the burden archetype [18].

4. Beyond the tool – a culture of reflection

This paper shows no concrete application with conclusions from a model's analyses nor a step-by-step guidance. Rather it recommends, together with the provision of some tips and tricks from other projects, to use participatory explorative cause and effect modeling to reflect on concrete challenges in order to make progress achieving SDG 11. The fact that a concrete example would not imply a best practice for elsewhere is the very reason one should refer to this methodology: the challenges this world faces need individual solutions that consider the unique circumstances of every region.

Yet, trying to apply this approach quite often faces typical resistance. People doubt the benefits from these models since they consider them to be based just on assumptions. Well, that is correct. But any other approach, even that of a mere copying of 'fact based' best practice from elsewhere, would be based on assumptions as well, with the only difference that a model visualizes these assumptions, allows for their discussion, fosters creativity, and reveals logical conclusions from abductive logic [4].

Best practices are helpful but for a better future we need to add well-reflected ideas. The following photos (figure 7) show two paintings from unknown artists from an international Degrowth conference 2014 in Leipzig, Germany. One depicts for a better future a good life for all "Gutes Leben für alle" next to best practice solutions a group of people standing around a cause and effect model developing a shared idea. The other picture shows the unhealthy automatisms of more growth "Mehr Wachstum" by mere copying of lifestyles.

Figure 6. Drawings comparing the current and alternative paths for society.

This kind of collaborative problem solving (CPS) is subject to a psychological science [5]. It is considered a crucial skill for the future that can be trained and measured. Politicians, consultants, actors for media and other organizations, and indeed all of us need to learn to ask for the interplay of many factors and discuss this with others instead of restraining ourselves to best practice or gut feeling just because knowing feels better than taking the effort of exploration.

Abstract. The literature shows a lack of environmental indicators able to support the transition from a sustainable to a smart city framework, since the priority area "built environment" is indeed more comprehensively addressed by urban sustainability assessment systems (13%), than by smart city frameworks (4%) [12].

As "smaller cities inside a larger agglomerate" [19], urban districts play a key role in defining effective and innovative paths toward a smarter city, but defining a sustainable urban district is not straightforward, and even less is capturing the induced impacts due to interactions between individual buildings and their surround urban setting [23]. The adoption of a quantitative method for evaluation, such as Life Cycle Assessment (LCA), emerges as an essential step for this purpose [24].

This article explores the application of a streamlined LCA on the urban district main issues (buildings, energy, water and waste), referring to an urban retrofitting intervention of Bolognina neighbourhood.

A set of mitigation strategies developed by an interdisciplinary research group (joining researcher team from the Department of Architecture of the University of Bologna and Institute of Sustainability in Civil Engineering of the RWTH Aachen University) provides the reference framework for the application deepened within the article. This work is a first application of LCA to a case study but it not includes a comprehensive sustainability framework yet, further activities are planned to finalize the analysis, e.g. taking account of social dimension by applying Social Life Cycle Assessment.

1. Introduction

Cities Climate Leadership Group (C40) emphasize that despite occupying just 2% of the world's landmass, Cities are responsible for over two-thirds of the energy consumption and account for more than 70% of global CO_2 emissions.

As a significant contributor to climate change issues, cities represent a key challenge in curbing greenhouse gas emissions and in taking adaptation and mitigation strategies.

Therefore, the consolidation of the common approach launched by the Paris Agreement, which focuses on transition to climate change, is encouraging cities, regions and businesses to take important steps in this direction, in order to contribute reduce global temperature rise to less than 2 Celsius degrees [1].

In parallel, an interdisciplinary group of academic experts who provided independent insights to COP21 French presidency and negotiation team, underlines that strategies foreseen in the Paris Agreement, on response to greenhouse gas rise, whilst being a laudable first step, requires scientific community to make further interdisciplinary efforts, as those regarding a broader use of Integrated Assessment Models [2].

According to several literature sources, the three interconnecting pillars: economic growth, societal development and natural resource conservation should be the reference to adopt in shifting towards sustainable urban development [3-5].

Life Cycle Sustainability Assessment (LCSA) is the life cycle-based approach built on the 'triple bottom line' or 'three-pillar' model of sustainability: environmental (LCA), social (SLCA) and economic (LCC) [6-7].

Since it is an accepted methodology for quantitative assessment of buildings over their whole life cycle, LCA has been increasingly used to assess the environmental impacts of construction products and buildings in the last 25 years, while it is still difficult to apply at urban level.

Despite the application at district level highlights the difficulties in shifting LCA to a wider scale [8], the methodology could provide a robust framework for an effective tool, suitable to assess environmental issues of urban blocks or neighborhoods. Which is a very promising issue within the actual debate on the lack of environmental indicators capable in providing guidance in the transition from a sustainable to a smart city framework.

This study applies a streamlined life cycle assessment to evaluate the mitigation strategies adopted by local authorities to enhance the environmental features of an Italian urban neighbourhood within its path to became a sustainable district.

2. Background

2.1 Towards a sustainability framework for new district urban concepts integrated in smart cities

The large variety of smart city definitions converge in European Union's view, under which the aim of the smart city is reducing greenhouse gas emissions in urban areas through the deployment of new intelligent technologies [12]. In fact, a large gap exists between a sustainable city and a smart one.

Recent scientific literature on the assessment of smart city performance suggests that there is a need to further integrating sustainability indicators in existing frameworks, or totally re-defining them. In particular, it recommends that not only output indicators should used that measure the efficiency of smart solutions deployment, but also impact indicators assessing the contributions provided to ultimate goals, such as environmental, economic and social sustainability.

A shift there has been in recent years by city policies striving for smart city targets instead of sustainability goals [9]. However, those two topics are interconnected and smart cities often share several goals with sustainable cities., despite the relation to sustainability targets is often lost within the large variety of definitions that exists of smart city [10]. Hence, there is a need to better understand the relation between smart and sustainable city concepts [11].

Built environment is an important aspect underlying the notions of both smart and sustainable cities. Comparing sustainable and smart city frameworks [12], the priority area "built environment" is more comprehensively addressed by urban sustainability assessment systems (13%), than by smart city frameworks (4%). It further highlights an additional lack of environmental indicators able to provide guidance in implementing the transition from a sustainable to a smart city framework.

However, these studies do not adopt the life cycle approach and can therefore only be assumed as a starting point, since impacts along the life cycle phases may have been neglected, e.g. energy embodied into buildings and infrastructure components to manufacture, ship, maintain and eventually demolish & dispose them [13]. Conversely, adopting a life cycle perspective will help understanding the up and downstream impacts of different technologies and concepts. This will also enable the identification of hotspots along the supply chains, providing a mean by which optimization potentials can be identified, while avoiding trade-offs.

2.2 LCA at urban level

A shift to sustainable districts has become urgent nowadays. This needs having tools to assess and measure the sustainability of Urban District, and especially their Retrofitting process. LCA is considered a valid scientific methodology for the purpose, but it could lead to uncertain outcomes and be highly time consuming, due to its specific nature which strictly relies on accurate and detailed input data. Many studies highlighted the need of removing this obstacle by adopting simpler methods or switching to other approaches (e.g. material flow analysis) [14]. Lotteau et al. [8] provides recommendations and guidance on applying LCA at this scale, based on the review of 21 case studies. In particular, the study suggests two good practice to adopt: a) declaring in detail the key features of the neighbourhood (i.e. number of inhabitants, number of non-resident users, neighbourhood area, total floor area and duration of study), in order to allow a better interpretation of results and data comparison; b) aligning LCA to the data as defined at master planning stage of the neighbourhood development, specifying key factors such as urban morphology, presence of vegetation, choice of materials and their influence on buildings energy consumption.

Figure 1. Analysis of site at Urban scale (redesigned by authors [17])

3. Case study

3.1 Bolognina district

The area under study is the Bolognina Neighbourhood, one of the 6 neighbourhoods which constitute the Italian city of Bologna. Located in the northern part of the city, this neighbourhood came into being as a result of urban expansion to provide residence for the working class at the end of 19^{th} century. It has a strategic location, close to the new stop for high-speed trains, the recent main City Hall building and the new residential area in the former fruit and vegetable market. Situated west of the trade fairground and east of the parallel Adriatica Motorway A14 and Tangenziale Nord Highway, it represents an important pivot between the historical city centre and the surrounding outskirts (Figure 2).

The Urban Plan of 1899 conferred to the area its peculiar chessboard pattern, made up of plots alternating homes, open yards, public services and shops. The most common buildings types are terraced houses aligned along the boundaries of the lots, and standalone often higher buildings in between. Some of the buildings are submitted to conservation plans as they are deemed of testimonial interest by city regulations. However, there is need for actions to address some critical issues, especially those due to the aging of the building stock and socio-economic conditions, as well as to improve the urban quality and to raise environmental and energy-related standards.

3.2 Critical issues

3.2.1 Heat island effect
A simulation was performed using ENVI.met software, in order to better understand the physical and micro-climatic behaviour of the urban area under study as wells as interactions among the elements present therein. This allowed us to identify heat island effect, air flow dynamics and vegetation related benefits. The simulation was carried out on three different levels: a large portion of the built environment including part of both historic city centre and surrounding area; the northern section of Bolognina neighbourhood; a single Bolognina block. This "zoom" sequence has highlighted significant heat island effects especially in no-shade unconstructed paved areas; low relative humidity (rarely higher than 40%); critical wind speeds often affecting zones without physical barriers such as vegetation and/or buildings (Figure 3).

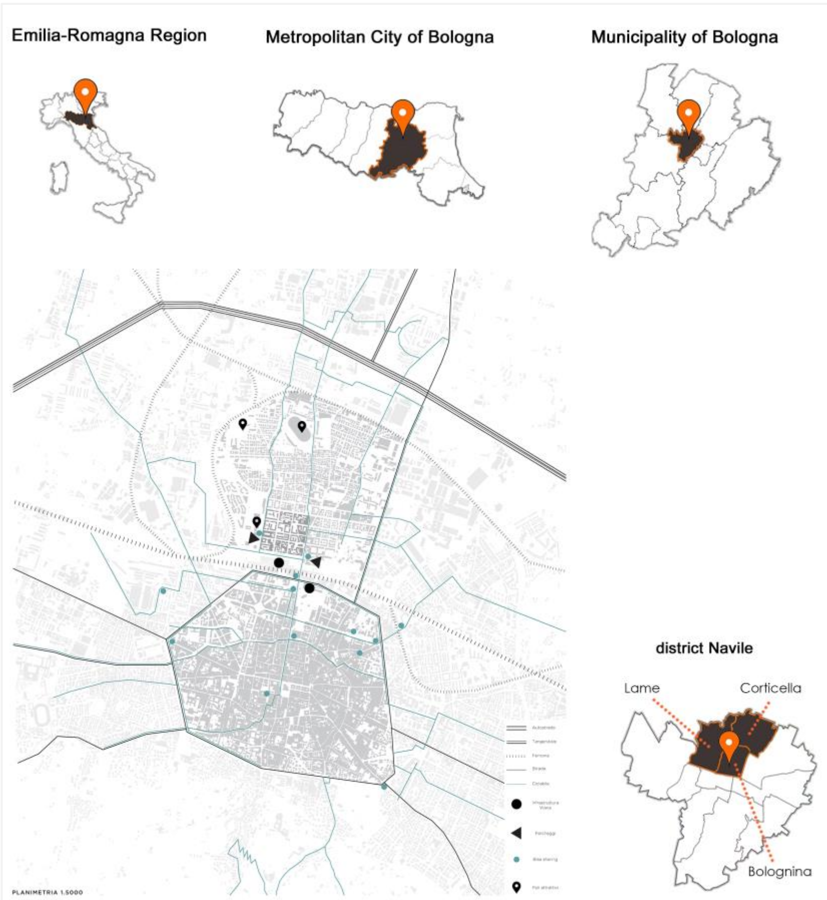

Figure 2. Territorial location of Bolognina neighbourhood

3.2.2 Open spaces
A more detailed study was also carried out on unbuilt areas, showing that green zones, parking lots, paths, home entrances (Figure 4) are left in abandoned and degraded situation due to the lack of a

hierarchical organization of the common spaces and their ordinary specific use, resulting in an inefficient use of the urban area.

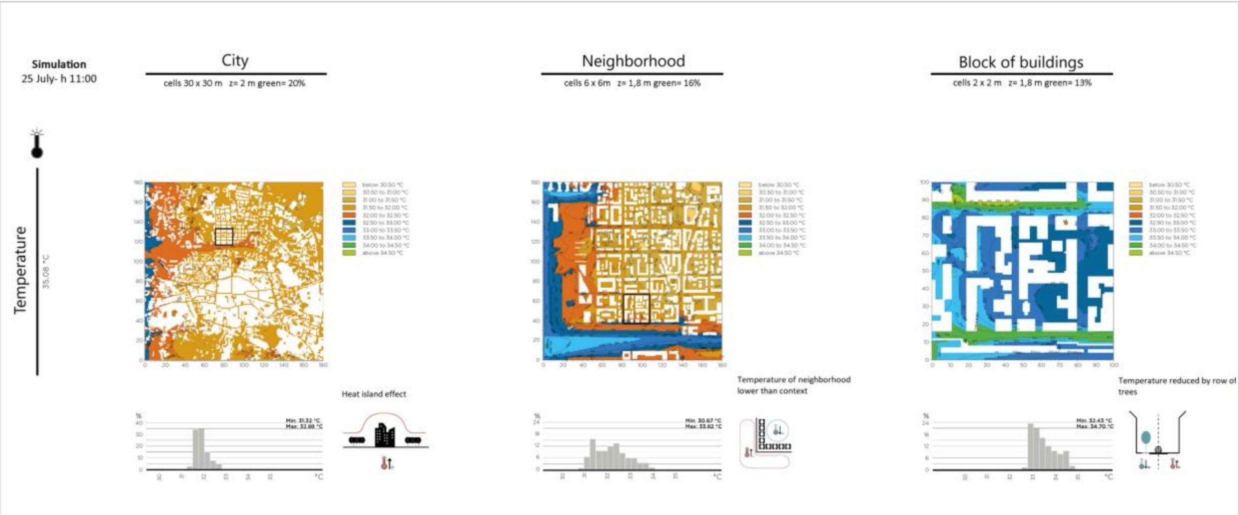

Figure 3. Head island effect on Neighbourhood (redesigned by authors [17]

3.2.3 Buildings

Residential buildings have inadequate performance levels: 70% of the rooms have lower surface areas compared to existing legal limits, 20% are under-sized by more than 70%. The type of lodgings, which today are mainly made up of 2-3 components, do not meet demands. The indoor comfort levels (exposure to sunlight and ventilation) are at critical levels; energy consumptions are very high (total energy performance Ep values range from 130kWh/m^2 corresponding to energy class E, to 230 kWh/m^2 corresponding to energy class G), mainly due to heat loss of the building envelopes, in particular windows, and to a high number of heat bridges.

4. Methods

4.1 Mitigation strategy of Bolognina and relevant environmental aspects

The opportunities and criticalities highlighted in previous analyses have been grouped in 4 categories: city, utilities, insulation and comfort. The strategic interventions were defined taking into consideration their repeatability at a higher scale, which means extending to other neighbouring blocks in order to involve the whole district. These interventions address 8 aspects of the built environment as illustrated in Figure 4.

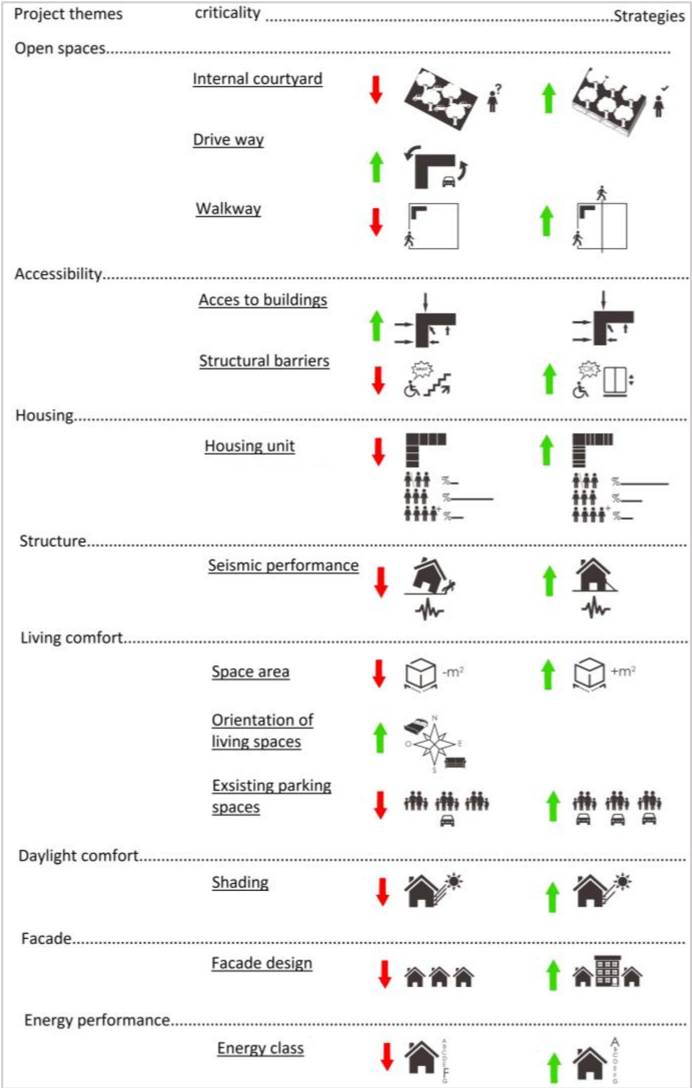

Figure 4. Mitigation strategies adopted

4.1.1 Urban district scale

The area defined by the courtyards and squares, as highlighted in the analysis in section 3.2.1 occupy a key function in the composition of the neighbourhood and shows serious functional deficiencies. The objective at the urban block scale, is to reorganize and requalify the open spaces in the internal courtyards, with the aim to re-establish a balance between built volume and open areas, reducing as much as possible the transit and parking of vehicles and extending the green surfaces.

4.1.2 Building level

The existing building stock plays a significant role in energy consumption and CO_2 emissions, accounting respectively for 40% and 36% of EU related amounts [15].

This occurs at district level too: there is therefore need to implement energy efficient and low carbon retrofit solutions which must be also affordable and designed for a long lifespan, since buildings are made to last for several decades (60 years, in accordance with the European Framework Level(s) [25].

By adopting pertinent solutions (building envelope insulation, window replacement, energy saving technical installations, etc), energy efficiency labelling could improve from class G (230 kWh/m2 year) to Class A2 (37,2 kWh/m2 year) and from Class F (160 kWh/m2 year) to class A4 (16,96 kWh/m2 year).

4.2 LCA of the Italian urban district

The LCA study was applied on the block bordered to the west by Via Nicoló Dall'Arca, via Fioravanti to east, Via Tibaldi to south and Via Albani to north, which is affected by intense traffic flows also due to daily local market here hosted and the proximity of City Hall.

These roads have uniform three-ways section: driveways are in the middle, two lines of public metered parking are located on both sideways which are lined with trees and sidewalks. Table 1 shows in detail the situation of the block under study.

Table 1. Dimensional characteristics related to the block under study

Characteristics	**UM**	**Value**
Height of the building (average)	m	16
Built volume	m^3	80,78
Open area	m^2	8910
Open/built area ratio		0.46
Green/pavement area ratio		0.75
Lodging area	m^2	1648,5
Lodging n. (+/- 5%)	n.	190
	m^2	10879,9
Green surfaces	m^2	3862
Pavement surfaces	m^2	5108
Block total area	m^2	13036
Built area	m^2	4111
Lodging average surface	m^2	65
Inhabitant/lodging average index	n.	2,5

The study firstly aims at exploring the application of a streamlined LCA on an urban retrofitting intervention of Bolognina neighbourhood. For this purpose and focusing on urban district main issues (buildings, energy, water and waste), a set of mitigation strategies has developed by an interdisciplinary research group (joining researchers of the Department of Architecture of the University of Bologna and Institute of Sustainability in Civil Engineering of the RWTH Aachen University).

The additional scope is to respond to some questions emerging in literature about the selection of functional unit suitable to allow effective interpretability of LCA results at neighboured scale, thus the studies comparability.

In order to reduce the number of variables involved and thus simplify the application model, LCA analysis focuses on some mitigation measures only, among those adopted in the retrofit intervention, as well as on two main life stages only, which are those defined in 4.2.2.

4.2.1 Functional unit

LCA standards define the functional unit (FU) as the quantified performance of a product or system that is used as the reference unit for the LCA and for comparability among assertions (ISO 14040-14044:2006). The standard EN 15978 (2011) on LCA calculation methodologies at building level relates the FU to the quantification of product identified functions or performance. For example, FU can be defined at building element level as $1m^2$ of insulation with sufficient thickness to provide a thermal resistance value of 3 m^2K/W, while at whole building scale it can be a unit of living area (1 m^2).

Given that an urban district - as the neighbourhoods it is composed of - are ecosystems, which characteristics are related to a considerable number of aspects (geographical location, space area, open spaces, building, culture and wealth of local residents to cite a few examples), the definition of a functional unit for these systems is extremely challenging [14].

As a matter of fact, state of the art on LCA studies applied at neighborhood level shows huge differences in FU choice However, we found an interesting reference in Norman et al. [15] and Stephan et al. [16] adopting a per capita FU (m2 of living space/inhabitant) but unfortunately it is cannot be used as a reference for our study, because is not clear how the amount of the open spaces is considered. This assessment is referred to dimensional characteristic of the block of Bolognina urban district, namely 8910 m2 of open area, about 190 housing units with 10879 m2 of living spaces and 475 inhabitants (see Table in Figure 2).

4.2.2 Boundaries and Life Cycle stages

Within the present study, the envisaged mitigation actions related to the built environment have been at first clustered by three main fields: buildings, open spaces and networks. This is in line with the model introduced by Popovici [18] and broadly taken over by the framework developed by Lotteau et al. [8], which allows to identifying the factors acting as major contributors within the LCA of an urban district (Figure 5).

In accordance with the boundaries defined by EN 15804 standard, the stages involved in the analysis are:

i) Product stage (raw materials extraction, manufacturing);
ii) Construction phase (Transport, building and infrastructures construction);
iii) Use phase (operation and maintenance) and vi) the Deconstruction phase (End of Life).

Therefore, in line with the goals defined in 4.2, the analysis is focused on the issues highlighted in the colored box in table 2, taking into consideration only 2 main lifecycle stages: process and use.

Table 2. Physical elements for the different fields of the built environment (readapted by authors from [8])

	PHYSICAL ELEMENTS		
	BUILDINGS	**OPEN SPACES**	**NETWORKS**
MITIGATION MEASURE	Insulation of the building's envelope	Reduce the heat island effect	District heating
	Replacement of windows	Green areas	Photovoltaic electricity in place of fossil fuels
	Reduced use of water	Parking lot	Waste collection and management services
	Reduced lighting consumption		Replace I-bulb sales with LEDs/CFLs
	Reduced energy consumption		

Elements assessed in the LCA

4.2.3 Assumption in the case study related the Life Cycle Inventory

The foreground flows are principally represented by real data collected during site visits, interviews and re-calculations based on appropriate software (e.g. energy related retrofit of buildings). Whenever primary data were not available, regional and national references sources were considered as shown in table 3.

Table3. Foreground flows output and waste

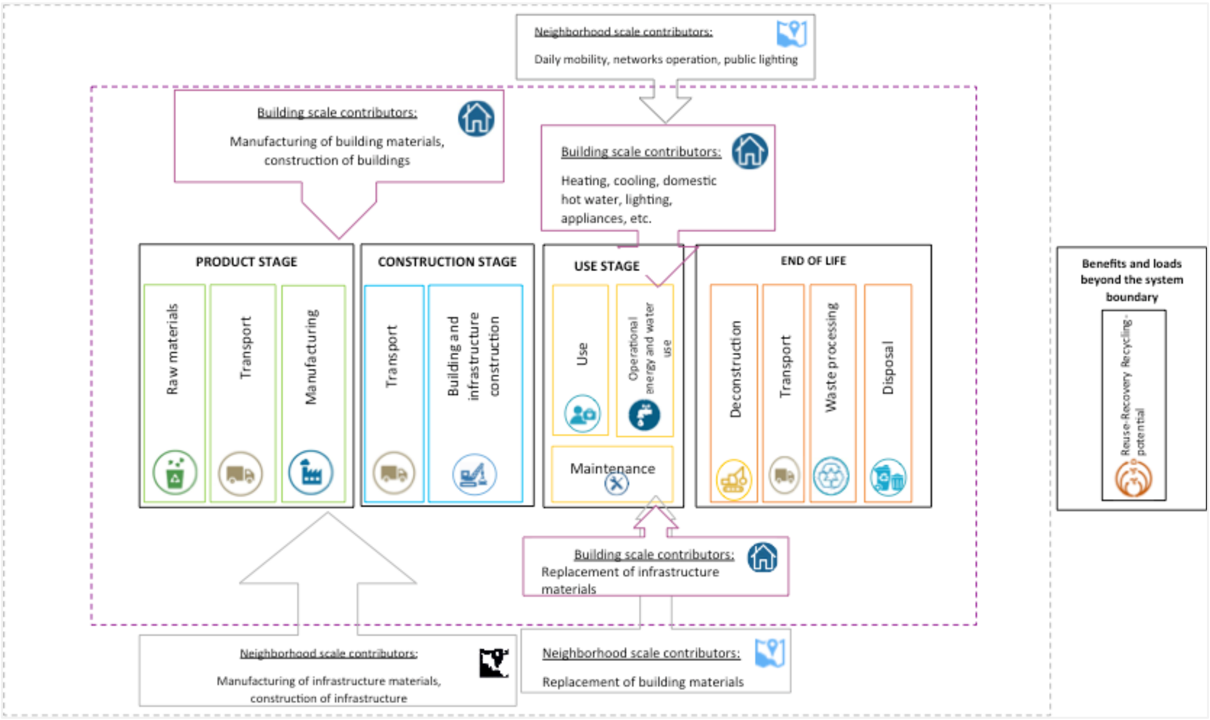

Figure 5. Neighbourhood life cycle steps and associated contributors at both building and neighbourhood scale (readapted by authors from [8])

The Life Cycle Assessment of almost all physical elements was performed using the Simapro© software [20] and the Ecoinvent database v.3.5 (2019). While Environmental Performance Evaluation for replace the windows in the building and to reduce the heat island effect in the open space was carried out adopting the impact indicators avowed by the related manufacturers in the Environmental Product Declarations (EPDs) [21-22]. Results showed in this paper are focused on only one impact indicator (Global Warming Potential, measured in kgCO_2-eq).

5. Streamlined LCA of retrofitting the block of Bolognina urban district

Outcomes provided in Figures 6 and 7 are related to only one of all the assessed LCA indicators. More specifically, Figure 6 provides the Global Warming Potential [kg CO_2 equivalent] related to the environmental impacts of the LCA applied to retrofitting the block of Bolognina neighbourhood associated to the two life cycle stages (product and use stage) in 1 year, while Figure 7 is referring to the entire Building's life cycle (reference service life value from [25]).

Although limited to the GWP indicator and restricted to two life´s stages only, the improvement due to the mitigation strategies is evident. The decrease of kg CO_2 equivalent is about 59% of the total value. It can be further appreciate if you consider the entire life cycle as it is highlighted in the Figure 7, in which is showed the increase of CO_2 value (vertical axis) in the years (horizontal axis).

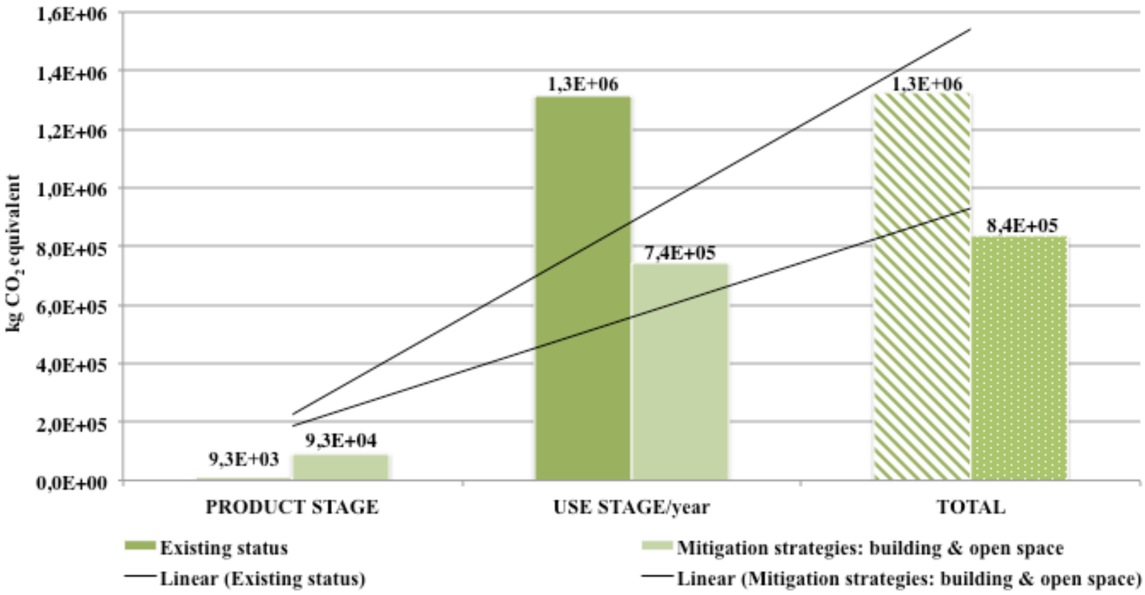

Figure 6. Comparative assessment related to Global Warming Potential (kg CO_2 equivalent) between existing status and mitigation strategies of the block of Bolognina neighbourhood in 1 year

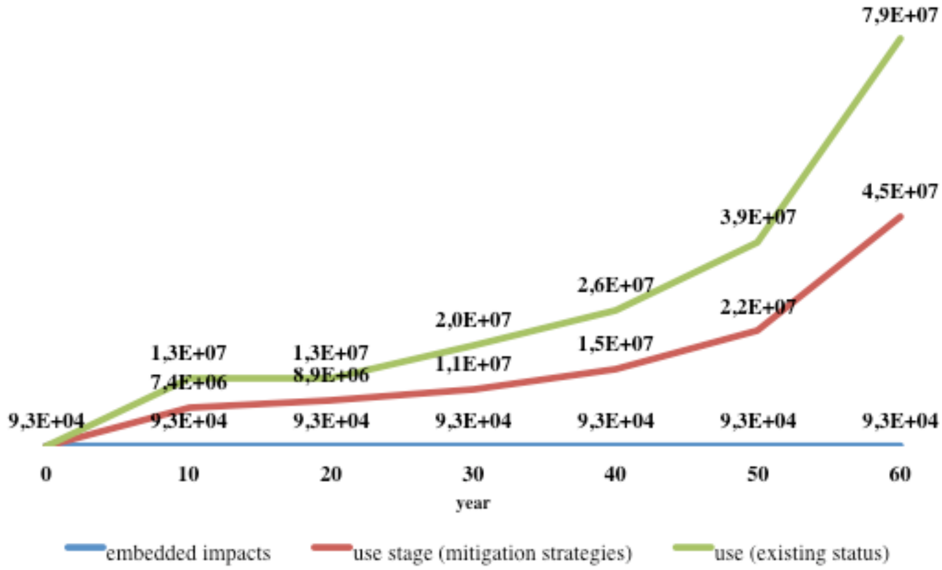

Figure 7. Comparative assessment related to Global Warming Potential (kg CO_2 equivalent) between existing status and mitigation strategies of the block of Bolognina neighbourhood during entire Life Cycle of Building (60 years)

More specifically, at building level the applied mitigation strategies have led to the reduction of energy consumptions in the building's use phase -heating, cooling, tap water and hot water- (i.e. 43,4% kg CO_2 equiv.), but increasing the embedded carbon generated in manufacturing of the materials used. However, total GHG emissions from mitigation strategies remains below the level of the existing status (37,8%). Likewise, actions on the open space (reduction of the heat island effect and drop of electricity consumption for public lighting) decreased GWP by ca. 41% (-52,1% in the use phase and + 90% in the product stage). As a first application, of a simplified application of LCA on an urban block, this study shows the potentiality of this methodology in the evaluation of the environmental performance of the built environment at urban scale. Next step will extend the evaluation to cover all other life cycle stages, but further researches are needed to complete the evaluation and to assess the three pillar of sustainability throughout a life cycle sustainability assessment.

6. Conclusions

Environmental assessments and, in general, the sustainability are nowadays relevant of most thematic areas, and particularly cities. Despite the evident irreversibility of environmental impacts like global warming, biodiversity and resource depletion, the environmental accounting in the building and urban sectors is presently based on subjective approaches and less precise [26].

Limited and simplified assumptions have been used in the present study focused chiefly on the methodologic implementation, but greater variation in context conditions would be useful to support a comparison of alternatives, notably in the design phase.

In terms of method the comparability among the case studies above all requires harmonization of the functional unit considered.

At the neighbourhood level, this is huge and complex, since that include elements different both as size that like typologies: buildings, infrastructure, public space.

Necessary gaps and implementations to build a complete and harmonized framework are presently showed from a recent study on the current state of the art [27].

Yet for application method improvement and to bridge the existing gap considerable efforts have still to be made.

Abstract. The environmental impacts of buildings can significantly vary with the dynamics of their energy demand and production. Significant variations have been modelled for buildings in the U.S., France, Denmark and Switzerland but the levels of variation are different between these countries. This difference can be explained by factors like the existing energy sources, the availability of renewable energy and the importation of electricity from nearby countries. With its high share of renewable energy and significant electricity exchanges with neighbouring countries, Switzerland presents a specific case where benchmark values from dynamic life cycle assessment should be well understood. The project's goal is to provide results from a dynamic life cycle assessment with a detailed study of the influence from temporal fluctuations in the national electricity production, electricity imports, decentralised generation and electricity demand from buildings. Additionally, consequences of changing the temporal precision (i.e. hourly, daily, monthly and annual) of energy dynamics are analysed. This assessment is conducted with demand and production estimations for the design of a residential building in Switzerland. Disparities of results are assessed for all temporal precision levels with a comparison to the values that are obtained with the current national methodology which operates with values based on average annual electricity production. Results thus suggest some methodological recommendations to develop the temporal aspects of the environmental impact assessment methodology for the Swiss building sector.

1. Introduction

Numerous life cycle assessment (LCA) studies of buildings have shown that energy demand, during their use phase, is often a key source of environmental impacts over their full life cycles. When combined with the inherent temporal variability of energy sources (e.g. gas, coal, photovoltaics), this observation raises the question of considering the energy dynamics to improve the representativeness of environmental impact assessment in LCA studies. Models of energy dynamics in recent LCA studies have mapped prospective scenarios of the future [1, 2], replicated the intra-annual electricity production variations [3-11] or simulated impact changes over time [12, 13].

When looking more specifically at the question of intra-annual variations of energy demand and production, the importance of such dynamics on LCA results have been investigated since 2013 mainly in the US [3-5], France [6-8], Denmark [9] and Switzerland [10, 11]. These studies have evaluated the impacts of rather recent residential [6-8, 10, 11], commercial [9] and institutional [3-5] buildings. The level of temporal precision on energy models varies between studies with hourly [5-11], daily [9] and monthly [3-5] averages and the effect of varying precision levels has been evaluated once [9] for Denmark. Overall, these "dynamic" LCA studies confirm that some environmental impacts might be reduced or increased substantially when compared to results from models which consider the average annual energy production mixes and demand from buildings.

While past studies clearly support a more regular account of energy dynamics in LCA of buildings, many aspects are still ambiguous for the specific case of Switzerland therefore raising some questions. First, how different would results be when compared to the current Swiss evaluation standard [14] which is based on annual averages for the electricity mix? Second, what is a useful level of temporal precision to describe energy production and consumption when considering a representativeness-to-effort ratio? Third, what is the importance of limiting the details on dynamic models of neighbouring countries when looking at the choices made in the recent Swiss studies [10, 11]? Further evaluations are therefore required to explore and answer these questions and they shape the goals of this work.

2. Case study

A project for a residential building near Fribourg in Switzerland is used as a case study to answer the three questions on energy dynamics from the introduction. This building is meant for three inhabitants and possesses an energy reference area (ERA) of 199 m^2. Standard appliances (i.e. oven, washing machine, dryer, dishwasher, domestic hot water and pumps), lighting equipment and an air-to-water heat pump are considered to evaluate the electricity demand of this single-family home. The building is also equipped with a roof-integrated photovoltaic (PV) installation of mono-crystalline technology with a peak power of 4.5 kW facing east.

The Swiss society of engineers and architects provides the SIA 2024 standard [15] which has been used to evaluate the hourly energy demand for the considered home during a "typical" year. This temporal curve of energy demand has been calculated by adding the provided curves for the standard appliances, lighting and heating. The "typical" heating needs for the year are based on the building components and climatic data from the SIA 2028 standard [16] which is the reference in the Swiss building sector for new projects. The home's energy demand amounts to about 8725 kWh/year (i.e. 43.85 kWh/year·m^2 of ERA). The hourly energy production from the PV installation is calculated with hourly solar irradiation levels in Fribourg for a full east orientation and 45º inclination during a "typical" year. The results, while more detailed, are coherent with values that are obtained from the PVopti Excel tool [17] which is widely used for projects that respect the MINERGIE® certification. The PV installation of this building is expected to produce about 3792 kWh/year (i.e. 19.06 kWh/year·m^2 of ERA). The hourly energy demand and production for a "typical" year are presented in figure 1 (from January 1st to December 31st).

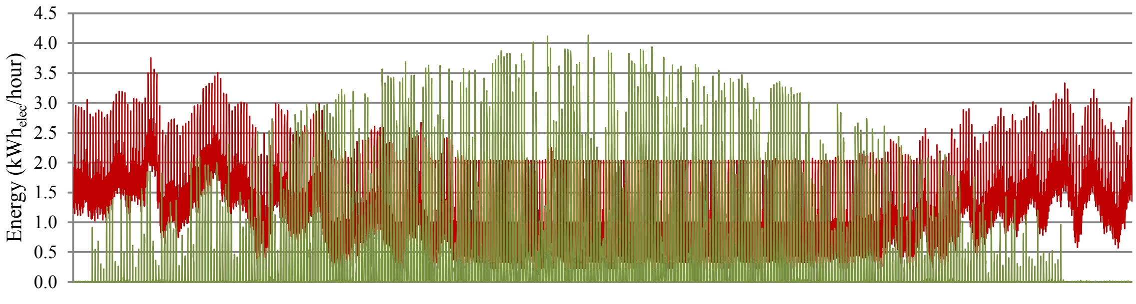

Figure 1: Building's hourly energy demand (red) and PV production (green) over a "typical" year

3. Scope of study

Many different modelling choices have been made to evaluate the potential environmental impacts of the home's energy flows and how different temporal precision levels will affect them within the LCA framework. This scope of study therefore lists all the key aspects which should be considered in the analysis of results and commonly found in LCA studies.

3.1. Functional unit

The chosen function unit (FU) for this assessment is the m^2 of ERA used during a year which represents the indoor floor area of heated rooms inside the buildings. The evaluated potential environmental impacts values are therefore given per $m^2 \cdot$year to present results for new homes which respects the Swiss energy standard.

3.2. Limits of the home's model

The focus on dynamics of energy demand and production for a Swiss residential building justifies the use of a model which concentrates on some components of the building's life cycle. Indeed, the only change between all considered options for this study is the temporal precision of electricity flows during the use stage. Modelling efforts are also directed on intra-annual variations meaning that no evolution on the long-term is considered and thus, analysis centres on variations of impacts for three "typical" years (i.e. 2016, 2017 and 2018). Figure 2 shows the boundary of the modelled system and offers a correspondence with stages defined in the EN 15804 document [17]. The model also details the energy sources of neighbouring countries (i.e. Austria [AT], Germany [DE], Italy [IT] and France [FR]) with a high level of temporal precision (up to hourly variation). The white boxes of figure 2 are defined as system processes since they list all the natural resource extractions and pollutant emissions that are related to the production of 1 kWh of electricity with these sources in respective countries.

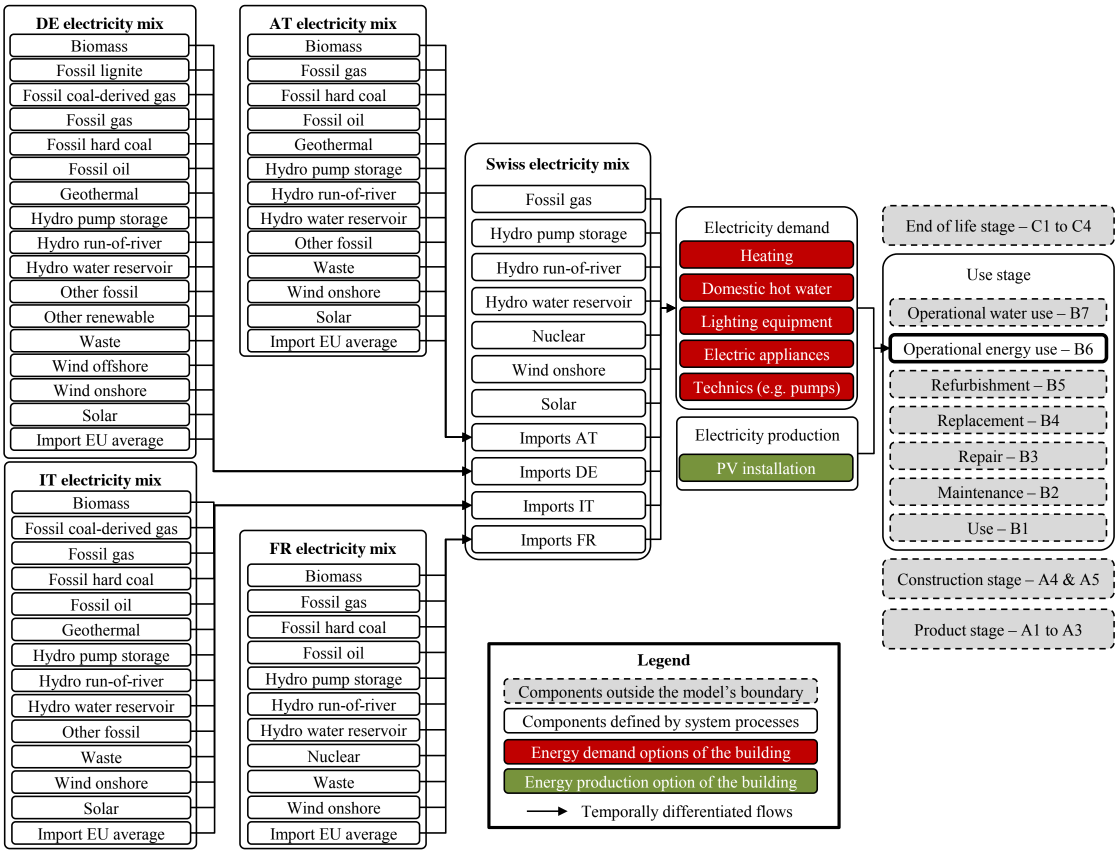

Figure 2: Considered components of the home's model with temporally differentiated flows

3.3. Sources of data

The model of figure 2 is informed mainly by two data sources: the ENTSO-E website and the ecoinvent LCA database. The ENTSO-E website [18] offers statistics on historical electricity generation from different energy sources and importation. The ecoinvent database [19] presents information that can be translated into potential impacts for these energy sources and the European average electricity mix. Combining these two sources of information requires some assumptions.

3.3.1. The ENTSO-E website: It was launched on the 5th of January 2015 and sources its information from electricity transmission system operators (TSOs) or other qualified third parties. The ENTSO-E transparency platform, in accordance with EU Regulation 543/2013, offers information on generation, load, transmission and balancing of 36 countries across the European continent (with Switzerland). The generation data describes the electricity mixes, with the different sources that are presented in figure 2, and informs on exchange values for importation and exportation between countries. The temporal precision of generation statistics varies between 15, 30 and 60 minutes depending on the data provider. Some gaps in the data can be observed which explains why this study only considers the period between 2016 and 2018. This interval of three years permits an analysis with four levels of precision: hourly, daily, monthly and yearly. Figure 3 presents an example of the provided information for the hourly electricity generation in Switzerland for one day (highest precision available).

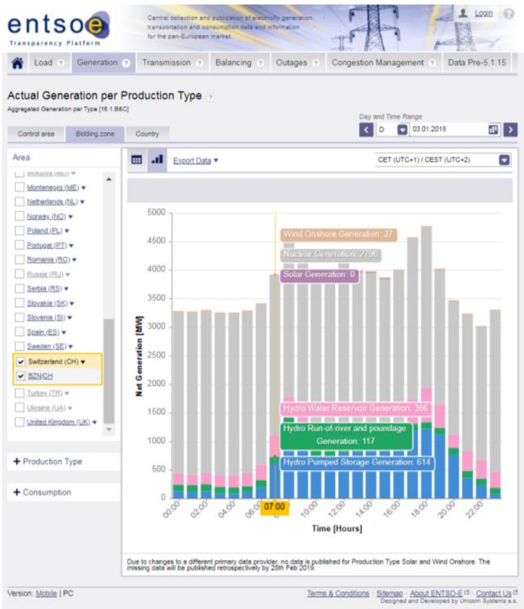

Figure 3: Example of information from the ENTSO-E website for the Swiss electricity mix

3.3.2. The ecoinvent v3.4 cut-off database: The organisation behind the ecoinvent database was founded by institutes of the Swiss Federal Institute of Technology (ETH) domain and the Swiss Federal Offices. It became a not-for-profit association in 2013. One of the core principles of this information source is “thrust in transparency” which means that it offers a comprehensive and detailed description of human activities and their effects (e.g. impacts) on the environment. Many processes of different electricity sources (e.g. coal and nuclear power plant production) are available for countries around the world. Such processes describe supply chains (i.e. link with other processes of human activities) and their elementary flows (i.e. extraction of natural resources and emission of pollutants). For all the relevant energy sources of this case study, the descriptions of processes (i.e. datasets), from version 3.4 cut-off, have been transformed into 4 potential environmental impacts (see subsection 3.4) per kWh of produced electricity with the help of the SimaPro v8.5.2.0 software.

3.3.3. Mapping connections between the data of ENTSO-E and ecoinvent. The differences in structures and levels of detail to describe the energy sources in the ENTSO-E and the ecoinvent database force the creation of a mapping structure to link environmental impacts (based on ecoinvent) to the energy sources statistics of ENTSO-E. These important modelling choices are necessary to calculate the potential environmental impacts of the Swiss electricity mix when ENTSO-E data is used for each hour of the day. Some assumptions on the shares of different technologies from ecoinvent (e.g. boiling or pressured water reactors) that relate to a common energy source in ENTSO-E (i.e. nuclear) were therefore made in this study. Table 1 presents these shares for the Swiss electricity mix. Mappings were carried out for all neighbouring countries (i.e. AT, DE, IT, FR) and readers are invited to contact the corresponding author if they would like to have access to this information. Table 1 shows that the ecoinvent database offers varying levels of details on technologies and it is important to mention that these levels of detail changes between countries.

Table 1: Mapping of links between energy sources for ENTSO-E and ecoinvent database

Energy sources in ENTSO-E	Energy sources as defined in ecoinvent v3.4 cut-off	Shares (statistics from 2014)
Fossil Gas	Natural gas, 500kW electrical, lean burn	100.00%
Hydro Pumped Storage	Hydro, pumped storage	100.00%
Hydro Run-of-river	Hydro, run-of-river	100.00%
Hydro Water Reservoir	Hydro, reservoir, alpine region	100.00%

	Wind, >3MW turbine, onshore	9.59%
	Wind, 1-3MW turbine, onshore	84.93%
Solar	Photovoltaic, 3kWp facade installation, multi-Si, laminated, integrated	3.74%
	Photovoltaic, 3kWp facade installation, multi-Si, panel, mounted	3.74%
	Photovoltaic, 3kWp facade installation, single-Si, laminated, integrated	2.48%
	Photovoltaic, 3kWp facade installation, single-Si, panel, mounted	2.48%
	Photovoltaic, 3kWp flat-roof installation, multi-Si	11.35%
	Photovoltaic, 3kWp flat-roof installation, single-Si	7.47%
	Photovoltaic, 3kWp slanted-roof installation, a-Si, laminated, integrated	0.43%
	Photovoltaic, 3kWp slanted-roof installation, a-Si, panel, mounted	6.32%
	Photovoltaic, 3kWp slanted-roof installation, CdTe, laminated, integrated	6.90%
	Photovoltaic, 3kWp slanted-roof installation, CIS, panel, mounted	0.86%
	Photovoltaic, 3kWp slanted-roof installation, multi-Si, laminated, integrated	3.74%
	Photovoltaic, 3kWp slanted-roof installation, multi-Si, panel, mounted	28.96%
	Photovoltaic, 3kWp slanted-roof installation, ribbon-Si, laminated, integrated	0.29%
	Photovoltaic, 3kWp slanted-roof installation, ribbon-Si, panel, mounted	4.02%
	Photovoltaic, 3kWp slanted-roof installation, single-Si, laminated, integrated	2.44%
	Photovoltaic, 3kWp slanted-roof installation, single-Si, panel, mounted	14.79%

3.4. Considered impact categories

The goal of comparing results from a dynamic assessment of energy flows with different temporal precision levels with the current Swiss standard based on annual averages (i.e. KBOB [14]) imposed the choice of three impact assessment methods that are used in this standard. The greenhouse gas (GHG) emissions (in kg of CO_2 eq.) were calculated with the characterisation factors (CFs) of the IPCC2013-100 year v1.03 method [20]. The renewable and non-renewable primary energy (in MJ primary) were computed with the CFs of the CED v2.05 method [21]. The environmental loading points (in UBP) were determined with the CFs of the ecological scarcity (ES) 2013 v1.05 method [22]. All these methods are available in the SimaPro v8.5.2.0 software.

3.5. Calculations of energy dynamics in a Swiss residential building

Once all the data has been obtained from the different sources and processed with a LCA software, it becomes rather straightforward to merge the temporally differentiated information of energy demand with the potential environmental impacts of the Swiss electricity mix for different hours, days, months and years. Then, the environmental impact of energy production from the PV installation is accounted while making the assumption that auto consumption is a priority. This means that only excess demand from the building will be covered by the Swiss electricity mix. The environmental impacts of electricity production from overproduction of the PV installation are not accounted in the impacts of the building (i.e. when production is higher than demand in figure 1). This modelling choice is explained by the idea that the Swiss grid, which uses this overproduction, should assume the impacts for its other customers. It should also be mentioned that the environmental impacts of 1 kWh of PV electricity is computed from the environmental impacts of the installation divided by its electricity production (in kWh) over its full life cycle (e.g. 0.093 kg of CO_2 eq. /kWh over 25 years). The following equation explains the calculation for any time period (e.g. an hour of day or a month).

$$Impact_{\Delta t} = P_{PV,\Delta t} \cdot EIF_{PV} + \left[\left(D_{House,\Delta t} - P_{PV,\Delta t}\right) \cdot EIF_{CH-mix,\Delta t}\right]_{if\ D>P}$$

Where:

$Impact_{\Delta t}$ is the impact of energy consumption for the selected time period Δt

$P_{PV,\Delta t}$ is the production of electricity from the PV installation during Δt

$D_{House,\Delta t}$ is the electricity demand from the different devices in the building during Δt

EIF_{PV} is the environmental impact factor of the PV electricity, which does not change

$EIF_{CH-mix,\Delta t}$ is the environmental impact factor of the Swiss electricity mix during Δt

4. Results and discussion

Figure 4 presents the potential impacts of the annual energy flows (i.e. demand and production) per m^2 of ERA for the four categories of the Swiss standard when system dynamics are considered. The dotted red lines are also offered to present the environmental impacts that are obtained when values of the Swiss standard (i.e. KBOB) are used (e.g. 0.102 kg of CO_2 eq./kWh for the Swiss electricity mix).

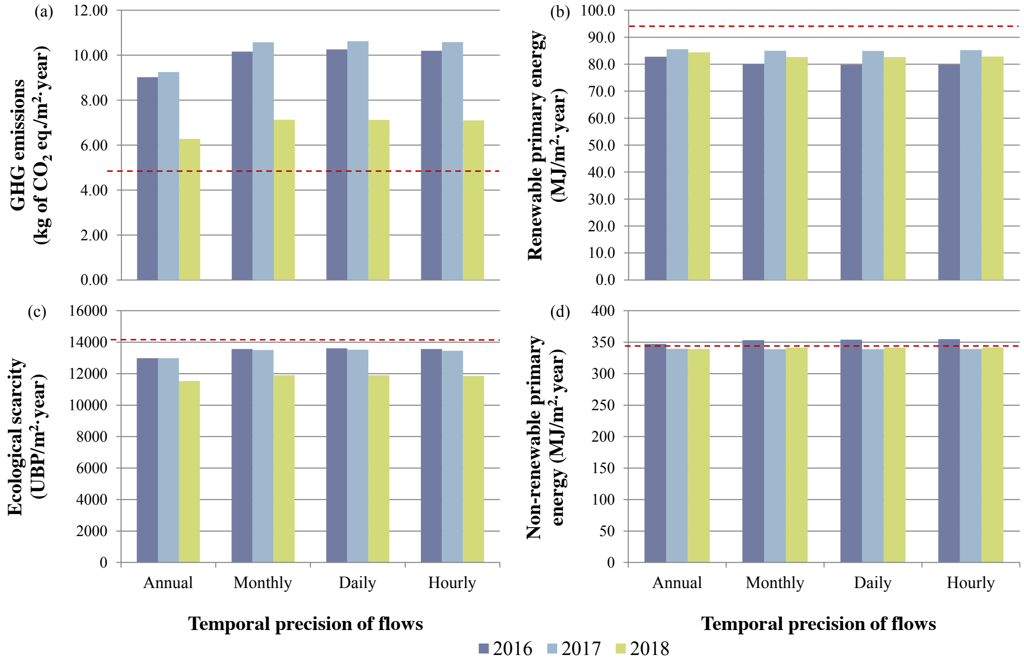

Figure 4: Potential environmental impacts from energy flows in 1 m^2_{ERA} for 2016, 2017, 2018

Results in figure 4 only show a significant divergence between the dynamic assessment and the outcomes of the Swiss standard evaluation tool (i.e. KBOB) for the GHG emissions (i.e. > +65%). The three other impact categories present smaller differences (-12% on average for (b), -7% on average for (c) and -1% on average for (d)). To go beyond this simple observation, two alterations between the annual static and dynamic models are presented in table 2 to show their importance on these observed total differences. It becomes clear that the change of background database (Δ1) and the description of the electricity mix (Δ2) have opposing effects on the three categories with relatively small variation (i.e. b, c and d). Table 2 also illustrate that both alterations have similar levels of importance when absolute difference are considered between the dynamic and standard results.

Table 2: Main contributors to the differences between the dynamic and standard results of KBOB

Categories of environmental impacts	*Step-by-step analysis*					*Share of absolute difference*	
	ecoinvent v2.2+ (KBOB)	**Δ1** database	ecoinvent v3.4 (static)	**Δ2** electricity mixes	Dynamic annual (2016)	**Δ1**	**Δ2**
(a) GHG emissions (kg CO_2 eq./$m^2_{ERA}\cdot$year)	4.40	+23%	5.42	+67%	9.03	31%	69%
(b) Renewable primary energy (MJ/ $m^2_{ERA}\cdot$year)	94.0	+19%	112	-26%	82.8	44%	56%
(c) Non-renewable primary energy (MJ/ $m^2_{ERA}\cdot$year)	347	-22%	272	+28%	347	46%	54%
(d) Ecological scarcity (UBP/ $m^2_{ERA}\cdot$year)	14065	-22%	11026	+19%	13151	59%	41%

Additionally, a relatively important variation of impacts between the annual average values and more precise options (i.e. monthly, daily, hourly) can be observed in figure 4 for GHG emissions (+14% on average) and ecological scarcity (+4% on average). Conversely, results for primary energy use (renewable and non-renewable) are not varying much with an increase of the temporal resolution. The same results show that most of the change for GHG emissions and ecological scarcity can be observed with the use of a monthly precision. This implies that a more detailed model will not change the conclusions of the environmental assessment for the analyses residential building which is representative of future single family housing in Switzerland.

The results of figure 4 also show that differences in electricity production between the years of a building use phase might relate to higher impact variability than the assessed intra-annual variations. Indeed, there is a much larger difference of impacts between 2017 and 2018 (i.e. -32% kg of CO_2 eq. and -11% UBP) than for any of the observed changes with different levels of intra-annual precision. A detailed analysis of the model clearly indicates that this difference is mainly explained by the reduced importation of German electricity during the beginning of 2018. Such an outcome stresses the need to consider the future of the Swiss electricity mix to obtain representative environmental assessments of buildings. Furthermore, it highlights one limitation of this study concerning the small amount of available historical statistics (i.e. 3 years) in comparison to the expected lifetime of buildings (i.e. 60 years). It is also worth mentioning that a detailed description of production sources for neighbouring countries was necessary to make this observation.

To go further on the question of a relevant complexity level for the model of energy sources in neighbouring countries of Switzerland, a comparison of results from this study and those of a recent publication [11] is necessary. In this publication, the temporal variations in primary energy use and GHG emissions have been modelled for the Swiss grid, but this model uses average values to describe the GHG intensity of France, Germany and Austria, while neglecting Italy. On this aspect, the complexity of the model is lower than the one that has been used in this study (see figure 2). The authors of this publication then obtain a level of GHG emission, based on hourly data, which is increased by 1.9% when compared to the result of a calculation with an annual average. This variation is significantly lower than what has been obtained in this study (i.e. +12%) which might partially be explained by the difference in the studied cases (i.e. buildings), but that also showcase the effects of considering a complex model of electricity importations.

5. Conclusion

A LCA study of a Swiss residential building has been conducted with different levels of temporal precision (i.e. hourly, daily, monthly and yearly) to model the potential environmental impacts of the dynamics of its energy demand and production during its use stage. When compared with values from the currently used standard in Switzerland, the results from this study show a significant difference for GHG emissions which can be explained by the use of different sources of data for energy statistics and environmental information. The comparison of results from models with different levels of temporal precision confirms previously observed variations, but also demonstrates that monthly precision is sufficient to make a representative assessment of new single-family housing in Switzerland. The separation of yearly demand and production for 2016, 2017 and 2018 then shows that prospective modelling might be more relevant than intra-annual precision to offer representative assessment. Finally, the consideration of temporal variation from energy sources in neighbouring countries reveals its importance when compared to models which considers average European electricity production.

Managing Construction Projects: Developing Complexity into Complicatedness

Eber W[1]

[1]LBI Bauprozessmanagement und Immobilienentwicklung, Technische Universität München, Arcisstraße 23, 80333 München, Germany.

eb@bv.tum.de

Abstract. Construction projects are understood as being complex and therefore in need of support through adequate tools to be successfully managed. Among others, the Building Information Model (BIM) is expected to provide a modern and powerful toolset allowing for reliable prediction of the respective development and behaviour. Based on Theory of Systems, the term of complexity in fact matches the principal capabilities of an object-oriented information system where e.g. the Building Information Modelling rests upon. However, any complex system tends to instable behaviour allowing principally for no reliable prediction, in particular in the single run required for unique projects with no possibility to rearrange processes without major losses. Correspondingly, experienced Construction Managers are judging the complexity of projects as a crucial obstacle to efficient execution but declare complexity as not measureable, thus as degree of unmanageability. Therefore, the inherent complexity of interdisciplinary projects needs to be reduced, i.e. transformed into complicatedness, not reducing the effort of elaboration but allowing for stable solutions. In order to achieve such a transfer, the inherent heterogeneity is utilized tracking down the strictness and linearity of the internal and external system borders, thus, investigating the separability of the adjacency matrices. These mainly topological considerations lead to criteria forming substructures finally allowing for predictable behaviour of the project structures with limited uncertainty. Therefrom, we expect some significantly improved understanding of the cybernetics of projects and consequently advanced possibilities in shaping and establishing activity-based risk management, which is crucial to nowadays construction and real estate projects.

1. Introduction

The introduction of Building Information Models (BIM) is currently expected to solve a wide range of construction problems [1]. Resting upon the principles of object-oriented database theories [2], this approach is bound to modelling the complete entirety of elements required for construction and their respective interactions [3]. If in particular the completeness of this model can be ensured undeniably the behaviour of the system can be predicted in detail [4] [5]. Thus, the expectations are based on the human ability to describe a very encompassing unstructured entirety with utmost precision [6]. Besides the fact that many issues required for operational prediction, like contracts, dates and operational i.e. capacity-induced interactions, are principally not available in advance [7], the major problem results from the system's inherent complexity, leading to unstable and therefore nevertheless unpredictable solutions [8][7]. Since the object-oriented approach of BIM is intentionally in no way restricted to systems of low complexity, the principal accessibility of prediction limited due to more abstracts reasons needs to be investigated. Thus, this article focusses on the term of complexity [9] and the therewith resulting inherent issues.

2. Definitions of Complexity

Considering the term of complexity [10] of a system, in particular complexity of the organisation of a project, some confusion exists.

2.1. The Understanding of Complexity in Construction Management

Recent surveys among project managers [11] reveal that complexity is considered to be an existing characteristic of a project, but state it not to be accessible by any kind of measurement. If this would be true, the parameter complexity would serve only as the description of the degree of a project to be not predictable and therefore not manageable. Then, any so-called "complex" project may under no circumstances be initiated since the expected result can in no way be achieved with some certainty. So, either projects are tackled on the background of hope and accidentally succeed or means of dealing with a high degree of complexity are available and hidden beyond the surface of management [12].

2.2. Theoretical Definitions of Complexity

Even if this understanding is more semantical at least the central idea is given by distinguishing between complex and just complicated behaviour. Caldarelli and Vespignani [13] state the criteria for complexity first as heterogeneity over all scales, indicating that average values are not representing the system's characteristics and second as being irreducible, i.e. any attempt of separating parts of the system leads to a fundamentally different behaviour [14]. These criterions in fact allow for no statistical description and therefore represent the absolute limit of unmanageable structures due to complexity. However, in order to transform organisational structures into manageable units, substructures need to be identified which can be treated separately without changing the system's behaviour significantly [15]. Thus, truly complex systems remain complex, but if they were separable to some degree the task would be to eliminate exactly this amount of complexity. Then, based on statistical methods incomplete complexity may be transformed into complicatedness, i.e. into a set of widely independent subsystems with less complexity. On this background, based on Systems Theory, several mathematical definitions of complexity are possible, which are mainly compatible to each other, leaving the difficulty with the translation of organisational systems into abstract systems. The parameter of complexity may be defined as

$$\alpha = \ln(\xi + 1) / \ln N \tag{1}$$

where N represents the cardinality, i.e. the number of primitive elements within the system, and K counts the interactions between them. The interoperability $\xi = K / N$ equals the average number of (directed) interactions per node [16]. In the following, this formal definition is subjected to more meaningful interpretation:

2.2.1. Measure for the Interaction Degree of Primitives. As a classical approach, the parameter connectivity focusses on the number of interactions K within the system related to the number of primitive elements. Based on the known cardinality N and K the complexity is just a logarithmic measure, scaled in a way that maximum connectivity, i.e. each element is connected to each other element, leads to $\alpha = 1$ [17].

2.2.2. Measure for the Relative Information of a Node. The local information of a particular node, based only on structures, is proportional to the number ξ of nodes actively connected to, i.e. where a local token may be transferred to. ξ needs to be increased by 1 to cover the node itself as a possible additional target of the information. According to [18], the information is measured as logarithm of the options, in this case related to the maximum available number of target options which is N. Then, complexity represents the average entropy of a node in comparison to the possible entropy according to Shannon [18]: $E_R = \ln(\nu + 1) / \ln N = \alpha$ [18].

2.2.3. Degree of Emergence of a System's Behaviour in Contrast to Complicated Behaviour. Describing complexity by the number of states a system can occupy leads to a similar explanation. At a certain point of time, the considered system is defined by a multidimensional state within the space of states. Focusing mainly on the dynamics of a system, complexity can be defined by the number of states which are available for a next step which is given by the transition from one state to any logically following step. This is only possible along the directed interactions which are represented again by the interoperability $\xi = K / N$ out of N states available. Then, the logarithmic measure for the number of available states is the given complexity α [17].

2.2.4. Dimension of the Configuration Space of a Project Structure. Positioning all elements in a way that each is the spatial next neighbour to all the targeting elements requires a virtual space with a number of α dimensions. Thus, complexity represents the dimension of the configuration space scaled to a maximum dimensionality of 1, where all nodes can be placed respectively [18].

2.2.5. Degree of Non-linearity of Propagation Deviations. Furthermore, α is determined as the exponent of the structural development of a modification $\Delta(\zeta)$ from one causal situation r to a next logically depending situation r+1. Thus, α reflects the degree of the linearity of the structural development $T(r) \simeq \xi^{1+\alpha r} \Delta(\zeta) / (1-\beta)$ with increasing structural steps r and the positive factor with each step $\omega \simeq \xi^{\alpha}$ [20].

2.3. Complex Solutions to Systems Theory Differential Equations.
Systems Theory describes the behaviour analysing the linear Taylor terms of functions which represent the interaction of nodes. For a set of linear differential equations the solutions are of the type

$$n_i : \frac{\partial Q_i}{\partial t} \simeq \sum_j c_{i,j} Q_j \qquad Q_i = \sum_j g_{i,j} e^{\lambda_j t} \left(+ \sum_j g'_{i,j} e^{2\lambda_j t} + \dots \right)$$

Without limitation to the generality, the solutions [21] are either oscillating, exponentially escalating or in rare cases approaching constant values. Therefrom, the authors conclude the restriction to very clear structures in order to maintain predictable systems' behaviour which is the same as manageable systems. Finally, graph-theoretical tree-structures and network-structures are the only remaining options which correspond well to the common understanding. In this paper, a different, however supporting approach is taken leading to a similar result but based on an investigation of a critical transition in consuming resources.

3. Critical Point of Complexity

A fairly simple consequence of complexity would be the asymmetrical distortion of average values due to higher interoperability values $\xi > 1$ if intermediate results are subject to limited uncertainty [22]. A purely sequential system corresponds to $\xi_{lin} = 1$ and therewith $\alpha_{lin} = \ln 2 / \ln N$. In this situation, the central limit theorem states average values of e.g. duration or consumption of resources for the whole system equal to the singular elements. However, increasing $\xi > 1$ leads to a loss of efficiency due to the absolute requirement of the contemporary readiness of all prerequisites for the subsequent process. In the following, this is presented exemplarily for the duration of processes but holds true for resources and products as well.

3.1. Local Consideration
Let the duration t of a process vary around a fixed value based on a constant distribution (figure 1 and figure 2): $t = t_0 \pm \tau / 2$ respectively $t = t_0 - \tau / 2 + \tau'$, where τ' is a random variable, according to the distribution

$$P(\tau') = \begin{cases} \tau^{-1} & if\, 0 \le \tau' \le \tau \\ 0 & otherwise \end{cases}. \tag{2}$$

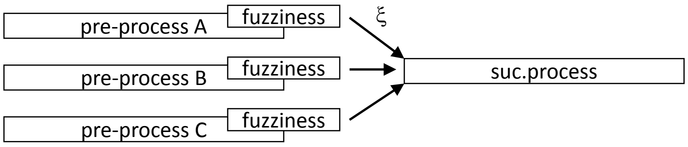

Figure 1. Definition of interoperability

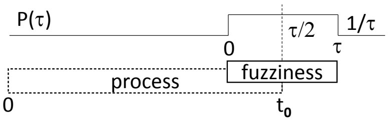

Figure 2. Probabilities of fuzziness

This distribution is normalised and, thus as expected, the average value is

$$\overline{\tau_1} = \int_0^\tau \tau' \tau^{-1} d\tau' = \frac{1}{2}\frac{\tau'^2}{\tau}\bigg|_0^\tau = \frac{1}{2}\frac{\tau^2}{\tau} = \frac{\tau}{2} \tag{3}$$

Combining two predecessors PrA and PrB into one process leads to the probability P of PrA times the probability, that process PrB is already finished, and *vice versa.* Any process duration "finished before" is determined:

$$P_{before\,\tau'}(\tau') = \int_0^{\tau'} P(\tau'')d\tau'' = \frac{\tau''}{\tau}\bigg|_0^{\tau'} = \frac{\tau'}{\tau} \qquad P_{\Pr A \& \Pr B}(\tau') = 2P(\tau')\cdot\frac{\tau'}{\tau} = 2\cdot\frac{\tau'}{\tau^2} \qquad (4)\,(5)$$

Thus, we find as average time for the combined situation:

$$\overline{\tau_2} = \int_0^\tau \tau' 2 \frac{\tau'}{\tau^2} d\tau' = \frac{2}{3}\tau \tag{6}$$

For each number of preceding processes to be taken in, the overall probability is a factor $1/\tau$ for the primary process, the number of processes to have finished before as they can be replaced by the primary process and a factor τ'/τ for each process that needs to have finished before. Thus, the probability for a number of ξ processes to be taken in is:

$$P_\xi = \xi \frac{1}{\tau}\left(\frac{\tau'}{\tau}\right)^{\xi-1} = \xi \frac{\tau'^{\xi-1}}{\tau^\xi} \tag{7}$$

The therefrom derived average time is

$$\overline{\tau_\xi} = \int_0^\tau \tau' \xi \frac{\tau'^{\xi-1}}{\tau^\xi} d\tau' = \frac{\xi}{\xi+1}\tau \tag{8}$$

Remark: The worst case scenario is considered $\overline{\tau_\xi} = \tau/2$ where the indeterminacy is completely turned into reality and therefore to be avoided by any means. Approaching this situation is described by average relative losses $\hat{\tau} = 2\bar{\tau}/\tau$ respectively as add-on to the $\xi = 1$ situation

$$\tau_{add} = \frac{2\xi}{\xi+1} - 1 = \frac{\xi-1}{\xi+1} \tag{9}$$

As can be expected, this equals zero for $\xi = 1$ (linear sequence, no add-on to the average duration of a single process) and approaches unity as the worst case of the given distribution for $\xi \gg 1$. This result can be easily formulated dependent on complexity α and volume, i.e. cardinality N of the system. With $\alpha = \ln(\xi+1)/\ln N \rightarrow N^\alpha - 1 = \xi$ we obtain:

$$\tau_{add} = \frac{N^{\alpha}-2}{N^{\alpha}} = 1 - 2N^{-\alpha} \tag{10}$$

This yields a value very close to the worst case for maximum complexity $\alpha = 1$ if only the number of elements is large enough. The minimal complexity for a linear chain is

$$\tau_{add,\min} = 1 - 2N^{-\alpha_{\min}} = 0 \tag{11}$$

3.2. System-wide Consideration

Within a system, repeated recombination of fuzzy processes needs to be taken into account. Causal interdependencies lead to a system structure, where all elements are ordered according to ranks. Thus, the maximum number of ranks Γ according to the Theory of Graphs describes the maximum length of any causal chain within the considered system. The density $\rho = N/\Gamma$ denotes the average number of elements on the same rank. On each rank r the number of ξ elements are combined and operate on a single element at r+1. Combining ξ elements on a singular rank position differs in no way from combining some elements on r+2 where these are combined from ξ elements on r+1. Therefore, only the number of elements combined on all rank positions needs to be known in order to elaborate the statistical add-on to the overall result. Since on each rank, each element combines from ξ elements, the result comprises the combination of ξ^{Γ} elements. Therewith we obtain for the total system:

$$\mathrm{T}_{add} = \frac{\xi^{\Gamma}-1}{\xi^{\Gamma}+1} = \frac{\left(N^{\alpha}-1\right)^{\Gamma}-1}{\left(N^{\alpha}-1\right)^{\Gamma}+1} \tag{12}$$

The following graph (figure 3) shows the dependency on the cardinality N, the complexity α and the maximum rank Γ.

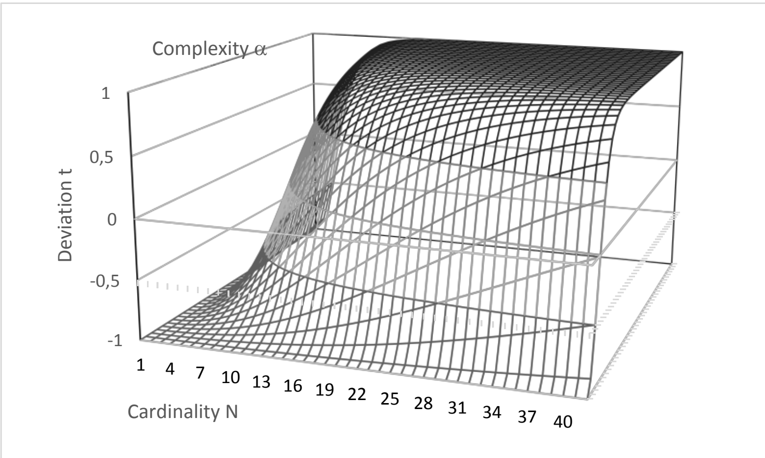

Figure 3. Critical transition of add-on T_{add} *vs* N and α .

The add-on is quickly rising to the worst case for higher cardinality or/and higher complexity. With increasing Γ, the transition becomes very steep and therefore marks a limit of criticality, which is described by

$$0 = \mathrm{T}_{add} = \frac{\left(N_c^{\alpha_c}-1\right)^{\Gamma}-1}{\left(N_c^{\alpha_c}-1\right)^{\Gamma}+1} \quad \rightarrow \quad 0 = \left(N_c^{\alpha_c}-1\right)^{\Gamma}-1 \tag{13}$$

$$\alpha_c = \frac{\ln 2}{\ln N_c} = \alpha_{lin} \tag{14}$$

The critical transition lies exactly where complexity equals the value given for a linear chain. Thus, for any substantial Γ we obtain strongly increasing losses due to complexity as soon as the limit of linear chains is exceeded. Still smaller values α indicate the breaking up of the system into smaller subsystems, where at least some elements have no successor and therefore no part in influencing the rest of the system anymore. The derivative with respect to ξ reveals the behaviour at this border:

$$\left.\frac{\partial}{\partial \xi} \mathrm{T}_{add}\right|_{\xi=1} = \left.\frac{2\Gamma \xi^{\Gamma-1}}{\left(\xi^{\Gamma}+1\right)^2}\right|_{\xi=1} = \frac{\Gamma}{2} \tag{15}$$

The rise of loss is closely coupled to the length of causal sequences Γ. Close to unity, i.e. for negligibly short logical chains, they play no role. Yet as they become longer as is typical for projects, they reach substantial values. Considering the scales of $T_{add} = 1$ as the worst case, this is particularly large as soon as Γ reaches values of significantly more than 2.

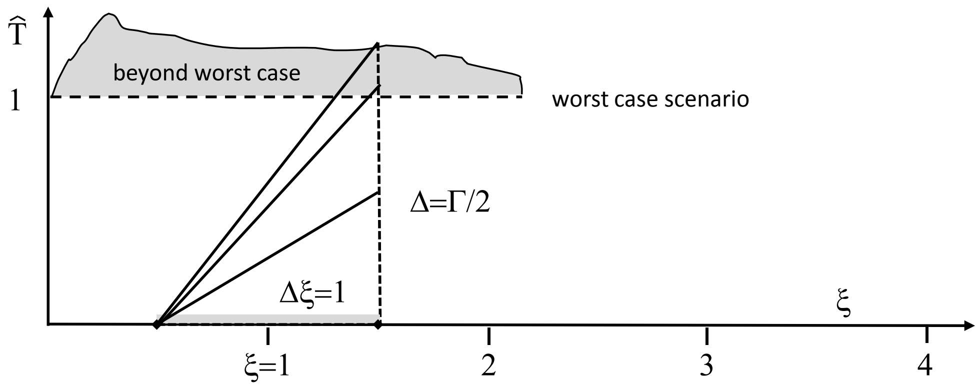

Figure 4. Scaling of derivative at the critical transition

Furthermore, the development close to criticality with respect to N and α can easily be achieved by differentiation. With $N^{\alpha} - 1 = 1 \rightarrow N = 2^{1/\alpha}$, we obtain

$$\frac{\partial}{\partial \alpha} \mathrm{T}_{add} = \frac{\partial}{\partial \xi} \mathrm{T}_{add} \left.\frac{\partial \xi}{\partial \alpha}\right|_{\xi=1} = \Gamma \ln N \tag{16}$$

and

$$\frac{\partial}{\partial N} \mathrm{T}_{add} = \frac{\partial}{\partial \xi} \mathrm{T}_{add} \left.\frac{\partial \xi}{\partial N}\right|_{\xi=1} = \frac{\alpha \Gamma}{2^{1/\alpha}} \tag{17}$$

Thus, at the brink of complexity, losses are rising further proportionally to $\ln N$ which does not compensate for the proportionality to Γ or viewed in regard of complexity α with a factor $\alpha / 2^{1/\alpha}$. Here, only low complexity $\alpha \ll 1$ in comparison to low Γ, i.e. short causal chains, are of help. According to figure 5 e.g. complexity of $\alpha \approx 0,45$ at max would just compensate for causal chain lengths of unrealistically low $\Gamma \approx 10$ for a worst case, but only $\alpha < 0,15$ is capable to secure such a situation to at least a few percent of complete indetermination.

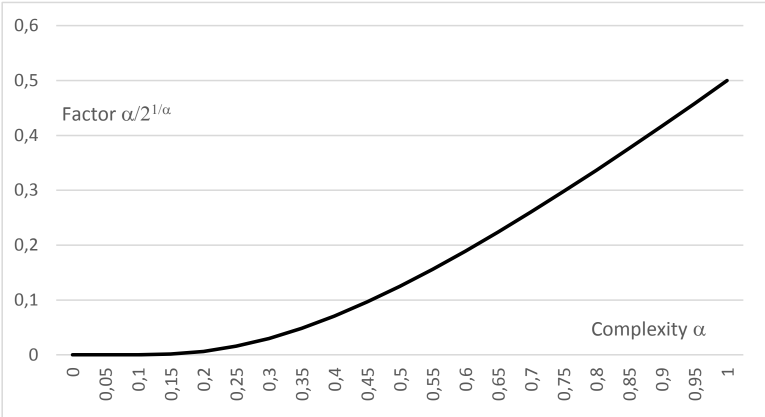

Figure 5. Factor eventually compensating for Length of Chains Γ

In both cases, as long as not all variables are perfectly well-known and not varying, i.e. $\tau = 0$, close coupling of processes leads to unbearable losses and must be avoided by all means. On this background, we conclude the general unmanageability of complex systems.

4. Reducing Complexity

Complexity is defined through the characteristic of a system that no element nor an interaction can be removed or ignored without modifying the systems' behaviour significantly [14][23]. On this background, in fact, no improvement on tackling the situation can be offered [24]. Yet, the question is whether real systems are factually that complex or can be separated into smaller subsystems, which act individually and are mainly not interfering with the remaining system. Then, the overall-behaviour would be just a linear concatenation of the subsystems, which is just complicated, since it demands only industriousness and effort to understand and describe the behaviour, but is principally possible – in contrast to truly complex systems. This leads to an investigation of the separability of a system, formally identical to the question of to which degree the adjacency matrix representing the systems interactions is separable into independent submatrices [25]. Considering the adjacency matrix includes the localisation and sorting out the singular elements, i.e. elaborates the systems' behaviour on local levels [26]. In order to judge a system on a more general level, adequate homogeneity is presupposed since only then statistical reasons will hold [13]. The demand of reducing complexity in order to increase manageability is here given by the attempt to minimize complexity losses. As already mentioned, a different approach by modelling the system via a set of linear differential equations and considering characteristics of stability [27] leads to the same conclusions.

4.1. Issues from Minimizing Losses

The strong dependency of losses on ranks Γ emphasizes the importance of rank-sorted structures, i.e. causal sequences, where cause and effect are clearly defined. This in particular enforces to avoid any fuzzy structures which can not be formulated as graphs.

4.1.1. Loop-Freeness. Obviously, high values of Γ indicate a very high positive gradient close to the $\xi = 1$ limit. This leads to the conclusion that in any case long causal chains need to be broken up. In particular, loops need to be eliminated completely since they principally lead to infinite values of Γ .

4.1.2. Control-Loops. If loops are very short, i.e. eventually comprising only two corresponding elements, the consideration is on a different basis. Such very local loops with no further impact may be understood in detail, therefore used in particular to stabilize elements as negatively effectuating control loops, exhibiting partly oscillating behaviour but dampened with reasonably short time constants. In this case, the behaviour is well understood and is not subject to the overall consideration of stochastic impact. However, since they would stabilize variables, they are strongly contributing to the separation of systems, as they lead to a high degree of independency of formerly strongly coupled segments [28].

4.1.3. Multiple Paths. The exceedingly high gradient of losses is bound to the multiplicity of impact. This implies the need to prefer structures, where impact is being distributed over the graph, but never united. On the background of these arguments only two well-known graph-theoretical structures [29] [30] [31] remain as the goal of restructuring complex systems.

4.2. Resulting Structures Tree and Network

Unidirectional tree-structures maintain clear ranking, no multiple paths and absolute freedom of loops. Since they certainly cannot model complete (complex) systems, they need to be used in particular to operate definition and responsibility issues. Including very local control-loops, for clear structural reasons, absolutely safe results can be constructed and finally obtained. All further interaction must be subjected to graph-theoretical networks [32]. Allowing for almost all kind and number of interactions, which cannot be avoided in production, at least ranks and freedom of loops is enforced. The remaining problem due to multiple paths and possibly high impact-values ξ, however can easily be tackled by subjecting the singular elements, i.e. subsystems, to local control-loops which would ensure the correct (according to the given unambiguous definition) outcome of the elements.

5. Conclusion

Summarising, we obtain a very plain methodology to treat complexity in organisational structures. In any case, complexity itself can not be cured but only reduced, i.e. by eliminating the tightness of interactions. Therewith, the former large complex system becomes separated into a set of less complex subsystems which can be understood and handled more easily. The resulting modified system comprising the subsystems is only helpful if this is less complex than the original, i.e. interactions are less and simple, ideally just a linear combination of the subsystems. Compatible with common understanding, but based on a much more substantial consideration, the resulting structures need to be either graph-theoretical tree-structures or rank-sorted, loop-less graph-theoretical networks. Possibly multiple but strict tree-structures serve to ensure completeness and systematical correctness of the elements to be identified. Separated from this elaboration structure, these elements may be (re-) subjected to their interaction on the basis of well-ordered networks. Factually complex systems would not allow for such ordering due to being irreducible by definition. However, in many cases, hidden separability to some degree is given and the attempt of applying these strict structures reveals less than assumed complexity. Otherwise, in order to artificially produce independency, short control-loops need to be applied. Based on dampening loops, random result variations of processes are forced back to tolerance corridors around the designed values so that successor processes are no more dependent on the exact performance of the predecessors. Within tree-structures, they help separate branches (horizontally) as well as keep hierarchical levels (vertically) apart. In network structures, they serve breaking up causal loops and shortening causal chains in longitudinal direction. Then complexity is transferred into mere complicatedness, where emergent behaviour is replaced by a larger set of independently operating subsystems and their local behaviour. To tackle this, only industriousness is required, but predictable solutions are principally available.

Abstract. Capturing uncertainty in multiple criteria decision analysis (MCDA) is not a new theme but a largely developing topic which is in close connection with uncertainty theories such as fuzzy set and grey systems theories. Due to growing complexity of construction processes mainly because of implementation of sustainability aspects it would be necessary to take advantage of a novel MCDA methodology as an efficient tool to handle the uncertainty in sustainable construction decision making. In this study, we utilise a novel neutrosophic modified best-worst method (NM-BWM) to deal with the uncertainty in decision making in the context of sustainable construction. The method is an integration of neutrosophic set theory (NST) and the modified best-worst method (M-BWM). The NST can provide insights on efficient uncertainty handling of decision makers (DMs) subjective judgements. The BWM is a MCDA method which utilises two vectors of pairwise comparisons (the best criterion to others and others to the worst criterion) to obtain the weights of evaluation criteria. Merits of the BWM include its capability in effectively remedying the inconsistency derived from pairwise comparisons as well as simplicity and less pairwise comparisons compared to other similar methods like analytic hierarchy process (AHP). We show the applicability of the method in a case study with focus on the implementation of sustainable construction.

1. Introduction

The way of thinking in simple logical contexts often leads to overlooking medium- or long-term effects on our immediate environment. Contrary to the objectives of sustainable development, future generations are endangered [1]. The drastic situation of climate change, as well as the increased number of storms, floods, droughts and forest fires, is thus rather due to the actions of mankind in the seventies [2]. As a result, climate protection and disaster control represent increasingly complex challenges for architects and engineers. Sustainable construction is the buzzword at the centre of this development. In order to deal with complex systems and the associated inherent dynamics of the system ”building”, systemic thinking is indispensable [3],[4].

The following article addresses the implementation of sustainability aspects in the early design stage of buildings. With a variety of criteria to consider, the tasks for architects are becoming increasingly complex. The human brain is not able to assess the effects of changes in one factor on more than four interrelated influencing factors [5]. In particular, medium- and long-term effects cannot be assessed without tools for such a large number of related factors. Construction projects exceed this number of interacting criteria by a multitude. One approach to make the complexity of numerous influential criteria manageable are multiple criteria decision making (MCDM) methods.

In the present article the application of a neutrosophic modified best-worst method (NM-BWM) is discussed in order to facilitate and thus advance the implementation of sustainability aspects in the early design stage of buildings - in which numerous non-quantifiable factors and multipe decision makers (DMs) are present. In real-world decision-making environment, there is an uncertainty in DMs opinions which cannot be dealt with properly in the original BWM. In the original BWM, two vectors of pairwise comparisons including best-to-others and others-to-worst vectors are treated with the same level of importance. The NM-BWM can help overcome this shortcoming by incorporating the NST into the original BWM in order to capture the uncertainty of DMs on two vectors. The NST has two main advantages over other similar uncertainty theories like fuzzy set theory; firstly, the information about rejection has effectively quantified in the NST and secondly it has the capability to independently quantify the indeterminacy membership, which adds an extra level of suitability to it for structuring DMs' confidence value acquisition process [6].

2. Literature Background

In this section the literature background of applied methods is described. It includes the subsections sustainability assessment in construction industry (2.1), multi attribute decision making in construction industry (2.2), best-worst method (2.3) and neutrosophic set theory (2.4).

2.1. Sustainability Assessment in Construction Industry

Due to the uniqueness of each individual building, planning according to recurring procedures and processes is not feasible. In addition to the complexity of a building, which is already given by static and physical building requirements, the design process is increased by sustainability requirements. Through standards harmonized at the European level (hEN) and through numerous normative and voluntary instruments - e.g. ISO 14000 series of standards "Environmental management" [7], [8] the implementation of sustainable construction is being promoted. In 2008, the ISO 15392 "Sustainability in building construction - General principles" [9] created a uniform understanding of sustainability in the construction industry [10]. According to the European framework of CEN/TC 350 next to the three classical dimensions of sustainability - environmental dimension, economic dimension and social dimension - additionally functional and technical qualities have to be considered within the sustainability assessment of buildings [11], [12], [13], [14]. Due to the multi criteria interdependencies of sustainability criteria, holistic consideration can only be achieved by a complete set of criteria [15]. Numerous building certification systems (BREAAM[1], LEED[2], DGNB[3], etc.) have already developed complete criteria catalogues for the sustainability assessment of buildings and are suitable for the assessment of the building performance [16]. The implementation of sustainable construction is a multidimensional concept that is gaining relevance in all areas of society [17]. Barbier states that sustainable development involves the simultaneous maximization of environmental, economic and social system goals [18]. However, as Munda has shown, it is generally not possible to maximize different goals at the same time. Therefore, a compromise should be found between different objectives, which can be achieved by applying MCDM methods [19]. The current challenges in the operationalization of holistic design and construction processes are mainly based on imprecise stakeholder requirements and the current lack of suitable methods for controlling life-cycle processes [20].

2.2. Multi Attribute Decision Making (MADM) in Construction Industry

Multiple attribute decision making (MADM) or multiple criteria decision aiding (MCDA) have been increasingly popular in various decision-making fields [49], [50]. For instance, Wang et al. [21] indicated this popularity in sustainable energy because of the multi-dimensionality of the sustainability goal and the complexity of socio-economic and biophysical systems.

In the course of the literature search numerous articles using MADM-methods for the different application in construction industry were found [22]. Already when selecting materials, decision makers have to consider numerous factors (mechanical properties, physical properties, material costs, durability, etc.). A model for the selection of building materials that weights criteria based on the three-pillar sustainability approach was proposed by Akadiri [23]. According to Jahan et al., MADM-methods such as TOPSIS, ELECTRE and AHP are the most frequently used methods in the course of material selection [24]. MADM-methods are also used for the selection of construction machinery. Temiz & Calis investigated the correct selection of an excavation machine for a construction site and compared the methods AHP and PROMETHEE [25]. For the selection of cranes Skibniewski & Chao investigated the application of AHP already in 1992 [26]. In addition, MADM-methods are also applied in the selection of concrete pumps [27]. A further field of application of MADM-methods are transport and logistics. Machharis & Bernardini investigated the application of multi criteria decision methods in transport projects [28]. According to Turcksin et al. the most frequently applied

[1] https://www.breeam.com
[2] https://new.usgbc.org/leed
[3] https://www.dgnb-system.de/de/system/zertifizierungssystem/index.php

decision methods in transport projects are MADM methods (AHP, ANP, MAUT, MAVT), outranking methods (PROMETHEE, ELECTRE) and regime analyses [29]. MADM-methods are also widely used in the field of logistics. Tuzkaya investigated the impact of transport processes on the environment, Wang & Chang applied MADM-methods in the field of green urban logistics or Moghaddam et. al in the field of clean energy for energy efficient buildings [30], [31], [32]. Within environmental topics MADM-methods were used in waste management, energy management, waste water treatment, water quality or air quality [33]. One method developed very late in the history of MCDM and rarely applied in the field of sustainable construction until now is the best-worst method (BWM).

2.3. Best-Worst Method (BWM)

In the field of construction industry BWM was applied in piping selection [34] and in areas of risk assessment [35], [36]. The BWM can help DMs in defining the weights of criteria in a decision-making problem. In BWM, firstly the best criterion (i.e. the most favourable) and the worst criterion (i.e. the least favourable) must be determined by the DM. Secondly, pairwise comparisons are carried out between each of the two criteria (i.e. best and worst) and other criteria. Then, weights of criteria are determined by solving a mathematical model. The simplicity of use, less number of pairwise comparisons and more consistent comparisons compared to other similar methods like AHP have made BWM a reliable method.

2.4. Neutrosophic set theory (NST)

Atanassov [38] introduced intuitionistic fuzzy sets (IFSs) as an extension of the well-known fuzzy set theory of Zadeh [39] to overcome its drawbacks by providing non-membership degree [40]. Smarandache generalised the IFS into the neutrosophic set (NS) to show insights on a more efficient DMs subjective judgements uncertainty handling [41]. It shows fuzzy information utilising the functions of truth, indeterminacy and falsity like IFSs. The distinction between NSs and IFSs is that the function of indeterminacy in NSs is independent of truth and falsity functions [42]. However, application of NSs in practical problems had been challenging because values of truth, indeterminacy and falsity functions were within]0-,1+[[42],[43]. To deal with this issue, Wang et al. [21] introduced single-valued neutrosophic sets (SVNSs) where truth, indeterminacy and falsity functions are real elements of [0,1] [42]. A single-valued trapezoidal neutrosophic number (SVTNN) is also considered as a generalisation of intuitionistic numbers. Recently, SVNSs has received increased attention by researchers from various fields of decision making.

In detail, in this article, the modification of BWM in combination with NST is applied which is called NM-BWM. The applied method is called neutrosophic modified best-worst method (NM-BWM). A decisive question in the selection of the appropriate MCDM method is the handling of uncertainties in the course of the evaluation. In the literature several approaches for the explicit consideration of uncertainties in MCDM methods are outlined which shows the importance of this topic. For mathematical basic definitions of the NST refer to [41].

3. The Neutrosophic Modified BWM (NM-BWM)

The original BWM is described in [37], [44] which follows a five-step approach, while the applied NM-BWM has two additional steps explained in [6]:

(i) DM's Uncertain Confidence on the Best-to-others Preferences
The neutrosophic value of the DM's confidence on the best-to-others preferences (ρ^+) is a SVTNN (Table 1). It reveals the degree of DM's confidence on best to-others vector.

Table 1: The confidence rating scale

Linguistic Phrase	Score	SVTNN	Crisp Value
No Confidence	0	$\langle(0.0,0.0,0.0,0.0),0.0,0.0,0.0\rangle$	0.00
Low Confidence	1	$\langle(0.2,0.3,0.4,0.5),0.6,0.2,0.2\rangle$	0.26
Fairly Low Confidence	2	$\langle(0.3,0.4,0.5,0.6),0.7,0.1,0.1\rangle$	0.38
Medium Confidence	3	$\langle(0.4,0.5,0.6,0.7),0.8,0.0,0.1\rangle$	0.50
Fairly High Confidence	4	$\langle(0.7,0.8,0.9,1.0),0.8,0.2,0.2\rangle$	0.68
High Confidence	5	$\langle(1.0,1.0,1.0,1.0),0.9,0.1,0.1\rangle$	0.90
Absolutely High Confidence	6	$\langle(1.0,1.0,1.0,1.0),1.0,0.0,0.0\rangle$	1.00

(ii) DM's Uncertain Confidence on Others-to-worst Preferences
The neutrosophic value of the DM's confidence on the others-to-worst preferences (ρ^-) is a SVTNN (Table 1). It reveals the degree of DM's confidence on others-to-worst vector.
Finally, by solving model (1) the optimal weights of criteria are achieved.

$$\begin{array}{lrcll}
\min & \varepsilon\left(\frac{\rho^-+\rho^+}{\rho^-\rho^+}\right) & & & \\
\text{s.t.} & & & & \\
& \frac{W_B}{W_j}-\frac{\varepsilon}{\rho^+} & \leq & a_{Bj} & \forall j \in N \\
& \frac{W_B}{W_j}+\frac{\varepsilon}{\rho^+} & \geq & a_{Bj} & \forall j \in N \\
& \frac{W_j}{W_W}-\frac{\varepsilon}{\rho^-} & \leq & a_{jW} & \forall j \in N \\
& \frac{W_j}{W_W}+\frac{\varepsilon}{\rho^-} & \geq & a_{jW} & \forall j \in N \\
& \sum_j W_j & = & 1 & \\
& W_j & \geq & 0 & \forall j \in N
\end{array} \tag{1}$$

4. Case Study

For a first application of the new developed NM-BWM in early design stages of buildings a case study was conducted. The interaction of building components, technical equipment and materials is of crucial importance for the sustainable performance of a building. An important step in early, sustainability-oriented design is the support for the selection of building components that fulfill all requirements of the involved DMs right from the beginning of a construction project. In the course of the case study, the developed NM-BWM approach is tested based on the decision problem "window selection".

4.1. Decision Problem

Window properties - i.e. aesthetics, size, position, relationship between transparent and opaque areas, frame, glazing - have a large impact on the building performance [48]. It is well known that a well-designed and constructed window must perform a number of functions - e.g. sun protection, glare protection, ventilation options, protection against the weather, sound insulation or burglary protection - simultaneously, which can lead to trade-offs in the design stage. Since the focus is on the application of the newly developed NM-BWM method, 8 window types and 6 criteria were selected to define the decision matrix.

4.1.1. Window Types (A1-A8)

In the applied case study a window type consists out of the frame and the glazing. The chosen frame types were timber frames, PVC-frames, aluminium frames and timber-aluminium frames. The glazing distinguishes between double glazing and triple glazing.

Table 2: Selection of window types

	Frame	Glass
A1	Timber	Double glazing
A2	Timber	Triple glazing
A3	PVC	Double glazing
A4	PVC	Triple glazing
A5	Aluminium	Double glazing
A6	Aluminium	Triple glazing
A7	Timber - Aluminium	Double glazing
A8	Timber - Aluminium	Triple glazing

4.1.2. Criteria (C1-C6)

Window selection decision can affect many other criteria. In our study, the identified criteria are exemplary and have been derived from the building certification system DGNB[4]. Regarding the literature, [47] has also analysed 6 exemplary criteria.

(i) **Global Warming Potential (C1) - [$kgCO_2 - eq.$]**
In all phases of their life cycle, buildings cause emissions. The objective of life cycle assessment is to gain information about the total life cycle, to reduce buildings emissions throughout their entire life as much as possible. The measurement of the indicator Global Warming Potential (GWP) happens in kg CO_2 - equivalents. To calculate the CO_2 - potential the EcoInvent V3.3 database[5] was used. The impact assessment was carried out with the EPD2013 method implemented in SimaPro[6]. For the life cycle assessment according to ÖNORM EN 15978 [44], in the case study, the modules A1-A3 were considered only.

(ii) **Initial Construction Cost (C2) - [€]**
All stages in the life cycle of a building generate costs: Construction, Operation, Maintenance and End-of-life [45]. From an economic view, the aim is therefore to minimise the buildings total life cycle costs (LCC). The quality of windows contributes to the building performance in terms of sociocultural and functional, technical, environmental as well as economic qualities. Therefore, out of a holistic sustainability perspective, the initial construction cost for windows must be considered. The costs for the chosen window types were calculated in [46].

(iii) **Sound Transmission (C3) - [dB]**
A minimum level of acoustic quality is necessary to ensure that a building can be used as intended, since the acoustic quality of the room is an important indicator of the comfort and satisfaction of its users. Windows with better sound insulation can contribute to an overall higher sound insulation of the whole building. The indicator for the measurement is the Rw value in dB. The Rw-values for the chosen window types were calculated in [46].

(iv) **Heat Transfer (C4) - [$W/(m^2K)$]**
Thermal comfort in buildings makes an essential contribution to an overall efficient working and living environment. The suitability of the indoor room climate depends on the temperature of the room, the temperature of the surfaces surrounding people, the air velocity in the room and also the relative air humidity in the cooling as well as in the heating period. Assessing the quality of the building envelope in terms of temperature and humidity requires an evaluation of the individual requirements for each of its components. For the measurement in this study, the Uw value of windows (frame+glass) was taken into account. The U-values for the chosen window types were calculated in [46].

(v) **Installation Time (C5) - [h]**
Construction time is a key indicator of the success of any project, as both construction costs and quality are strongly influenced by construction time. The time required to install each component thus contributes to the total construction time of a building. An indicator to characterise the installation time is the effort value. For the component window, the effort value is given as h/pc (hours per piece). The installation time for the chosen window types was calculated in [46].

[4] https://www.dgnb-system.de/de/system/zertifizierungssystem/index.php
[5] https://www.ecoinvent.org/database/ecoinvent-33/ecoinvent-33.html
[6] https://simapro.com

(vi) **Recyclability (C6)**
The construction sector is one of the largest sources of material flows in the world. Construction accounts for almost 50 % of national waste. This criterion describes the recycling options for different window types according to the different materials. For the individual assessment, we use a qualitative evaluation scale such as *excellent recyclability* (1,0), *good recyclability* (1,5), *moderate recyclability* (2,0), *bad recyclability* (2,5), and *very bad recyclability* (3,0).

4.2. Decision Matrix
The decision matrix which shows the performance of each window type (A1-A8) under each criterion (C1-C6) is represented in Table 3.

Table 3: Decision matrix

	C1 [$kgCO_2 - eq.$]	**C2** [€]	**C3** [dB]	**C4** [$W/(m^2K)$]	**C5** [h]	**C6** [-]
A1	188	268	35	1,434	3,795	1
A2	227	336	37	1,159	3,795	1
A3	246	224	38	1,371	3,226	2
A4	366	290	40	1,096	3,226	2
A5	684	403	37	1,5	4,175	2
A6	723	448	38	1,229	4,175	2
A7	334	493	38	1,402	4,554	1,5
A8	373	672	36	1,128	4,554	1,5

4.3. Decision Makers Profile
To obtain the importance weights of criteria (C1-C6), eight DMs who were recognised with their high experience and knowledge in the field of sustainable construction have been asked to participate in the study. They have been contacted by email to provide their pairwise comparisons of 6 criteria using a scale of 1 (equally important) to 9 (extremely more important) based on the original BWM. The participated DMs profile along with their weights (as they were not equally experienced) is provided in Table 4.

Table 4: Decision makers profile and importances weights

	Years of Experience	**Education**	**Weights**
DM1	20	Below BSc	0,13
DM2	31	MSc	0,23
DM3	25	MSc	0,17
DM4	4	MSc	0,08
DM5	6	BSc	0,08
DM6	3	MSc	0,05
DM7	20	MSc	0,13
DM8	20	PhD	0,13

5. Results and Discussion

After obtaining the consistent pairwise comparison data of eight DMs (CR<0.1) then the NM-BWM has been applied and weights of six criteria (C1-C6) have been computed as shown in Table 5. The aggregated weight of each criterion based on obtained weights of eight DMs has been also calculated and revealed in Table 5.

Table 5: Aggregated criteria weights of decision makers

	DM1	**DM2**	**DM3**	**DM4**	**DM5**	**DM6**	**DM7**	**DM8**	**Aggregated Weights**
C1	0,2000	0,3214	0,5217	0,2414	0,2258	0,2060	0,2500	0,2738	0,3044
C2	0,2286	0,1607	0,0580	0,1034	0,2258	0,2698	0,0417	0,1788	0,1450
C3	0,1714	0,0357	0,0580	0,1724	0,1613	0,5151	0,2083	0,0604	0,1277
C4	0,2000	0,3214	0,1739	0,2414	0,1613	0,1714	0,2083	0,1788	0,2206
C5	0,0286	0,0536	0,0580	0,3448	0,3226	0,1349	0,0417	0,0323	0,0957
C6	0,1714	0,1071	0,1304	0,2069	0,1935	0,1663	0,2500	0,2758	0,1778

The decision matrix (Table 3) has been normalised knowing that all the six criteria are of cost nature meaning the lower value of them is better. The final normalised decision matrix has been represented in Table 6. Applying obtained weights of each criterion (C1-C6) shown in Table 5 and getting the weighted average of the normalised values in Table 6, the total weight of each window type (A1-A8) has been obtained as shown in Table 6.

Table 6: Normalised decision matrix and total weights of window types

	C1	**C2**	**C3**	**C4**	**C5**	**C6**	**Total Weights**	**Ranking**
A1	0,7400	0,6012	0,1250	0,0440	0,1667	0,5000	0,4429	2
A2	0,6860	0,5000	0,0750	0,2273	0,1667	0,5000	0,4459	1
A3	0,6598	0,6667	0,5000	0,0860	0,2916	0,0000	0,3508	3
A4	0,4938	0,5685	0,0000	0,2693	0,2916	0,0000	0,3201	4
A5	0,0539	0,4003	0,0750	0,0000	0,0832	0,0000	0,0920	8
A6	0,0000	0,3333	0,0500	0,1807	0,0832	0,0000	0,1025	7
A7	0,5380	0,2664	0,0500	0,0653	0,0000	0,2500	0,2676	5
A8	0,4841	0,0000	0,1000	0,2480	0,0000	0,2500	0,2593	6

Findings (Table 5) showed that based on involved DMs opinions, global warming potential (C1) is the most significant criterion in choosing the best window type. The other significant criteria are as follows respectively: heat transfer (C4), recyclability (C6), initial construction cost (C2), sound transmission (C3), and installation time (C5). The obtained two most important criteria highlight the significance of preserving the heat while providing thermal comfort (i.e. C4) and at the same time taking into consideration the global warming potential (i.e. C1).

The analysis of results (Table 6) revealed that the second window type (A2) with timber frame and triple-glazing is the best choice followed by A1 (timber frame and double-glazing), A3 (PVC frame and double-glazing), A4 (PVC frame and triple-glazing), A7 (timber-aluminium frame and double-glazing), A8 (timber-aluminium frame and triple-glazing), A6 (aluminium and triple-glazing) and A5 (aluminium and double-glazing) respectively. According to the high CO_2 - potential of the alumium frame (see Table 3) the findings are in line with DMs preferences.

6. Conclusion

In this study, a NM-BWM method was applied to capture uncertainty in the DMs opinions in order to obtain weights of criteria derived from the building certification system DGNB. The identified criteria are global warming potential (C1), initial construction cost (C2), sound transmission (C3), heat transfer (C4), installation time (C5) and recyclability (C6). The weights of criteria then used to reveal among a list of eight predefined window types (A1-A8) which ones can perform more/less appropriately in the early sustainable building decision-making process in terms of various six criteria. The analysed eight window types are A1 (timber frame and double-glazing), A2 (timber frame and triple-glazing), A3 (PVC frame and double-glazing), A4 (PVC frame and triple-glazing), A5 (aluminium frame and double-glazing), A6 (aluminium frame and triple-glazing), A7 (timber-aluminium frame and double-glazing) and A8 (timber-aluminium frame and triple-glazing).

The results confirmed that global warming potential (C1) is the most significant criterion in choosing the best window type while installation time (C5) is the least important one in that manner. Furthermore, A2 (timber frame and triple-glazing) is the best window-type choice under various six criteria and A5 (aluminium frame and double-glazing) is least proper one.

One of the limitations of this study which opens an avenue for future research directions is the partial incomprehensiveness of the derived criteria and explored window types. In future studies, researchers may take advantage of a more comprehensive list of criteria to investigate alternatives not only window type but also other components of sustainable buildings. The other shortcoming was a limited number of DMs or experts which can be increased in future investigations to improve the validity of the findings.

The application of MCDM methods in early design stages of buildings was identified as a research gap. Many different MCDA methods were applied for single issues within the field of sustainable construction - e.g. material selection, selection of energy systems, selection for waste management types, window selection - but not for the holistic design of a new building in early design stages. Reasons for that are the numerous criteria and the missing alternatives in the early design stage.

Abstract. Life Cycle Assessment (LCA) is a suitable method to analyse the environmental impact of buildings' design choices. However, the nature of the building design process leads to a dilemma when applying LCA in early phases. LCA can be fully performed only in the later design phases when complete information is available, but it is too costly to make changes. As a result, LCA is scarcely employed as a decision-making tool. Building Information Modelling (BIM) can assist LCA during the design process. So far, two different approaches are usually adopted to perform the BIM-based LCA of buildings. The first approach concerns performing LCA with a detailed BIM at the end of the building design process. The second approach involves simplified methodologies for early design stages with uncertain data. This study proposes a novel approach for applying a consistent BIM-led LCA from the early design stages to the detailed ones based on lower to higher level of accuracy. Since the BIM elements are specified with increasing level of detail in each design phase, the method uses different LCA databases for the Level of Developments (LODs) of the building elements. Accordingly, LCA calculations are based on mixing the databases in every design phase. This is possible as long as the databases use identical background data. The framework helps to provide consistent information for decision-making throughout the whole design process, both in the later design phases and early ones with a simplified BIM.

1. Introduction

The building sector consumes a large amount of natural resources [1], contributing to their depletion and to the emission of a significant amount of greenhouse gases (GHG) [2]. The growing interest in environmental issues has led to several studies based on Life Cycle Assessment (LCA) since it is recognized as a powerful tool to predict the overall environmental impacts of buildings [3,4].

Over the last years, several studies have combined Building Information Modelling (BIM) with the LCA methodology to investigate the environmental performance of a building element or of a whole building. On the one hand, BIM supports integrated design and improves data management and collaboration between the different stakeholders. BIM also provides an effective way to investigate the options for the reduction of GHG emissions with regards to the materials processing, delivery, and construction methods [5]. On the other hand, LCA is a suitable method for assessing the environmental performance of buildings during their whole life cycle.

However, methodological challenges on the BIM-based LCA can be found the literature. For example, existing studies focus on a specific stage when conducting BIM-based LCA calculations without referring to the entire design processes. Moreover, most papers on BIM-based LCA methods do not declare the Level of Development (LOD) which the BIM model refers when conducting the LCA [6]. The LOD concept is crucial for BIM-led LCA. It defines the minimum content requirements for each BIM element at different progressively detailed levels of completeness.

The aim of this paper is to provide a framework which empowers LCA to be used as a consistent decision-making tool during all phases of the design process. The novel approach considers the available information in the BIM with as much accuracy as possible in each stage. This way it is possible performing continuous LCA over the entire building design process by using the data provided by BIM. Different LCA databases are employed with regards to the LODs of the BIM elements. Since different types of BIM elements are modelled with different LODs in each design phase, the LCA is performed by consistently mixing the LCA databases. This is made possible as long as the databases use identical background data. This approach has not been considered by any of the published studies before and helps to provide information for decision-making throughout the whole design process, both in the early design phases and later phases with a more detailed BIM.

2. Literature review

The use of the BIM-based sustainability assessment tools is increasing together with the studies focused on methods for the environmental impact assessment. The development of methods that integrate BIM and LCA is dramatically growing.

In general, two different approaches exist to perform the LCA of buildings based on BIM. The first trend concerns performing detailed LCA with specific building performance simulation tools. However, it requires linking LCA with a detailed BIM and can only be applied in the advanced design stages because of the lack of data in the early design stages. Additionally, only experts can use the method and designers find difficult to apply it at the early design stages due to the number of variables and tools involved. The second trend refers to simplified approaches only for early design stages. This simplified approach cannot match the complex data available in detailed BIM in advanced design stages.

The existing literature for both trends is summarized in Table 1. As can be seen, all reviewed papers only refer to a single trend, without considering the entire design process. Furthermore, only few studies set the LOD of BIM elements. Ajayi et al. [7] and Röck et al. [8], for example, set the LOD 200 to support their early analysis. Also LOD 300 was declared in two cases by Lee et al. [9] and Yang et al. [10] to support detailed analysis.

The main problem is that these trends are not linked and they require different tools, databases and assumptions. To overcome these limitations, this paper proposes a framework to link both trends by performing continuous LCA calculation through the entire design process.

3. Method

The framework is based on the authors' previous work and it is developed for the Swiss context, but it could be applied for other countries as well [11]. The approach is based on the application of different LODs for the LCA calculation depending on the design process phase. The method is depicted in Figure 1.

The first step is the definition of the LOD evolution. For this paper, the design process is divided into five phases that correspond to the phases 31 to 52 as defined in the Swiss Order for services and fees of architects SIA 102:2014, namely Project Planning (PP), Project (P), Building Permit Application (BPA), Tendering (T), and Construction (C). Then, the LODs are defined in four steps, from low information content (LOD 100) to the highest one (LOD 400).

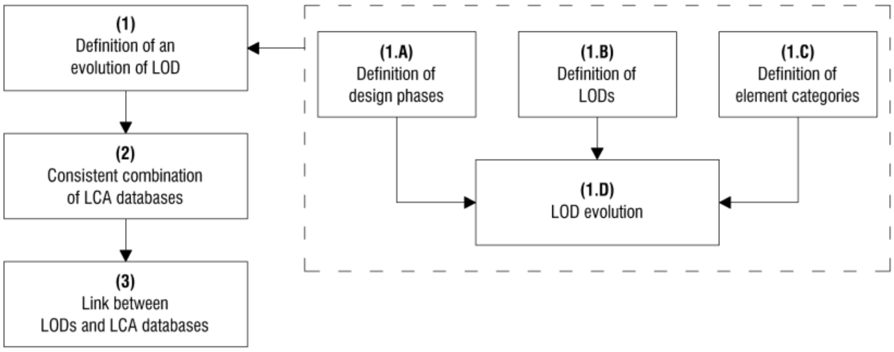

Figure 1. Schematic workflow of the proposed method.

The LODs of different BIM elements do not always simultaneously evolve across the design process, but refer to the aim of the different design phases. While general decisions such as the size and the shape of the building are usually already fixed in the PP phase, decisions on material choice are taken along all the different phases. For example, the load-bearing elements are typically defined with a higher detail in the early design phases while the finishing may only be defined late during the construction phase. Therefore, the different construction categories have a different LOD evolution. For that reason, the Swiss building element classification scheme for cost estimation e-BKP-H SN 506 511 is used to identify the building parts. It is depicted in Figure 2. The scheme considers the building as composed of eleven *building elements*. Each *building element* consists of several *building components*, which have different functions, and belong to different *construction categories*. For this paper, four construction categories are defined according to this scheme, namely *Structure* (all load-bearing parts), *Envelope* (façade and roof covering), *Interior* (non-load-bearing walls and floor finishing), and *Technical equipment*.

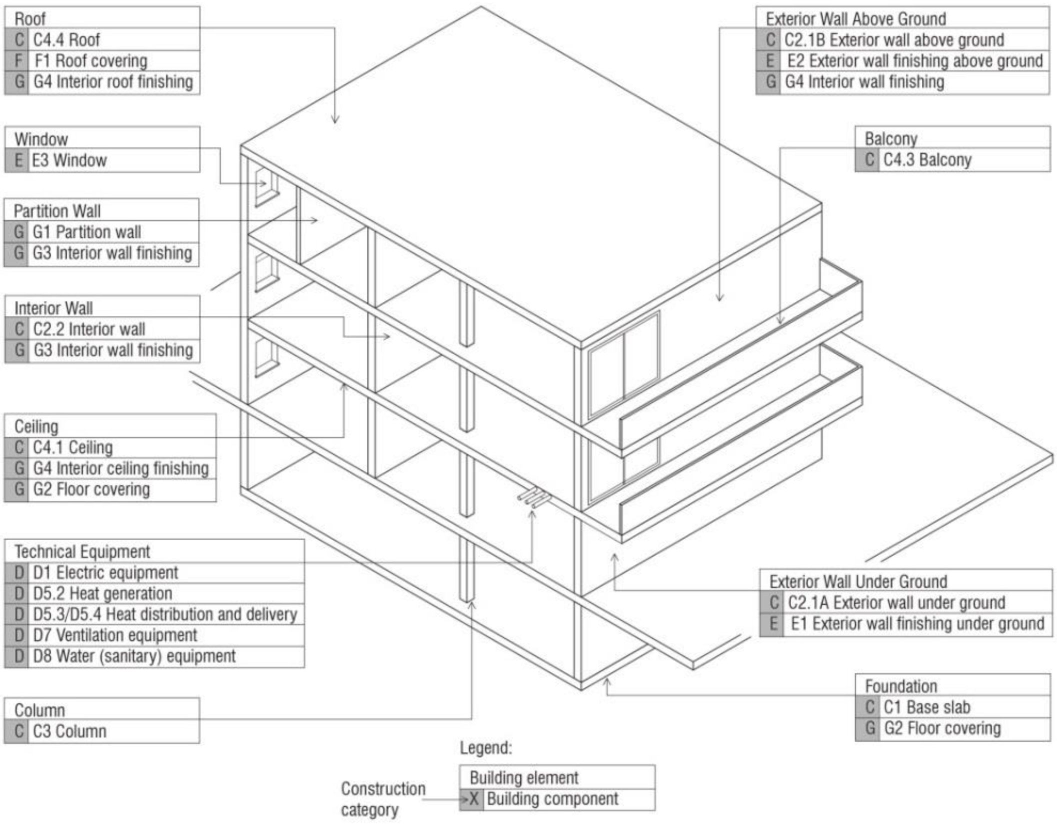

Figure 2. General description of the building, building elements, building components, and construction categories.

Here, it is assumed that all building components belonging to the same construction category are developed at the same LOD at a specific design phase. The LOD evolution is shown in Figure 3.

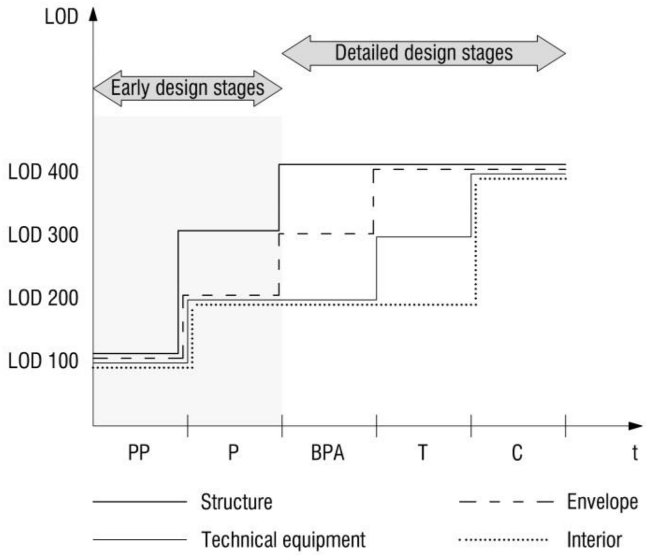

Figure 3. Design process and LODs for different construction categories. (PP) Project Planning, (P) Project, (BPA) Building Permit Application, (T) Tendering and (C) Construction.

The second and the third steps of the framework aim at proposing a consistent combination between different LCA databases and linking them to the LODs. Here, various LCA databases are employed. In Switzerland, LCA data for building materials are provided in a list called *KBOB Ökobilanzdaten im Baubereich*, but to facilitate the application of this data, the building component catalogue *Bauteilkatalog* has been developed by providing the environmental impact of pre-defined typical Swiss constructive solutions according to the Swiss building classification system. Both databases are based on the same background data (Ecoinvent 2.2) and they can be consistently mixed.

The LCA databases are linked according to the LODs as shown in Table 2. Before the design process starts there is no BIM. At that stage, only the square meters of floor area could be known. Therefore, it can be called pre-LOD. Hence, the environmental impact is calculated using the average impact per m^2 of floor area.

When LCA databases are used averaging the values (e.g. Pre-LOD, LOD 100 and LOD 200), the minimum and maximum values can be calculated to show the LCA variability. In fact, in the early design stages the exact final technological solutions of the building elements are unknown.

Table 2. LCA databases used for different LODs.

LOD	Database	Use of Database
Pre-LOD	Swiss Buildings Database	Average value at building level
100	Bauteilkatalog	Average value at building element level
200	Bauteilkatalog	Average value at building component level
300	Bauteilkatalog	Specific value at building component level
400	KBOB	Specific value at material level

4. Results

The method is applied to a real building called *WoodCube*. All material properties are obtained from a published LCA report [32]. Quantities information of different materials and components are extracted from the 3D model to an excel spreadsheet. These are then used to perform the LCA according to the method. The building elements and related building components are provided by Cavalliere et al. [11]. The functional unit of the performed LCA is the whole building with a reference study period of 60 years according to SIA 2032:2012 [33]. Regarding the system boundaries, the LCA is performed focusing on the cycle modules A1-A3, B4, C3 and C4 [34].

The life cycle impact assessment provides results using the GWP in kg CO_2-equivalent as the environmental indicator. The values are provided per year.

When performing the analysis at the building level, the LCA results show a general coherence throughout the design process. From the PP phase to the C phase, the GWP in each design phase is within the variability of all the previous phases. The use of the Swiss buildings database at the Pre-LOD leads to a consistent result until the BPA phase. The results in the T and C phases do not fall within the variability of the Pre-Design phase. This is due to the limitation of the Swiss buildings database because it is based only on fifteen residential buildings resulting in a limited variability range.

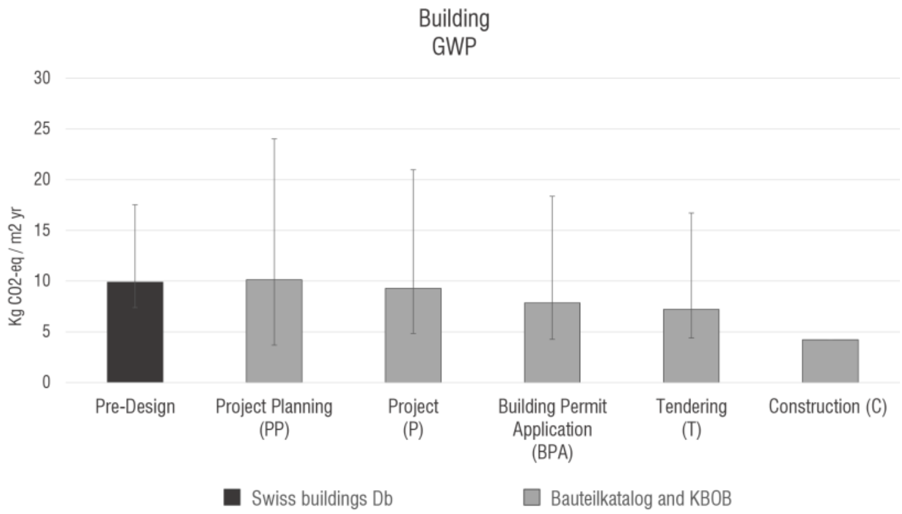

Figure 4. GWP of the building during the design process

Here, the LOD evolution of building elements is based on the typical Swiss architecture practice. Actually, LOD evolution for the building components can be different, because design teams could adopt different LOD evolutions according to their own design best practices. Therefore, different scenarios concerning the LOD evolution have been considered (see Table 3). This allows testing the sensitivity of the method towards the LOD evolution.

Table 3. Evolution of LOD during the design phases depending on the scenario

Building components	Design phases				
	PP	**P**	**BPA**	**T**	**C**
Structure	LOD 100	LOD 300	LOD 400	LOD 400	LOD 400
Envelope	LOD 100	**LOD 200/300**	LOD 300	LOD 400	LOD 400
Technical equipment	LOD 100	LOD 200	**LOD 200/300**	**LOD 300/400**	LOD 400
Interior	LOD 100	LOD 200	LOD 200	**LOD 200/300**	LOD 400

The results considering the different scenarios show a general coherence throughout the design process phases and a low sensitivity to the assumed LOD evolution. As can be seen in Figure 5, bottom and top values do not change much as well as the value after the tendering phase, but they can change the decision choice in the PP phase.

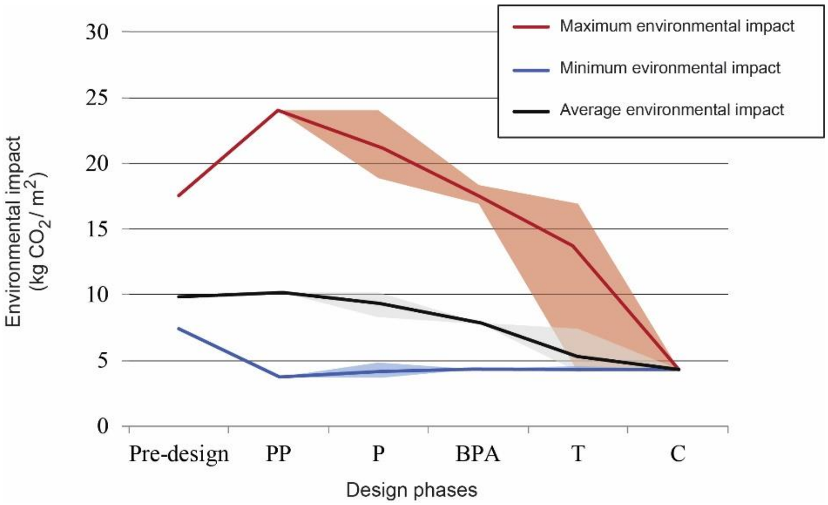

Figure 5. Variability of top/bottom values and LCA results for all scenarios considered.

5. Discussion

The application of the proposed method demonstrates one way to solve the dilemma of applying LCA in the design process. Within the information processes at the different design stages, it is crucial to define which information is needed and how detailed it must be. BIM objects are modelled with different LODs depending on the BIM uses and the project milestone, which usually grow reflecting the project progression. Hence, as the project grows, BIM elements are modelled with more information in order to support more detailed analyses.

The proposed method and its application to a real case-study building show that it is possible to continuously perform the BIM-based LCA throughout the whole design process by mixing various LCA databases, which is possible as long as they use identical background data. The previous work carried out by the authors shows that the LCA results are consistent in general in terms of variability of the different building elements [11]. Minor inconsistencies for individual elements are not visible in the overall results. In fact, the environmental impacts of the case-study building in a specific design stage fall within the variability range of the previous one. Furthermore, it could be shown that results have a low sensitivity towards the assumed LOD evolution, allowing the method to be adapted to the individual workflow of the design team.

The method should evolve in the future. The study is mainly based on the embodied impact calculation since it will became more relevant when referring to very energy efficient residential buildings as demonstrated by recent studies [35]. To further improve the proposed framework, the operational impact should be included and additional case studies should be investigated since the general approach of the methods is identical. The study was applied to the Swiss context by using Swiss databases and standards, although different LODs scenarios were evaluated. Further investigation could be integrated in the future with the reference to different national contexts.

6. Conclusion

BIM-led LCA is recognized to be a powerful approach to reach sustainable building projects. However, it is currently difficult to apply the LCA during the entire building design process because the necessary data are only completely available in the latest phases. The proposed approach divides the building into functional elements, which consists of several building components. Then, the building components have different functions, and belong to different construction categories because they are typically modelled at different LODs in different planning stages. The LCA is consistently performed by mixing the LCA databases according to the LOD of the building elements at different design stages. By involving the use of different databases that match the LOD of the BIM elements, LCA can be conducted with the maximum level of information available at the current design stage, providing a continuous workflow over the building design process. Hence, the LCA results are as accurate as possible at all times.

As demonstrated by the case study, it is possible to forecast the final environmental impact from the early design stages. According to the method, the results show that the variability of the environmental impact decreases from the early design phases to the final one because estimations are performed from lower to higher accuracy based on increased LOD. The environmental impact in a certain design stage is within the variability of the previous one, confirming the reliability of the proposed method. As a result, the method enables the use of LCA as a decision-making tool to reach more sustainable solutions from the early to the detailed design phases.

BIM-integrated LCA - model analysis and implementation for practice

Forth K, Braun A, Borrmann A

Chair of Computational Modelling and Simulation, Technical University of Munich, Arcisstr. 21, 80333 Munich, Germany

kasimir.forth@tum.de

Abstract. Ecological impacts of buildings can be quantified using the method of Lifecycle Assessment (LCA). With the help of digital methods and semantic building models (BIM), those impacts can be reduced by investigation of variants and their LCA comparison. However, there is a large deviation in the results due to inaccuracies in the modeling and the calculation tools. This paper proposes an improved workflow of BIM-integrated LCA avoiding those inaccuracies. As a first step, various sources of error are identified using a model analysis, which is examined with 25 models focusing on geometry and materiality. Thereby different workflows are investigated, modeling recommendations are derived based on the error analysis, and the findings are implemented in a prototype. Through an optimized calculation process, the semi-automatic calculation of life cycle assessments becomes faster, more consistent and more accurate due to the improved integration in BIM.

1. Introduction

Since ancient times, buildings have great importance for society. Today, they account for most of humans' daily lives and, according to the broad definition, real estate accounts for 19% of total gross value added [1], making it an important economic sector with many jobs. However, the construction industry also contributes significantly to climate change and other environmental problems. According to the European Commission, European buildings account for 42% of final energy consumption, 35% of greenhouse gas emissions and 50% of materials produced in their production, use, and dismantling [2]. Also, they are responsible for 30% of water consumption and a third of all waste [3]. This increases the need to identify and reduce the environmental, economic and social impacts of buildings. A promising approach lies in the formal assessment of a building's environmental footprint. Individual analyses and, since the 1990s, holistic approaches such as the sustainability certification of buildings, which are also known as Green Buildings, are an important step forward.

In a proposal for discussion for the new "Building Energy Act" (GEG) from February 2018, the German Sustainable Building Council (DGNB) proposes that in future the resulting CO2 emissions should be balanced rather than primary energy consumption. "Embodied emissions (production, usage, and maintaining, recycling) will also be accounted for from 2025 so that in future the entire life cycle will be covered" [4]. This approach, which has been extended to include embodied energy, is intended to create a goal-oriented, holistic approach.

In this respect, there are great opportunities to benefit from the ongoing digitization of the construction sector to cope with the environmental challenges. This means that in the long term it is desirable to automate criteria for sustainability certificates, such as life cycle assessments (LCA), to the greatest extent possible using the BIM method [5] which includes a comprehensive digital representation of a building.

The integration of the BIM method into the LCA calculation is intended to simplify the work process and thus make it possible to optimize the LCA in earlier planning phases. Also, increased efficiency regarding time and complexity can reduce the workload and thus contribute to broader dissemination of the performance of life cycle assessments.

Although there are already existing software products which try to use the BIM method in the LCA calculation, the use of the BIM method in the LCA calculation is not yet optimized. However, the quality of BIM models is not yet thoroughly mature due to the short application time. Therefore, there are still different problems with the application of these programs, which should be analysed in more detail.

The paper presents an experimental study that shows that problems and requirements of the BIM-integrated LCA considering different workflows and model requirements, to make the data transfer between architect and Green Building Auditor or the life cycle assessment experts smoother in the future and to minimize the loss of data. On the basis of this results, the concept for an improved workflow was developed. It has been implemented in a software prototype that is discussed in detail. Using the prototype, it was possible to show that errors were significantly reduced.

2. Related work

In this section, a short overview of the state of the art is shown. The major challenge is the semantic linking of the BIM model with the LCA model. BIM programs can be used to determine areas and masses automatically. The goal, however, is a fully automated LCA process that can be realized with the help of an integrated BIM and LCA model. This increases data consistency, makes the verification process for sustainability certificates more accurate and increases efficiency by shortening the processes.

García-Martínez et al. compared different integration approaches in their paper "Critical Review of BIM-based LCA method to buildings" [6]. They find that there are major difficulties in mapping all life cycle phases, especially the use phase and end-of-life phase, in the calculation. In most studies, manual adjustment and addition of mass constellation and material properties were required. Therefore, they call for further research to improve and standardize the BIM integration of LCA and propose user-friendly handling of the calculation tools.

Furthermore, Díaz and Álvarez Antón have investigated different approaches to LCA calculation in the planning process [7]. It becomes clear that through BIM integration a BIM model is already available in early phases, which leads to early optimization of the results through automated calculations. Furthermore, a real-time calculation is desirable to reduce the time required for an LCA.

Díaz and Álvarez Antón distinguish between two approaches, how such integration can look like [8]. The first method presented contains an automatic inventory analysis linked to LCA datasets. To ensure a consistent calculation, the BIM model must be created and maintained without errors. This avoids the repeated manual input of data for the LCA. A further disadvantage is the lack of research into the compatibility between BIM models and LCA tools as well as errors in IFC (Industry Foundation Classes) export and import.

The second approach provides for the implementation of environmental impact information in BIM objects. This means that the impact categories and environmental impacts can already be displayed when the architects and planners select materials. However, this method requires training of the designers so that this information can be evaluated correctly. To counteract an excessive demand, Schlenkrich suggests alternatively listing only selected categories [9]. This method can already be applied in the earliest planning phases and thus actively intervene in the decision-making process of material selection. However, this approach has the disadvantage that material alternatives are compared and the quantities of materials in the comparison are neglected. Thus, the estimation is less precise than an LCA that addresses the complete building model [8].

As early as 2003, Neuberg developed a "software concept for the Internet-based simulation of the resource requirements of buildings" [10]. As part of his dissertation, he realizes an ecological assessment of buildings with the help of the IFC data format. In addition to a life cycle assessment, he also implements an integrated energy demand calculation by German energy efficiency regulations of building (EnEV). "The implementation of these dynamic component properties takes place as a module for extending the AutoCAD database" [10]. At that time, not enough LCA databases were available, and life cycle assessments were mainly carried out for research purposes. In addition, impact categories other than those established today, such as cumulative energy consumption and cumulative material consumption, were taken into account. Neuberg's method makes use of an open interface, where the parameters of the materials can be individually adapted and extended by external data sets. However, the addition of additional component layers afterwards and the assignment of end-of-life scenarios or the consideration of composite materials is not possible. For these reasons, his approach not fully applicable for today's practice.

Tsikos and Negendahl have developed a method using *Revit*, *Dynamo,* and *Excel* to calculate an LCA using an Integrated Dynamic Model (IDM) [11]. Their aim was to achieve a fully automated work process. Material allocation is carried out with the aid of a "permanent link" between an external *Excel* database and the materials in *Revit*. The encoding is performed according to the Danish system BIM7AA [12]. Although LCA calculation results are generated within one minute, the quality depends strongly on the BIM model, the accuracy of the database and the take-off method implemented in Dynamo [11]. Inaccuracies of the BIM model can be adjusted later in the model, although this procedure seems cumbersome. On the contrary, this paper is intended to make a specific contribution to optimizing the compatibility between BIM models and LCA tools and to find a consistent and transparent calculation approach.

3. Methodology and procedure

The aim of this chapter is investigate different workflows and occurring problems of BIM-based LCA. The general workflow of the model analysis consists of three stages. The first stage is the creation of models based on the catalog of the investigated BIM-models. The models are modeled with two BIM-capable authoring tools, *Revit 2018* by Autodesk in "Revit" data-format (RVT) and *ArchiCAD 19* by Graphisoft in "Plan" data-format (PLN) and exported into the vendor-neutral IFC data format. Then *Solibri Model Viewer* is employed to check the data quality of these models and adapt them so that the models have identical masses and materials if necessary.

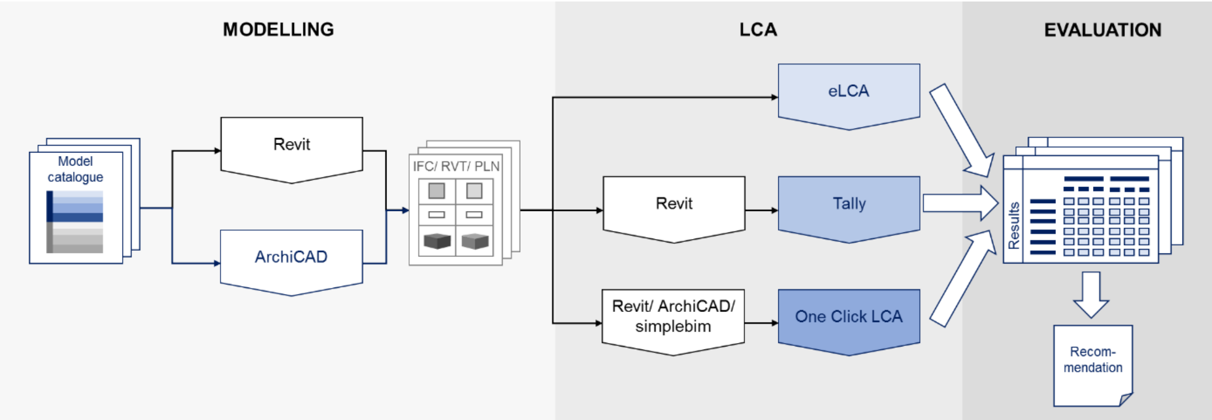

Figure 1. The procedure of the model analysis of BIM-integrated LCA workflows

The second stage is the actual life cycle assessment. This consists of the application of the three different work processes. The tool for the conventional workflow used is *eLCA*, which draws its mass balances based on the models created in *Revit*. In the semi-automatic working process, the data models are imported into *Revit* and calculated with the LCA tool *Tally*. In the fully automated working process, the models are loaded into *ArchiCAD*, *Revit,* and *simplebim,* and the life cycle assessment is calculated there using the *One Click LCA* plug-in.

The third stage consists in the evaluation. All results of the respective eco-balancing with *eLCA*, *Tally* and *One Click LCA* result in a result matrix for each model. These are analysed, and problems and conspicuities are described to formulate general and specific findings finally and to derive recommendations from these. The different work processes, as well as the results of the respective programs and data exchange formats, are taken into account. As the different result of each LCA-software are not compareable with each other due to different databases, the results of each LCA-Software have their own Ground truth which are investigated in the error analysis [13].

3.1. Boundary conditions

The investigation presented here does not aim at improving the LCA results through different material or design choices of the models, but helps finding the best possible implementation of BIM-integrated life cycle assessments about the work process and data requirements. Clear framework conditions are the prerequisite for a reliable evaluation and preparation of recommendations.

Initially, the same databases and an identical approach should be defined for all LCA tools. Due to large data gaps in building technology, this topic is not addressed in this paper. However, for the LCA calculation of the models according to the calculation system of the German Sustainable Building Council (DGNB), the energy consumption in the use phase according to the current German regulations (EnEV) is required, which is not available for the individual models. Here, the focus is on the building construction in the manufacturing (A1-A3) and end-of-life phase (C3-C4), as well as module D. Operational energy, plant technology, and transport are neglected.

Due to the great diversity, ÖKOBAUDAT serves as the common database for all life cycle assessments, which is based on GaBi data records. The impact categories considered are Global Warming Potential (GWP), Ozone Depletion Potential (ODP), Photochemical Ozone Creation Potential (POCP), Acidification Potential (AP), Eutrophication Potential (EP) and Primary Energy, differentiated into non-renewable (PENRT) and renewable (PERT) depending on the LCA calculation program. The service life of the structures is set to 50 years.

3.2. Case studies

Table 1 + 2. Model catalog for Case studies of the model analysis, grouped by Form and Material.

		Modellgroup	Model	
Form	F1	Ground floor	angular	F1e
			round	F1r
	F2	Multistory	suspended ceiling	F2z
			galery with cloumns	F2g
	F3	Sloping walls	outside inclined straight wall	F3ag
			outside inclined round wall	F3ar
			inclined inside straight wall	F3ig
			inside inclined round wall	F3ir
	F4	Roof	saddle roof	F4s
			saddle roof with corner	F4e
			hip roof	F4z
			pent roof	F4p

		Modellgroup	Model	
Material	M1	Monolithic	reinforced concrete	M1s
			brick wall	M1m
			timber	M1h
	M2	Multi-layer	reinforced concrete + EPS	M2s
			brick wall + XPS	M2m
	M3	Construction	mullion-transom facade	M3p
			wood frame construction	M3h
	M4	Windows/ doors	wood frame	M4h
			aluminium frame	M4a
			plastic doors	M4k
	M5	Roof	warm roof (flat)	M5s
			brick covering (saddle roof)	M5z
			sheet metal cover (pent roof)	M5b

To produce a valid and meaningful evaluation of the data requirements for a successful BIM-integrated life cycle assessment, a wide range of applications using BIM models is required. Table 1 + 2 show the model catalog, which was first created and then converted into BIM models using *Revit* and *ArchiCAD*. They are then made available on the proprietary and the IFC data exchange format. In the model catalog, different complex geometries, materials and building constructions are covered. The model catalog differs in the two groups “shape” (subdivided in the groups “ground floor”, “multistory”, “sloping walls” and “roof”) and “material” (subdivided in “monolithic”, “multi-layer”, “construction”, “windows/doors” and “roof”).

The nomenclature of the individual model groups results from the initial letters of the group's form and material, the sequential numbering depending upon the complexity of the investigation as well as the clearly characteristic model abbreviation. The basic form has a square ground plan (10.00m x 10.00m), which is slightly modified depending on the study model. The height of the floors is 3.00m with a clear room height of 2.80m for the most part. The outer walls of the models are 30cm thick, the ceiling 20cm.

Legend: ● correct result
◆ slight deviation
■ strong deviation

Table 3 shows a matrix of all 275 LCA calculations categorized by models and its BIM Authoring software, data format, LCA-Plugin and LCA-Software. The results are divided into the categories “correct”, “slight deviation” and “strong deviation”.

Most errors occur during the software-independent export into the IFC file format [13]. Also, IFC imports in the respective BIM programs also result in deviations of the model about geometry and material assignment. The more complex the original model, the higher the error rate. There are major problems and thus optimization potential especially with unconventional geometries, such as sloping walls, as well as window and door components and multi-layer roofs.

The causes for the calculation deviation are mainly because of differences of quantity take off in ArchiCAD and Revit and their IFC im- and export and missing or incorrect building components or material layers. One of the reasons are different geometric representations of connecting walls in ArchiCAD and Revit. IFC models of more complex models are missing components like roofs, walls, windows or component materials and layers.

The LCA software Tally couldn’t calculate the construction phase of reinforced concrete for the Revit models. Also incorrect IFC-export of dummy-material in ArchiCAD leads to deviations in the

LCA results. One Click LCA has partially calculated all layers of multi-layer component structures (IFC models) together.

In general, it can be stated for all BIM-integrated life cycle assessments that these can only be as accurate as the BIM model was generated. In current practice, the BIM models should not be assumed as complete. Even in the analysis of simplified models, even minimal differences in modeling had a strong impact on the results. Missing parts or component components lead to poor calculation results without being recognized at first glance. It is sometimes only possible with great effort to adjust the missing information for the calculation afterwards since the programs usually lack the necessary transparency in the calculation steps.

Also, there is no interface in the LCA programs where specific data records, such as EPDs (Environmental Product Declaration), can be individually and easily integrated into the specified database. This is desirable if specific products are used for which EPDs are available. The datasets are partly based on different sources, so that large differences in the results also arise here. For the German market, Ökobaudat has established itself, which is available transparently to everyone and can be supplemented with individual EPDs.

As far as the working process is concerned, it can be said that the conventional method of operation is extremely time-consuming, especially when drawing up the mass balance. This problem intensifies by large, complex construction projects and is impracticable in the long run. Therefore, an automated component-specific material setup with subsequent manual or automated material assignment should be preferred and is associated with considerable time and cost savings.

A fully automated work process is not necessarily more effective than a semi-automated. Smaller errors in the model and the material allocation are not noticeable at first in full automation and have to be searched for afterward. In a semi-automated process, all materials are assigned manually, whereby missing component layers or components can also be adapted directly in a single step.

Although the promise of a fully automated LCA calculation sounds convincing, transparency and comprehensible adaptability suffer from this. With an ideal BIM model, the results can achieve a high degree of accuracy. Nevertheless, to skip the step of material allocation or its control would be negligent, since it sometimes leads to considerable error divergences. A check of the component-specific building materials for completeness and quantity is therefore urgently recommended, as is precise post-processing of the material take-off through correction and additions.

A semi-automatic work process is therefore recommended. A component-specific allocation of the materials allows these to be allocated exactly even in the case of inaccurate models with missing information's. A unique, direct assignment of the same materials is desirable. Faulty components should be marked as such to correct them during post-processing. Also, specific information such as layer thickness, composite content, service life or end-of-life scenarios of the building materials can be adapted in more detail.

4. Improved workflow with a prototypical implementation

We propose a workflow whose aim is to enable complete transparency and the possibility of exerting influence in the LCA calculation process, in which the data for calculation and allocation are presented in a comprehensible manner. Adjustments for individual parameters can be made easily, quickly and precisely using *Excel* interfaces. This includes the modification of layer thicknesses, composite proportions, lifetimes or end-of-life scenarios of building materials. With this approach, however, the real-time calculation is still not possible. Also, this interface is only intended for *Revit* models, so no qualified evaluation of an IFC model is created. Although the planned procedure is more cumbersome than the fully automatic calculation, it can ensure sufficient quality of the life cycle assessment with exact results.

4.1. Procedure

As with all life cycle assessments, a distinction is initially made between three parts: the model, the life cycle inventory analysis and the impact assessment. For this reason, any model is first created or loaded in *Revit*. In the next step, the Life Cycle Inventory Analysis, Dynamo Player is opened, and the *Excel* file is linked to create the material allocation. The Dynamo Player is a reduced application that makes it easier to execute Dynamo scripts without having to open them. All you need to do is specify all the required input parameters in the *Excel* sheets.

Once the Dynamo script has been executed, the *Excel* file opens to check the boundary conditions, such as net-space area, project lifetime, LCA phases, etc. The following parameters can be checked. Subsequently, the components and the corresponding materials are checked and adjusted if necessary. In the last step, the Life Cycle Inventory, the energy sources, and the electricity and heat requirements are set up using German regulations (EnEV).

During the impact assessment, the LCA calculation file is opened in Dynamo Player, and the completed material allocation and the still empty output *Excel* file are linked to export the LCA calculation. The dynamo player file is then executed, and the LCA results are automatically inserted into the *Excel* template provided for this purpose.

4.2. Implementation of the prototype in Dynamo and Revit

After a comparison of relevant component groups in the calculation according to DGNB, LEED, *Tally,* and *One Click LCA*, a selection was made for the prototypical implementation in *Dynamo* for *Revit*. First of all, a distinction is made between volume components, which include walls, ceilings, roofs, and foundations. The second group is referred to here as element components and consists of windows, doors, stairs, facade elements and posts as well as ceilings. Structural elements such as columns and girders also form a relevant group but are initially left out due to their implementation in *Revit*. The plant technology includes all mechanical, electrical and plumbing (MEP) components and forms the last grouping.

First, all component-specific materials are summarised, different information, like component name, area, volume and quantity is queried and compiled and finally exported to an *Excel* template for the Life Cycle Inventory. For the sake of simplicity, problems with the geometry export of windows, facade posts and stairs are no longer taken into account for the rest of the process and can be further developed as the prototype is further developed.

The subsequent *Excel* export contains the folders boundary conditions, material assignment, component overview, and energy requirement. Under boundary conditions, the net space area calculated from Dynamo as well as the pre-defined information on the observation period, relevant life cycle phases and calculation methods according to DGNB can be adapted. When assigning materials, the individual materials must be referenced to an LCA data set, and the values of density, service life and composite materials can be adapted or supplemented. All components can be adapted in the component overview folder. This includes the addition of layers, geometric checking of the volume, the characteristic length, the area or the number. In the last folder, the energy requirements and any missing MEP components are supplemented with the respective data sets.

The impact assessment is then calculated automatically. The calculation follows the formulas of the DGNB calculation system using the information of the *Excel* sheet Boundary Conditions, the references from the material allocation and the datasets of the structural and MEP components. The results are shown for the whole project grouped by construction, equipment, and usage, subdivided by production, preservation and deconstruction.

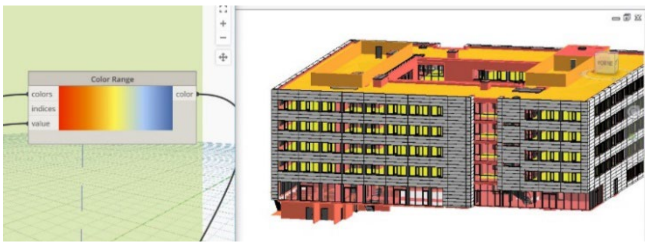

Figure 2. Visualisation of component specific results with colour coding in *Dynamo* and *Revit*

On another *Ex*cel sheet, the results are shown component-specific, which can be used to color code the Revit Model according to their total impact on the embodied energy (Figure 2). This visualization helps to identify optimization potential during the planning phase and has a positive effect on the optimization workflow.

4.3. Validation of the prototype

In the following, the prototype will be quantitatively validated. For this purpose, the model M1s is calculated as an example reference object. The calculation method corresponds to the life cycle assessment according to the DGNB system 2018. The service life of the building was assumed to be 50 years. The data basis is Ökobaudat 2013.

The error deviation of 1.13% results from the more accurate mass determination through BIM integration. The actual volumes of the component-specific materials are determined, whereas in conventional balancing the calculation is based on the product of component area and layer thickness. Besides, with the own prototype, the approach of density accumulation can be bypassed by the method of the specific assignment of composite materials and thus a more exact calculation can be achieved. The correct results of the own prototype validate the calculation method and functionality of the prototype.

5. Discussion and Outlook

This work aimed to investigate BIM-integrated life cycle assessment about its operability and weaknesses. Initially, model analyses were carried out with existing software programs.

The calculation results show that even with simple models of the IFC files there are large deviations in the results. This leads to the conclusion that the "open BIM" approach is error-prone and often leads to incomplete and incorrect BIM-integrated LCA.

In general, a more precise nomenclature of materials with qualitative name affix is recommended to guarantee a correct, component-specific material allocation. For example, this can be the minimum compressive strength class for concrete, the tree species or material type for wood, or the type and processing of metals.

Therefore, the core of this approach was to develop a separate concept for an LCA calculation tool using *Autodesk Dynamo* and *Excel* interfaces. It realizes a compromise between the automation of the component-specific materials and subsequent adaptability according to the given component catalog. All components relevant for the LCA calculation are read out via dynamo, whereby problems still arise with the geometric export of stairs, windows, and doors, facade elements as well as beams and supports. In contrast to existing programs, this approach ensures a precise and transparent LCA calculation even for imperfect, complex projects. Due to the open interfaces, it is possible to make comprehensible adjustments to the materials. However, programming complex models with *Dynamo* and Python scripts are still computationally complex and was just used to prototypical implementation. Together with the exact geometric mapping, this offers further optimization potential.

The modeling recommendation for an effective BIM-integrated LCA is the naming of the components according to the component catalog and a precise nomenclature of the building materials, which also includes qualitative material properties. Post-Processing of the mass installation as error correction is necessary to ensure a correct and complete life cycle assessment.

For future work, a workflow with real-time calculation would be the next step. This way of feedback of BIM-based design decision support helps optimizing the design according to its ecological impacts in early design stages. The difference to Hollberg's Parametric Life Cycle Assessment [14] would be that BIM models could be used for existing semantic information about the building constructions and materials.

Another focus of future work in this field of BIM and sustainability is to supplement Life Cycle Assessments with the aspect of life cycle costs (LCC) to take the economic dimension into account. Further BIM-compliant criteria according to green building certificates are available in the areas of socio-cultural and functional quality as well as technical quality. After a general potential analysis, which criteria are suitable for a BIM-integrated verification, it is necessary to integrate the different calculation criteria into BIM programs.

Identification and comparison of LCA-BIM integration strategies

Wastiels L, Decuypere R

Belgian Building Research Institute (BBRI-CSTC-WTCB), Belgium

lisa.wastiels@bbri.be

Abstract. With increasing use of BIM (Building Information Modelling) in the design of construction projects, opportunities arise to integrate Life Cycle Analysis (LCA) in early design phases efficiently with minimum additional burden for the design team. Different levels of integration can be envisaged, ranging from a BOQ export (Bill Of Quantity) based on the BIM-model to import in native LCA-software, up to a real time LCA-calculation within the native design environment, giving real time feedback on design decisions, or alternatively utilizing the standardized BIM-information exchange format IFC. Based on the evaluation of existing tools, this paper focuses on the possible workflows for the integration of LCA and BIM. A comparative analysis between these different information flow structures exposes their advantages and disadvantages, depending on the design phase they are used in and the availability of generic, product-specific or manufacturer-specific LCA-data.

1. Introduction

The AEC sector (Architecture, Engineering and Construction) is going through an important digitization process, with the rocketing adoption of BIM (Building Information Modelling) in the different design and construction phases, allowing for an efficient exchange of building information between the different specialists and reuse of information in different phases. This creates opportunities to more efficiently carry out multiple analyses based on the available building information while minimizing the need for manual data entry in the discipline specific simulation tools.

At the same time, growing concerns about the environmental impact of buildings trigger a demand for thorough Life Cycle Analysis (LCA) in the design phase. However, the integration of LCA in the design process is not mainstream yet. LCA databases and tools being in full development, and there is still uncertainty on how to best align the demands from the LCA practitioner with those of the rest of the design team. Consequently today it remains unclear how to seamlessly integrate the LCA analysis in the global BIM based design workflow.

Many questions on how to unambiguously include discipline specific parameters in the Building Model are being treated in CEN TC 442 WG4 on 'Data Dictionaries' already. However, in order to tackle certain issues specifically associated to the execution of LCA studies based on BIM models, more insight in the possible workflows for this integration is needed.

Whereas most papers focus on the evaluation of the results of different BIM integrated LCA tools (including [1]) or the user requirements for individual LCA tools (including [2]), the objective of this study is to identify and develop feasible workflows to perform building life cycle analyses based on BIM models, together with the industry. Based on these workflows further guidelines can be developed for structuring the LCA data (generic, product/brand specific, sector average) for use in BIM workflows.

Insights were gained through an evaluation of existing tools in combination with focus group discussions with BIM and LCA experts from the construction sector (engineers, architects, contractors, manufacturers, government, research bodies).

2. Screening of existing tools and methods

For this study existing national and international tools and methods were screened, amongst which Elodie (France), Totem (Belgium), Tally, One Click LCA and USai. For the selection of tools, the main goal kept in mind was the establishment of a building LCA study and the link with a BIM software environment for (part of) the data collection or modelling. The evaluation focused on the integration of the LCA calculations with the BIM model, and more specifically on the type of data and calculation steps occurring within the BIM environment and those occurring within a separate LCA assessment tool. Specific attention was given to the required modelling approach in order to allow for the linking between the BIM and LCA environments (e.g. level of material or level of building element). The design and evaluation process is evaluated and broken down into different steps in order to better understand the interaction between them, as well as the implication in terms of possibilities and workflow.

2.1. Main elements and terminology of the BIM and LCA integration

Based on the evaluation of the tools a set of main elements and terminology can be described, relevant for the understanding of the integration of BIM and LCA and the definition of BIM-LCA workflows. Below an overview of the most relevant items is included.

Generic LCA database. Database containing generic LCA data that is not linked to a specific manufacturer or product.

Specific EPD database. Database containing LCA data that is specific for a certain manufacturer or product, usually based on a EPD (Environmental Product Declaration).

LCA profile. A set of LCA data for a certain material type or a combination of materials. This can either be a generic set of LCA data, an EPD, or a combination of both.

LCA software. Software tool specifically developed for the execution of an LCA. Expert tools include the possibility to calculate according to different LCA methodologies. Other tools usually include a specific database of LCA profiles (for a specific methodology). These tools support the insertion of material quantities (directly of via a file-import), the linking of LCA profiles to the materials or compositions, and the calculation, visualization and analysis of the environmental impact.

BIM objects. BIM objects are digital representations of building products which are used to build up a BIM model. BIM objects can be generic (e.g. a generic masonry wall) or can be provided by a manufacturer who can include all product and manufacturer specific parameters in the BIM object. A BIM object contains information on different parameters. LCA data can be associated to a BIM object through specific parameters.

Native BIM software. Software tool for modelling a building in 3D with the attribution of additional information to the elements within the model.

LCA plugin. An LCA plugin is a software component that runs within an existing computer software (e.g. a native BIM modelling software) and adds functionality to this software specifically designed to support a life cycle analysis.

IFC. IFC (Industry Foundation Classes) is an open file format facilitating the exchange of BIM models between software tools from different vendors.

BIM viewer. A software tool which allows for a BIM model to be inspected. A BIM viewer does not support the creation or modification of the (geometric) BIM model. However, certain BIM viewers support the addition or modification of certain parameters.

2.2. Landscape of tools and process steps for BIM based LCA

Since the introduction of BIM based design and life cycle analysis in the design practice, a wide variety of tools both for BIM and LCA have been developed, each supporting different steps in the BIM based and LCA based design process.

The process for designing a building in BIM and then using this information for performing an LCA study, contains at least these steps:

1. Modelling: The BIM model is developed by a BIM modeler. The geometry of the building is modelled based on BIM elements containing additional information.
2. Setting up a bill of quantities or BOQ: Based on the BIM model, a list of elements and/or materials with their respective quantities is established.
3. Establishing LCA profiles: the environmental impacts of the different materials and products used in the building are identified and quantified in LCA profiles. Depending on the situation, the LCA practitioner can fall back on generic or EPD-data. These LCA profiles can either be developed at the material level, or at the level of a building component (assembly of materials).
4. LCA profile attribution: The material quantities from the BOQ have to be linked to the corresponding LCA profiles (which are expressed in environmental impacts per unit). This might not always be an explicit step and could be integrated within the previous step where the LCA profiles are established.
5. Calculation of the environmental impact: based on the BOQ, the attributed LCA data and the LCA methodology specified in the tool, the LCA calculation can be executed.
6. Visualization and analysis: The results of the LCA calculation are visualized and analyzed by the LCA practitioner.

For this paper, we differentiate between four different types of tools: native BIM software, BIM viewers, LCA software and LCA plugins for native BIM software. The table below visualizes the supported steps in the design process for these different types of tools (**Table 1**).

Table 1. Supported steps in the design and life cycle analysis according to the type of tool.

	Modelling	Setting up BOQ	Establishing LCA profiles	LCA profile attribution	Calculation of env. impact	Visualization and analysis
Native BIM software	✓	✓				(✓)
BIM viewer		✓		(✓)		(✓)
LCA software			✓	✓	✓	✓
LCA plugin for native BIM software		✓		✓	✓	✓

3. Workflows for the integration of LCA and BIM

Different strategies can be used for organizing a design workflow that integrates building data coming from a BIM model in the LCA analysis. In relation to the direction of the data flow, two main strategies can be distinguished:

1. Geometrical and possibly also material related information is extracted from the BIM model in the form of a bill of quantities (BOQ). Based on this information on the quantities (and type of material) the LCA calculations are performed in specialized LCA software.
2. Specific LCA data can be added to the BIM model by use of specific parameters. The LCA calculation is performed within (a plugin for) the BIM software.

Some intermediate strategies can be determined between these two extremes. Below, five main strategies are described into further detail based on the screening of existing tools and expert discussions. In practice, more strategies can be conceived, combining aspects of the five proposed strategies. The choice for a strategy depends on the tools used by the designer and LCA professional, and their respective available functionalities for integration, the availability of the relevant information in the BIM model, the availability of LCA data, the scope of the evaluation, etc.

3.1. Strategy 1: Bill of quantities (BOQ) export

A life cycle analysis always starts with an inventory of the building materials based on a bill of quantities (BOQ). For a BIM based project design, this BOQ can be extracted from the native BIM model in the form of a spreadsheet.

In this first strategy, the BOQ is (directly) imported in a dedicated LCA software. The remaining workflow takes place within the LCA software. The LCA practitioner manually links the different building components (with their quantities) to predefined LCA profiles available in the LCA software database or creates new LCA profiles where needed. The LCA calculation, visualisation and analysis is performed within the software as for a traditional LCA study. A representation of the workflow is available in **Figure 1**.

Iterative design might not be supported using this strategy. Depending on the tool used, importing an updated BOQ spreadsheet in an existing LCA calculation set, while preserving the already defined links between the building components and the LCA profiles, might not be possible. The data availability and verifiability depend on the quality of the data in the LCA software. A visualisation of the results (environmental impacts) in relation to the building elements depends on the visualization possibilities of the LCA software.

This workflow describes how most BIM integrated LCA calculations are currently performed.

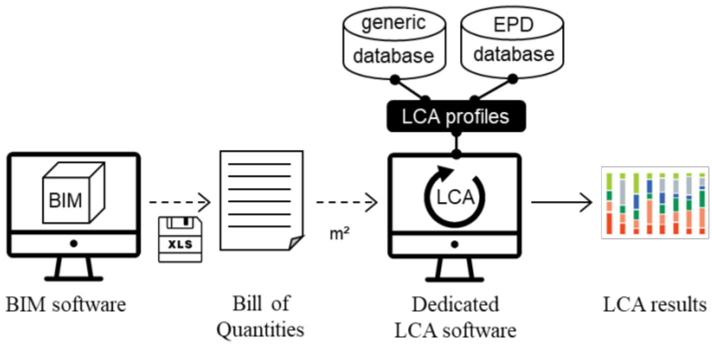

Figure 1. Workflow based on a bill of quantities (BOQ) export from the BIM model

3.2. Strategy 2: IFC import of surfaces

In the workflow defined by strategy 2, the geometric BIM model is imported "as such" in the dedicated LCA software. Usually, an open exchange format like IFC is used for the transmission of the BIM model, but the use of native BIM file formats is also possible, depending on the features the LCA software provides.

The imported data includes at least the geometric parameters, based on which the material quantities (surfaces, volumes) can be determined, but will in many cases include the Global Unique Identifier (GUID) and the component or material name as well. Based on these imported data, the LCA practitioner will link the building components to predefined LCA profiles available in the LCA software databases (which could be a generic or a product specific database, or a combination of both). Finally, the LCA calculation, result visualization and analysis is performed within the dedicated LCA software. See **Figure 2**.

The main difference with strategy 1 is the automatic import of the data and the possibility to maintain a link between the data. When the GUID is imported and stored in the LCA software, an iterative design process could be supported, allowing for quantities and descriptions to be updated based on a new version of the IFC file without losing the existing links to LCA profiles.

The Belgian TOTEM-tool is an example of this strategy [3].

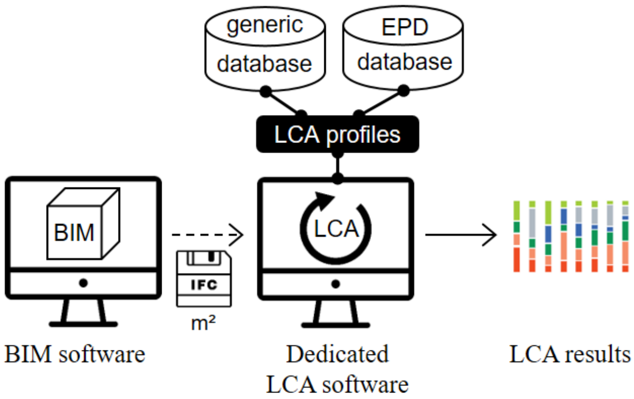

Figure 2. Workflow making use of an IFC import into the LCA software

3.3. Strategy 3: BIM viewer for linking LCA profiles

In the third strategy, the LCA profiles are attributed in an intermediate step in a BIM Viewer environment. This requires the export of a BIM model from the native BIM software by means of an IFC file. Within a specific BIM viewer, containing functionalities for this task and a list of available LCA profiles, the LCA practitioner or potentially the BIM modeler can attribute LCA profiles to the building components.

The geometric data is then sent to a dedicated LCA software, together with their associated LCA profiles. Based on these LCA profiles, the LCA calculation can be completed in the LCA software, followed by result visualization and analysis. The workflow is represented in **Figure 3**.

The advantage of this approach is that the attribution of the LCA profiles can occur within a 3D environment, while keeping the in-depth LCA analysis in a dedicated LCA environment. Also the link between the geometric data and the LCA profiles can be maintained for further reference during an iterative optimization process.

An example of this strategy is the eveBIM-viewer where FDES-profiles (=Environmental Product Declarations from the French program Inies) can be attributed to building components before exporting to the dedicated Elodie software [4].

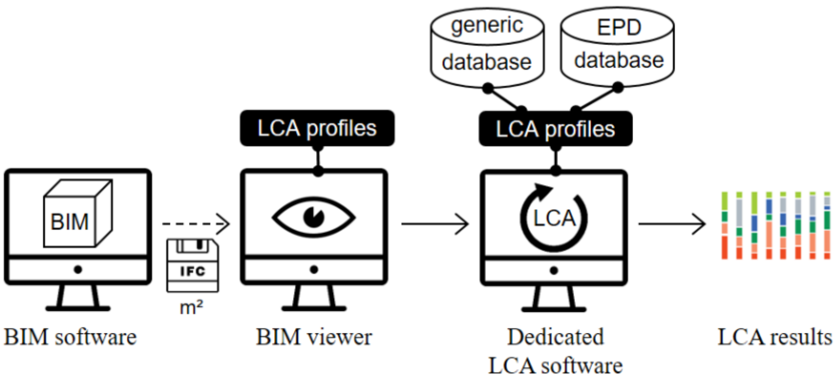

Figure 3. Making use of a BIM viewer to associate environmental data (LCA profile) to the building geometry.

3.4. Strategy 4: LCA plugin for BIM-software

Strategy 4 strives for a maximisation of design process steps to be performed within the native BIM environment, by means of specific LCA plugins. With these plugins, LCA profiles can be attributed to

BIM objects within the native BIM environment. All further steps, including the calculation, result visualisation and analysis are done within the LCA plugin (see **Figure 4**). Consequently, the dedicated LCA software is no longer used but replaced by the use of a plugin.

Up to now, this strategy seems to allow for LCA analyses with generic LCA data only (based on the databases of LCA profiles included within the plugin). An important advantage compared to the previous strategies is that the LCA results potentially can be visualized in the geometric model providing an instant view on the hot spots or most important impacts.

The tools Tally [5], One Click LCA [6],USai/Eco-Sai [7] and CAALA [8] work with plugins for BIM software.

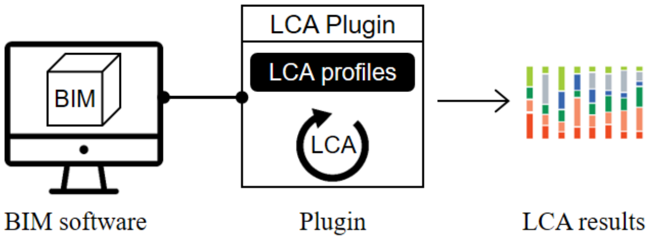

Figure 4. Workflow based on use of an LCA plugin for the BIM software.

3.5. Strategy 5: LCA enriched BIM objects

In the fifth strategy, LCA information is included in the BIM objects that are used in the BIM model, instead of being attributed to the appropriate building components in a later stage by an LCA practitioner. The LCA profiles are thus immediately associated to the geometric and material data inserted in the BIM environment. The further steps of this workflow could include a calculation and analysis with a plugin in the dedicated BIM software, or an export to a dedicated LCA software. A visualization of the workflow is given in **Figure 5**.

When generic BIM objects are used, generic LCA data will be used. However, manufacturer or product specific BIM objects could contain manufacturer or product specific LCA data as well. These BIM objects do not necessarily contain all the LCA data themselves, but could contain a reference to an LCA profile for which the data is stored in a dedicated LCA tool or database.

This strategy has a high potential as all data can be centralised within the BIM objects and a design optimisation process can potentially be supported with real-time information on the environmental impacts. On the other hand, with LCA profiles linked directly to the BIM objects, a trade-off between different materials might necessitate changing the BIM objects in the model, which is more laborious than changing the LCA profile in a dedicated LCA software.

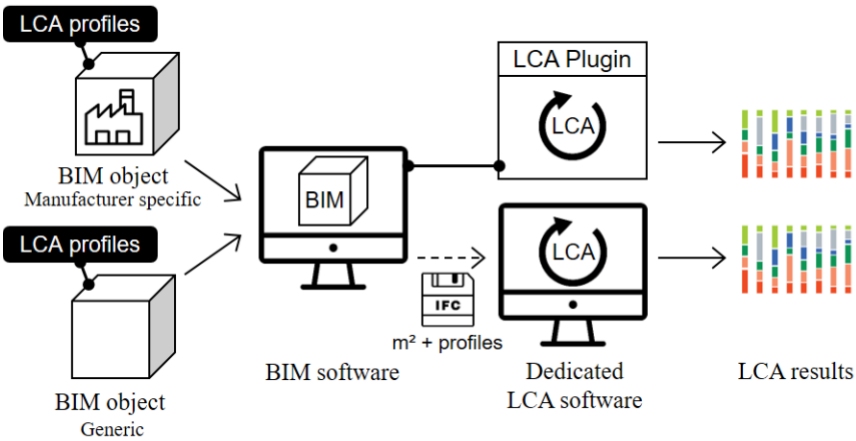

Figure 5. Workflow where BIM objects are enriched with LCA-based information or references.

For now, it appears this strategy has not been implemented yet, due to a lack of available BIM objects with LCA data, and a lack of consensus on how to structure LCA data and profiles. The level at which LCA data is available (e.g. EPD data for cement) will not always coincide with the level for which BIM objects are provided (e.g. wall). Furthermore, other difficulties have to be tackled first. LCA data is often valid for specific situations only (e.g. for a specific size of a certain building component). As a result, the LCA data might not be valid anymore after resizing of the BIM object.

4. Expert discussion on workflow and user needs

An expert group with Belgian LCA-practitioners was brought together in order to assess the current workflows for LCA analyses and to evaluate the future applicability of the different proposed workflows. Insights from these discussions have been integrated in the workflow assessment in the previous part. A more comprehensive report of the discussion on the applicability of the proposed workflow strategies for different disciplines and design and construction phases is given below.

4.1. Applicability of workflow strategies for disciplines and construction phases

Different needs exist in relation to the different disciplines making use of LCA and BIM, and the objective of the LCA study.

For example, for structural works, due to the low variety in used materials, it is feasible to perform an LCA in the early design phases based on a rough BIM model. Quantities are fairly easy to specify and the number of materials to be associated is limited. It would therefore be feasible to implement any of the proposed strategies for this type of analysis. Even in the absence of readily available BIM objects containing LCA data, a design office could invest in creating a set of BIM objects for the limited amount of materials used themselves, and thus implementing strategy 5 internally.

For the architectural design, the specifications have to be more detailed (loadbearing materials, insulation, finishing materials). Differences in materials will have significant impacts on the LCA results. When there is a trade-off between different building materials in an early design phase, it is very likely that an optimization from an environmental point of view is performed at the level of the building element, rather than at the building level, thus ignoring the relative weight of the building material in the total building. This optimization can easily be done within a dedicated LCA environment.

For a thorough building level LCA study for an architectural design to be executed in an early phase, Moreover, due to the large quantity of materials used in architectural design, an easier access to LCA data is needed. Several material choices and technical execution details are still open or specified with a very low level of detail. In that case, it is very likely that the BIM model does not contain sufficiently detailed information at the material level to allow for an LCA calculation. At that moment a need exists for a database with generic information on building compositions and their associated LCA profiles.

In this early phase, support for an iterative design process is essential too, rendering strategy 1 unfit for this situation.

Strategy 5 seems a promising workflow from an architect's perspective for providing easy access to LCA data, notwithstanding the current lack of LCA data enriched BIM objects and the difficulties this poses for manufacturers. However, it is less supportive for an iterative approach. When multiple material options without important geometric differences are to be evaluated, different BIM objects would have to be incorporated in the BIM model. In this situation, strategies 2, 3 or 4 might be more efficient, since multiple material options can be compared based on only one BIM model.

Special attention has to be given to public tenders, where the BIM model needs to be manufacturer independent. In these projects, the use of BIM objects with EPD data could therefore cause problems.

If the goal of the LCA is a "post-construction" assessment of the environmental performance (and thus not an optimization process) it becomes easier to determine which information should be available to allow for a calculation. In that case an approach where environmental data is linked to the objects in the BIM model (by means of parameters with a GUID) seems feasible. A complete BIM model of the building "as-built" can be fed with this specific information.

The most suitable workflow will thus be related strongly to the objective of the LCA calculation, the time phase in the project and the discipline.

4.2. EPD data in BIM models and objects

A specific point of attention concerns the use of EPD data associated to BIM objects. First of all an EPD can be country specific, including specific indicators or not, or being representative for the transportation or End of Life treatment in a specific country of region. The use of EPD information from different EPD programs within one BIM model should be avoided. A second point concerns the verifiability of the environmental data associated to BIM objects in a BIM model. For example, data from an EPD might be valid for a specific product with specific dimensions (e.g. a window of a certain size) but might lose its validity when the object is being scaled. Thirdly, it is very likely that EPD data will not be available for all materials or components of the building. In order to allow for a correct LCA evaluation within the BIM environment, there is a need for databases with generic objects including generic LCA data and for guidelines for the proper use of EPD data linked to BIM-objects.

5. Conclusions

The digitization of the design process through the use of BIM, and the growing need for the inclusion of environmental considerations early on in the design process, urges for an efficient exchange of building information between the design team and the LCA practitioner. Even though different tools supporting this integration already exist, there is still much uncertainty on how to best integrate the LCA analysis in the BIM supported design process.

This paper proposes five strategies for workflows, ranging from a BOQ export from a native BIM model to be imported in a dedicated LCA software, which corresponds to how most LCA practitioners perform the integration today, to the inclusion of LCA data in BIM objects before they are incorporated in the BIM model.

Besides the availability of tools and databases to support the proposed workflows, many other considerations influence the choice for a strategy to be implemented in a design practice, including the need for support for an iterative design approach, the use of generic versus product specific LCA data, the need for real-time feedback for design decisions, etc. Nevertheless, the five proposed strategies form a basis for further research on the optimization of the integration of LCA studies in BIM supported design processes.

Abstract. The building permit is an indispensable connection between the approval authority and the executive client within the construction process. Moreover, sustainability criteria do not have sufficient regard in the building permit process in the area of research. To lay the foundation for a state-of-the-art digitalization of the building permit process, the study identifies the information requirements relevant to implement the BIM methodology taking into consideration the available sustainability aspects relevant to the process. A detailed evaluation of the building permit process and the analysis of projects that have gained building permission in the last five years in the area of study of South Tyrol (Italy) gives us a better understanding of the organizational structure and responsibilities in the process. The authors use the data of in-depth process analysis to assess a defined catalogue of basic requirements for BIM methodology in the building permit process. As a result, the analysed BIM-integrated approach enables an early-stage identification of approval compliance, which can be evaluated in the building permit process. A good understanding of the current process must be considered a key factor of a successful introduction of BIM for the building permit procedure.

1. Introduction

Dealing with building permits is regarded to be one of the main business regulations indicators in a country's business environment [1]. The building permit is, therefore, an indispensable link between the approval authority and the executing client. At the same time, the inclusion of sustainability criteria is one of the most important steps in the promotion of sustainable housing [2].

The current state of the art on the building permit process shows that the successful use of digital information systems contributes to the increased efficiency of the building permit handling process [3]. A notable example is CORENET, COnstruction and Real Estate NETwork, which is used in Singapore and has significantly shortened the processing time since the introduction in 1995 [4]. As predicted by Michael Hammer in 1990, the use of the power of modern information technology to radically redesign business processes has contributed dramatically to improvements in their efficiency [5].

In Italy, the DM 560/2017 [6] regulates the gradual implementation and mandatory use of BIM in public procurement from January 1, 2019. While the majority of the stakeholders of the construction industry expects BIM to be a priority in the next 5 years [7], BIM in the public administration of the research area suffers from a relatively low level of awareness. Considering the fact that local provincial and municipal governments play a fundamental role in the implementation of the EU and national policies [8], the Italian Autonomous Province of Bozen (South Tyrol) was selected as research region for the purposes of this research.
This study aims to define the basis for a standardized procedure for the implementation of BIM in the building permit process. Studying the building permit procedure in the area of study is important for three main reasons: 1) The insufficiently investigated requirements represent a barrier to the standardized implementation of BIM in the building permit process; 2)The gap in informational knowledge on the building permit procedure in the area is a potential loss of efficiency in the construction process; 3) It is consequently intentional to enhance the information that is already available in the current process, by furthermore highlighting redundant information requirements, and make it available as a future BIM-based process. Therefore, it is fundamental to investigate, whether BIM would partly help to resolve the data handling issues [9]. Although many new buildings have sustainability ratings, they comprise a minute amount of the total impact of the built environment [9]. The consideration of sustainability criteria in the early design stage of the building permit planning stage is therefore essential for the support of sustainability in the construction industry.

2. Methodology

The methodology is structured in three investigation sections: The introductory section covers a comprehensive building permit research of the current as-is process. It is followed by the statistical evaluation of past building permit applications and then an information requirements analysis is performed.

2.1. Building permit process research

To define the legal framework of the building permit process, the authors analysed the regulations and laws in the area of investigation. In this research, the authors divided regulations and laws into two groups of primary and secondary sources. The primary sources are defined as documents of the direct legislation such as the National Legislation and the legislation at the provincial and municipal levels. Secondary sources are documents that have been deduced from them, such as relevant documents for the energy certification of buildings in South Tyrol. These are provided, for example, by the KlimaHaus Agency, a subsidiary corporation of the Autonomous Province of Bolzano. The agency was founded for the energy certification of buildings in South Tyrol.
The energy certification class directly influences the building permit approval in relation to the maximal permissible building volume. In fact, if the applicant declares that the new building – he/she wants to build – will achieve an energy certification class higher than the minimum prescribed by the legislation, a larger building volume can be built.
For each of these sources, the relevant content for the building permit has been identified and referenced in a data sheet.
Based on the legal basis, the authors determined the triggers of the building permit process, the individual process steps, the key individuals involved in the execution of the process steps and recorded the corresponding process in diagrams.

2.2. Statistical evaluation of past building permit applications

For the statistical evaluation of the submitted building permit applications in the area of study, the authors asked the association of municipalities in South Tyrol (Consorzio dei Comuni della Provincia di Bolzano) for insight into the database of the software G-Office. G-Office is a back-office software solution used by the technical offices of the South Tyrolean Municipalities, for the management of the administrative procedure documents, including the building permit procedure. The data from the building permit application is inserted manually into the G-Office software as shown in figure 1. For the scope of this research, the association has granted access to the following G-Office data: project title, project description, construction typology, data details (application date, date of approval), land-use plan zoning and the KlimaHaus certification classes. In consultation with the municipal authorities, the authors have studied the data of the building permits of the last 5 years (2014 – 2018). The analysis of the data has been performed using SPSS, a software package for statistical analysis.

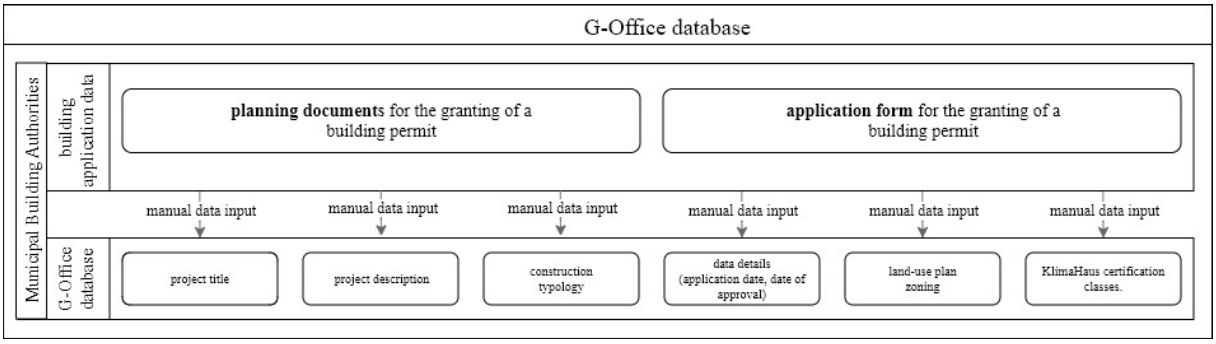

Figure 1. The figure shows the data information flow of the data analyzed in G-Office.

In order to be able to better allocate and compare the data sets, municipalities have been sorted according to their geographical size and population.
From the data set, the authors determined the number of building permit applications submitted per year. This information was supplemented by the duration of the building permit procedure (i. d. from the application to issuing of the building permit). The authors continued the investigations by determining the distribution of the building typology, the distribution of the applications per land-use plan and the present frequency of the KlimaHaus certification. In conclusion of the analysis, the authors determined the number of applications submitted as a variant.

2.3. Information requirement definition
The requirements for the implementation of BIM in the building permit procedure were derived from the laws and regulations investigated in 2.1. In more detail, the technical specifications based on the legal requirements and the specifications defined by the process were analysed by the authors.
The following six source documents were analysed: the application form for the granting of a building permit, the municipal building code (regolamento comunale edilizio) [10], a questionnaire of the National Statistics Institute (ISTAT) on building permits [11], the "Decreto del Presidente della Provincia 9 novembre 2009 , n. 541" (the Regulation concerning the Removal and Overcoming of Architectural Barriers) [12], the "Decreto del Presidente della Giunta provinciale 23 maggio 1977, n. 22" (the Regulation on Hygiene and Health Standards) [l3] and the KlimaHaus technical guideline for new constructions [14]. The requirements were listed individually in a data set and grouped into information categories. This analysis highlighted all the redundant information and the duplicates information currently requested by the applicant. Moreover, the authors determined whether the individual requirements are directly objectifiable and quantifiable and if a unit of measurement can be assigned to the values.

3. Results

3.1. Building permit process research - As-is Analysis
At the national level, two sources regulate the building permit process: the "Testo Unico delle Norme per l'Edilizia", the Italian consolidated building law (Decree of the President of the Republic no. 380/2001) [15] and the Public Procurement Code (Decree-Law no. 50/2016) [16].

Legislation at the provincial level is based on two relevant laws: the valid Regional Planning Law No. 13/1997 [17] and the Regional Law of 17 December 2015, no. 16 [18], which regulates public procurement. At the municipal level, the municipal building code [10] regulates essential parts of the building permit procedure. The principles that are decisive for the building permit procedure are defined in the municipal land-use plan.
The authors identified the following entities as key figures for the process:

- Applicant: the client who submits the application for a building permit to the building authority of the relevant municipality.
- Municipality: the authority is mainly responsible for the processing of the building permit application.
- Within the municipality, the building authority, the mayor and the building commission: they are responsible for the execution of the building permit approval.
- Provincial administration: issues expert opinions and permits in special cases.
- Planner: a qualified person authorized to submit building documents and drawings.

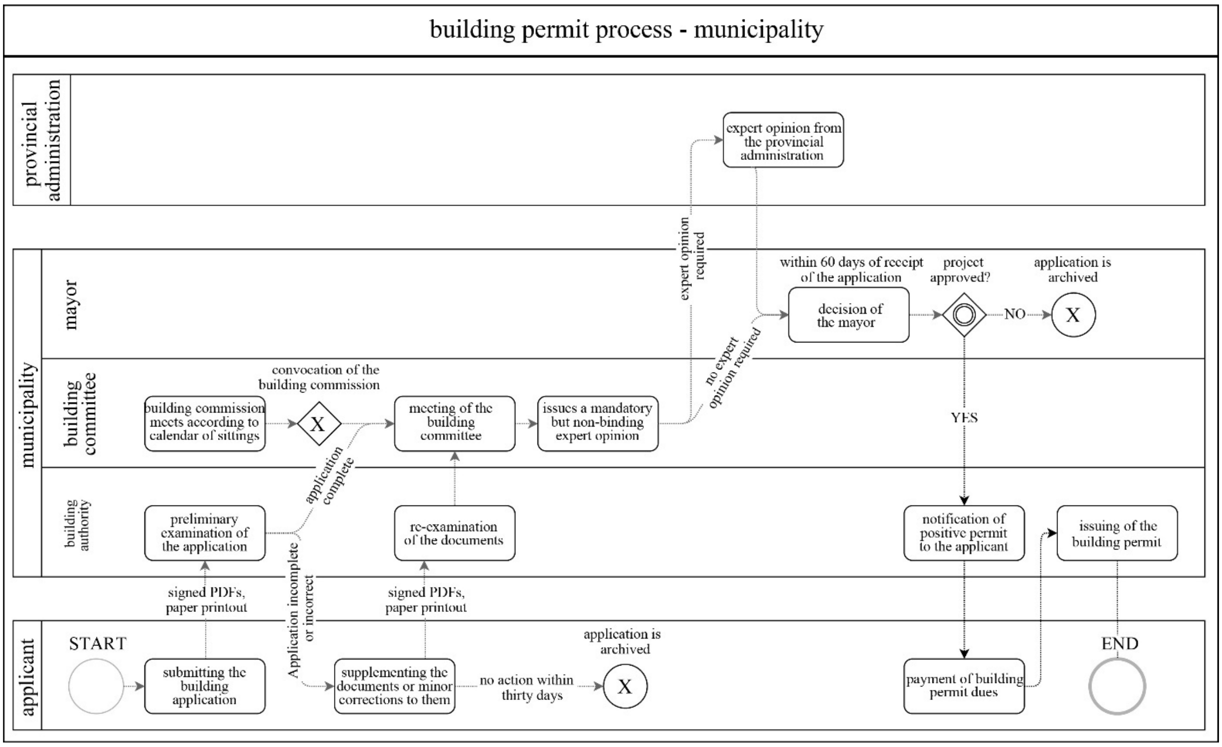

Figure 2. This figure shows the as-is building permit process analysis.

The process for obtaining a building permit, as illustrated in figure 2, starts with the submission of the building permit application. In the next step, the submitted documents are pre-checked by the building authority. At this stage, if required by the building typology, the applicant will submit a self-declaration for the KlimaHaus class. However, this document is not checked for technical content or otherwise analysed. All further steps of the sustainability certification process take place at a later stage after the building permit has been issued. This reflects the weak role of sustainability aspects in building permit process. If the building permit application is incomplete, the staff of the municipal administration will ask the applicant to complete the documents within 30 days. Once this deadline has passed, the application will be archived without further notice. Upon the complete submission and the successful examination, the building committee reviews the application and delivers a non-binding expert opinion on the building permit application. The composition of the members of the building committee is defined in Art. 115 of the Regional Planning Law No. 13/1997. If reports from the

provincial administration are required, the mayor may not grant any authorisation before the final report has been received. The mayor's decision on the application for authorisation will be sent to the applicant within 60 days after receipt of the application or after submission of additional documents requested.
This process shows that the review of the project documents takes place at an early stage in the process for obtaining a building permit and concentrates on the authorities within the municipality. This fact facilitates a possible implementation as there is a limited number of parties involved.

3.2. Results of the statistical evaluation of past building permit applications
Categorization: The municipality category is allocated based on the population size. Municipalities with less than 3000 inhabitants are classified as small municipalities in the study area (3 units), municipalities with 3000 - 10000 inhabitants as medium-sized municipalities (3 units) and municipalities with more than 10000 inhabitants as large municipalities (2 units).
Typology: Since the building typology is not predefined in G-Office, the number of typologies found is high, reaching 287 different records. The evaluation of figure 3 shows the top 10 of the evaluated building typologies. The evaluation of the percentage distribution of the submitted building permit procedures shows that the typologies "renovation" 17.3%, "attention" 15.9%, "extension" 11.6% and "new building" 10.8% were most frequently found.
The "attention" entry suggests that the building typology was not accurately specified, and a placeholder was used instead.

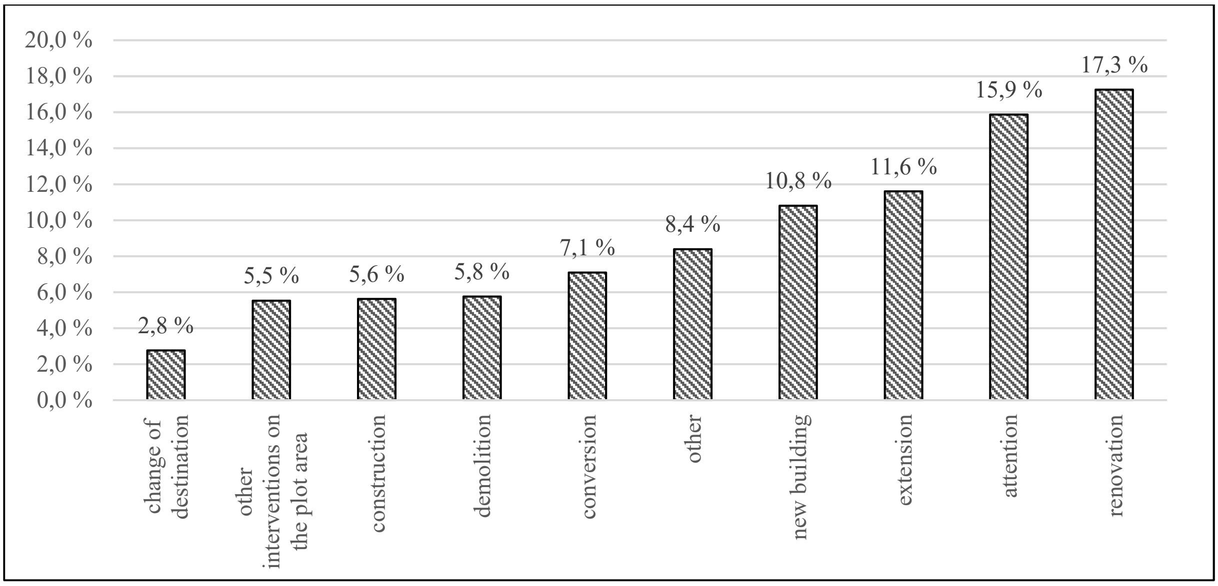

Figure 3. The graphic shows the top 10 distribution of the building typologies of the past building permit applications.

Duration of the building permit process: A cross-comparison of the different municipalities shows that the distribution varies from municipality to municipality. The average duration of the procedure is 90 days. In large municipalities, the duration of the proceedings is the shortest, 77.93 days and 81,15 days respectively. In the small and medium-sized municipalities, by contrast to the large municipalities, there is no clear difference in the average process duration.
KlimaHaus classes: Only 3,3% of the building procedures analysed provides the KlimaHaus class. The 30 %, of the KlimaHaus classes recorded, are Class A, the second-highest climate house. This class corresponds to the nearly zero-energy building – NZEP class according to the EU Directive 31/2010/EU, Art. 2, Para. 2.

Variant: The data set shows that 16.8% of the building permit procedures involve subsequent changes to the building application that has already been approved. This procedure is necessary, if for example, changes are to be made to the planning prior to the start of construction or if changes to the project are necessary during the construction phase.

3.3. Results of the information requirement definition
The subsequent analysis of the source documents revealed that there are nearly 450 specifications requirements by the building permit. These include technical specifications, legal requirements as well as specifications required by the building permit procedure itself.
Requirement categories: The authors classified the information specifications, detected from the six source documents listed in 2.3, into the following requirement categories: specifications of the building (60.0%), building services systems (9.4%), surroundings (4.9%), urbanistic specifications, (3.8%) owner of the property (3.8%), location of the building (3.8%), energetic specifications (3.8%), planner (3.8%), applicant (2.9%), other (1.6%), materials (0.7%), infrastructures (0.4%), description of the work (0.4%) legal specifications (0.2%).
Redundant information requirements: In the categories, the authors found that 20.2% of the information requirements are redundant. Two different types of duplicates can be detected. Information requirements can be found multiple times in the same source document (8.9%), or multiple times in different source documents (11.3%).
Objectifiable and quantifiable information requirements: As illustrated in figure 4, the evaluation shows that 91% of the requirements are objectifiable and quantifiable. Only 9% of the requirements are neither objective nor quantifiable. These requests are, for example, reports, descriptions or undefined specification. 37% of the requirements are immediately objectifiable and quantifiable. 63% of the requirements must be calculated or derived and are therefore not directly derivable from the requirement.

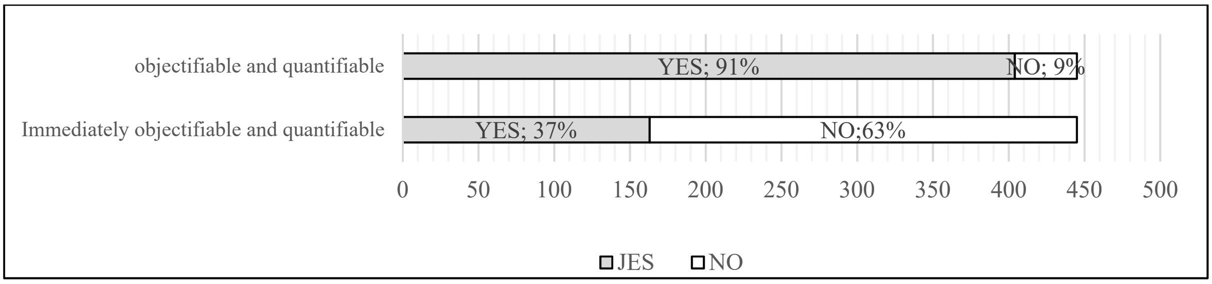

Figure 4. The graphic shows a representation of the objectifiable and quantifiable entries of the information requirement definition

Unit of measurement of the information requirements: To each information requirement, the authors assigned a unit of measurement. In total, 37 different units of measurement were assigned. The most frequent units in the data set are meters (26%), followed by text entries (23%), true-false entries (11%), drawings (8%) and 7% both for generic number entries and square meters.

4. Discussion

All three methodical investigation sections unanimously reveal weaknesses points for general procedures of the building permit process as well as for the application of the sustainable criteria. The currently partially digitalized information flow can be supplemented by the BIM methodology without far-reaching adjustments to the approval process. The results show that the current process is BIM adaptable in a fundamental way without major changes to the processes currently in use. It is reasonable to assume that a considerable shortening of the duration of the building permit processing

time can be achieved. However, the complex legal frame and the resulting high number of necessary procedures are expected to limit the overall efficiency of the building permit procedure.
The low data quality of the examined G-Office database indicates that at present the building authorities are feeding the database in a partially negligent way. Since the information-technical complexity increases further with BIM-based procedures, it is necessary to asses which measures can support the acceptance by the users and the required careful handling of the data.
A further explanation for the low data quality can be traced back to the lack of preselection datasheets. So, for example, to describe the same information requirement, often different terms were chosen. This shows that the use of templates and standards is essential when managing information requirements.
Based on the evaluated data, the authors determined that the detail level of the information requested by the approval process is noticeably high. In addition, a sufficient set of sustainability aspects can be found in the analysed documents. In fact, in many cases the data required for an early-stage assessment and/or consideration for the approval compliances is available. Due to the current processing procedures for the building permit documents, a significant part of this data cannot be directly retrieved and is therefore not accessible to public administrations. The unification of the requirement catalogue is necessary in order to avoid duplicate data.
It can be assumed that the immediately objectifiable and quantifiable information requirements can be seamlessly integrated into a BIM-based workflow. Since the information requirements are mostly clearly objectifiable and quantifiable, a considerable degree of semi-automated verification of today's information requirements is possible.
The research is to be understood as proof of concept to define the information requirements for a building permit process in the area of research.

5. Conclusion

The paper represents a starting point for the technical implementation of a BIM-based building permit process in the area of study and provides the basis for the first use cases. The determined process-based requirements show that sustainability aspects are not taken into consideration sufficiently. Without much additional effort, existing information requirements can be used for the early design stage implementation of basic sustainability aspects. The very complex approval structures and requirement profiles need to be adapted and streamlined to enable a smooth implementation. There were notable positional differences between the municipalities, with the consequence that the implementation in a first step will be limited to individual building typologies. The results show, however, that significant performance optimization is to be expected in the investigated area. The investigation is the first step towards a broad application of digitised information systems in the approval process.

6. Acknowledgements

Abstract. In recent years the application of Life Cycle Assessment (LCA) for assessing and improving the environmental performance of buildings has increased. At the same time, the automated optimization of building designs is gaining attraction for both design and research purposes. In this regard, a number of issues persist when aiming to optimize building's environmental impacts along the design process. Firstly, as LCA applies a life cycle perspective, many aspects have to be considered (e.g. energy demand in operation as well as consumption of resources and energy for production and end of life treatment) and a variety of specific calculations is needed (e.g. building energy performance simulation, material quantity take-off). Secondly, sophisticated software packages are available and being used for each of these calculations (e.g. software for building modelling, dynamic energy simulation, quantity surveying). Though many of these software packages are currently standalone applications that rely on human interaction, there is an increasing trend to provide an application programming interface (API) that enables customization and automation. Thirdly, the mentioned processes and calculations are influencing each other in various ways and several scenarios have to be assessed. Thus, a comprehensive and modular approach is required that promotes interconnectivity of the different software solutions and automation of the assessment. In this paper we propose a modular cross-platform framework for LCA of buildings aiming to support flexibility and scalability of building LCA. We present a conceptual framework, example data exchange requirements and highlight potential implementation strategies.

1 Introduction

The building and construction sector is related to around 40% of global primary energy consumption as well as a similar magnitude of global greenhouse gas (GHG) emissions and waste produced. Assessing and reducing the energy consumption, GHG emissions and other related environmental impacts across the building life cycle – i.e. from material production and construction, to building operation, incl. maintenance and replacement, down to the final processing at the end of life of buildings – has thus become an important point on the global agenda. Most measures in recent years have been focusing on increasing the energy efficiency of building operation in order to reduce energy consumption and the related GHG emissions. However, in recent years, the importance of assessing and optimizing the environmental performance across the building life cycle is becoming evident. In order to achieve a science-based quantification of environmental impacts of processes and products, the method of Life Cycle Assessment (LCA) has been developed and is increasingly applied. However, its application to buildings is still hindered by several challenges, e.g. compilation and processing of extensive inventories of the complex product system 'building', mapping of inventories with related data from LCA databases, as well as the handling of trade-offs between embodied and operational impacts, to name just a few. In recent years, the application of Building Information Modelling (BIM) has gained interest, hoping to increase the applicability of LCA by managing the related data via a digital building data model. This integration of LCA into BIM has since been demonstrated in several papers with different maturity. In the following we give a brief overview into the state of play based on a literature review.

1.1 Literature review

The application of LCA for buildings' environmental assessment has been of increasing interest for more than 5 years in the literature. However most of the papers were focusing on the applicability of BIM for building LCA [1] or the extension of BIM [2] to include environmental data. Soust-Verdaguer and colleagues [3] evaluated the limitations of BIM-based LCA in a comprehensive review. They identified three levels of integration, from which only the third level includes automated data exchange. It is also recognized that this is not the current practice yet. On the other hand Hollberg and Ruth [4] applied a different approach focusing on the parametric definition and optimization of the model instead of starting from a predefined BIM geometry model. They emphasized the advantages of a parametric model in optimization processes and in early design stages. Other studies were focusing on the data management to bridge the gap between the input requirements of an LCA and the data availability in BIM. Cavalliere et al. [5] defined the minimum requirements to include environmental data in BIM models. They developed an "architecture of variables" so that the various parameters can be included depending on the life cycle stage and the available data. Tecchio et al. [6] on the other hand described a hierarchic decomposition structure for building model data and proposed a method to conduct LCA even if the data availability is low and the information is underspecified. Further studies applied LCA on case studies [7]–[9], most of them facilitated some features of BIM (e.g. extract material quantities, visualization of 3D building model, etc.), but they either use some self-developed tools (e.g. Excel spreadsheet) [9] or apply commercial plug-ins [8] to evaluate the environmental impacts. Both approaches have their limitations that is discussed later in this paper. Some papers were focusing on the evaluation of LCA results through different visualization techniques by using the capabilities of a complex 3D building model [10]–[12]. The extended integration of LCA into the design practice [13] and into certification systems [14] is also in focus of recent research.

1.2 Analysis of existing practice

Based on the literature review, there has been increasing interest in the last few years focusing on the application of LCA in building design practice. However, no common practice or exact specification has been developed yet that facilitates the implementation of different software independent from the used methodology. There is an increasing number of existing software tools, and each of them is based on the own considerations of the developer team. In this research, six experts from different countries have been interviewed about their practice in the application of LCA for buildings. The detailed assessment of the interviews is carried out in the framework of the IEA EBC Annex 72 [15], and is out of scope of this paper, but the most important findings are summarized in the following.

There are two major different approaches to achieve the integration of LCA into design practice. The first one has evolved from the traditional practice of design that is based on human interaction between stakeholders supported by CAD drawings and text documents (legacy method). Throughout the years, usually import and export possibilities have been developed to speed up manual work, or automation facilitates the fast processing of the input data. This approach has the advantage that full control over the calculations is in hand of the expert. The other approach is the extension of BIM solutions to include LCA in the workflow. This is a more straightforward solution to support information exchange between stakeholders, but on the other hand the exact specification of the calculations is usually out of the hand of the LCA expert if a deep integration is achieved.

Based on the experts' opinion the following major requirements can be expressed against a platform for building LCA: *Transparency*, that covers both the background data that the assessment is working with (original source, presumptions, uncertainties) as well as the calculation methodology (bill-of-quantities, replacement, energy demand, etc.). *Interchangeability*, that allows the integration of external solutions such as BIM, and finally *automation*, so that the assessment does not need too much manual work, and as a consequence it might be accessible for a wider audience.

1.3 Scope of this paper

There is a high need for the integration of Life Cycle Assessment into design practice [13]. However, there are some challenges that need to be faced before implementing such a system. First, the steps of the calculation need to be interchangeable, which means that alternative solutions should be easy to apply for each component. Second, the framework should be interoperable so that many external existing solutions (e.g. BIM software) can be connected to provide input to the calculations. Third, the system should be scalable in terms of the level of detail of the calculation. In an early design stage low information granularity is available, but after construction the calculation can be done based on much more specific information. The framework should be able to handle this problem.

Additionally, there is high focus in current research [13] on how the calculation can be transparent for externals. This includes the transparency of the source data, the way how the bill of materials is extracted, as well as the consideration of time-specific issues of the environmental impact or the application of generic or manufacturer-specific construction products, etc.

In this paper we propose a conceptual structure that supports the modular implementation and the interchangeability of modules as well as the other requirements stated above. First, we introduce the modules and the components, after that we define the conceptual exchange requirements in the system of the modules. The novelty of this approach is that the focus is on the application of existing solutions for each module instead of creating the next software from scratch. The same requires that a change of one component shouldn't necessarily mean a new structure for the framework.

2 Definition of the modules of the framework

The following concept is based on own considerations concluded from the analysis of the current practice and the requirements of the experts. The structure of a building LCA calculation can be generalized to four major modules: background data, modelling, calculation and postprocessing. The main data flow is represented on Figure 1. In the usual case input is provided to the background data and to the modelling module, however, the background data is established prior to and independently from a single calculation (e. g. database), on the other hand the input to the modelling is given specifically for each calculation (usually manually). Output is provided either directly after calculation (e.g. raw data for further use in other systems), or after post-processing (e. g. visualization). The splitting of the latter two modules is necessary because both incorporate various methodological questions that are independent from each other (e. g. how to account for the replacement of the building elements in the calculation component, or how to aggregate the results into a single indicator in the postprocessing component). Each module consists of components that are described in the following.

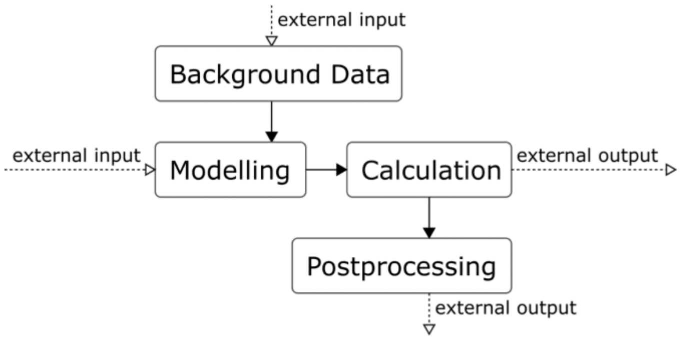

Figure 1. *Conceptual representation of the modules and the data flow in the framework*

2.1 Background Data module

The first separate major module of the framework is called the background data module. This incorporates all the predefined information that is established independently from an assessment case. A component in this module is represented usually by a database (or a table in a simple case) that holds static data. The module includes five optional components (Figure 2).

2.1.1 Material Environmental data

First and most important is the database for material environmental data. There are two different options for this component. The first and most commonly used is a collection of environmental impact information for a wide variety of building materials and for multiple environmental indicators. The impact is quantified on a per mass/volume/piece basis and the characteristics of the impact assessment method (e. g. weighting) is hardcoded into the results. This is called a Life Cycle Impact Assessment (LCIA) database. An example for this case is an EPD database. The other option is a link to a full LCA database, including all unit processes and elementary flows (e. g. ecoinvent processes). In this case the impact assessment method can be later incorporated in the calculation and is not limited to the predefined impact categories. This option also facilitates the update of other related processes in the database (e. g. electricity mix) during calculation.

A further issue related to this component is the inclusion of time- and geographical dependency for the environmental impact associated to the material. Time is an important factor since the reference service period of buildings is most of the times estimated to be longer than the service life of the building components, so replacement is necessary. But the impact associated with the production of the replacement component is going to happen in the future when the available technological circumstances may be different from the current situation. The geographical location is also an important factor since many construction materials are locally produced and may rely on different technology and may use different energy resources (e. g. electricity mix). There are two proposals to overcome this issue: the use of a multi-dimensional database (time and geolocation as the second and third dimension), or the use of an adaptive database, where the environmental impact can be recalculated based on the time and location variables.

2.1.2 Material life cycle data

The second component of this module hold information on the life cycle properties of the materials that are independent from the environmental impact. The most important property is the service life of the materials, but other life cycle related data could be included such as transport and disposal scenario as well.

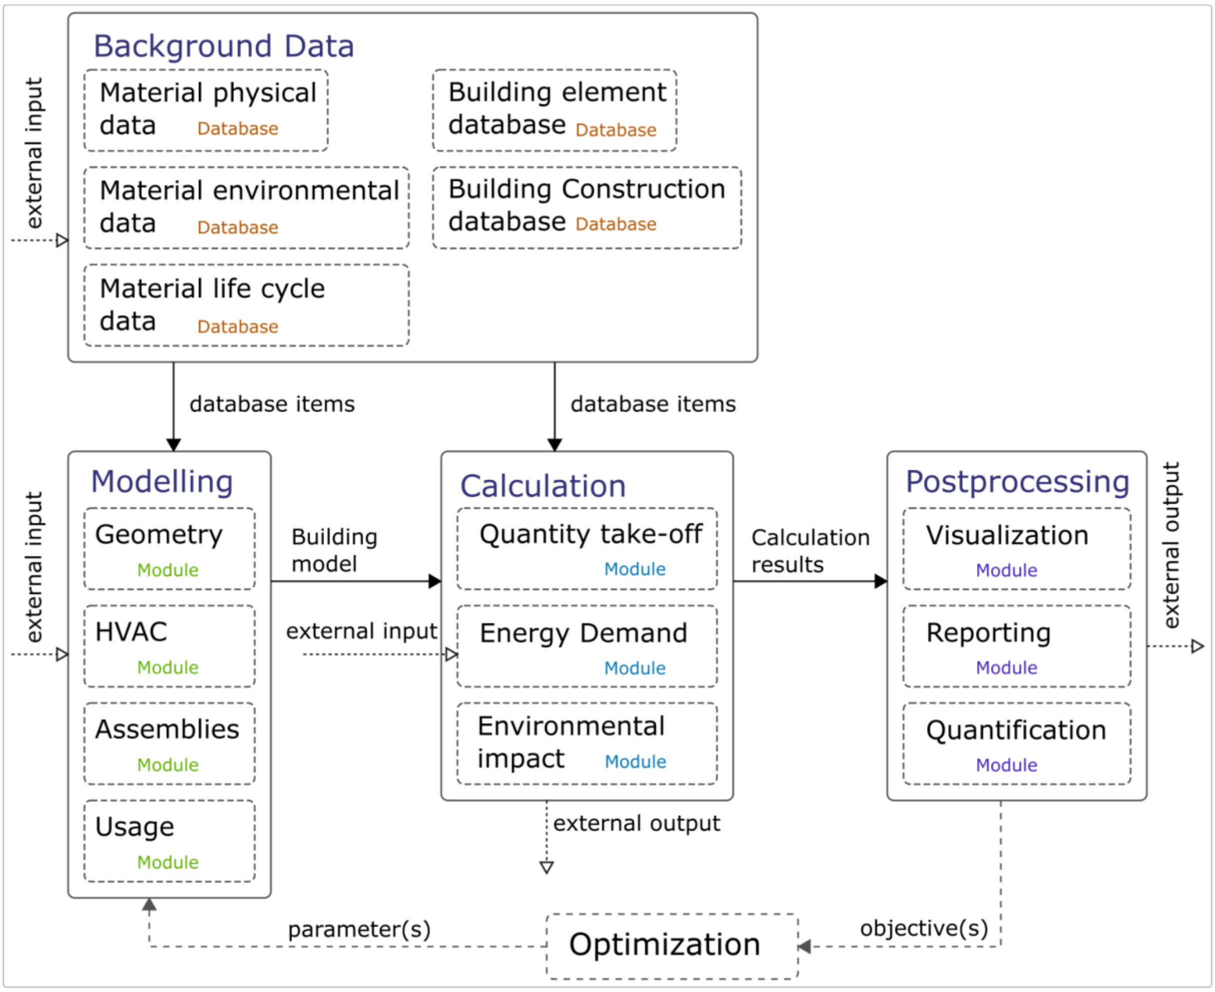

Figure 2*. Visual representation of the framework structure and components*

2.1.3 Material physical data

The third component incorporates all physical data related to the materials such as density, thermal conductivity (λ) or specific heat capacity. Depending on the type of energy and building physics calculation, the entries can range from a single number to complex temperature- and humidity-dependent functions.

2.1.4 Building element and Building construction data

The last two components facilitate the use of the system in early design stages and for decision support [10]. In this case the environmental impact is associated to a construction (assembly of building materials, e. g. masonry structure) or to a building element (multi-layered construction, e. g. wall). The entries in this database can be established prior to the modelling of a building based on industry practice and existing solutions with help of the Material Environmental Database component.

2.2 Modelling module

The second major module is called the Modelling. This incorporates all actions that aim to establish a complete building model that is further used in the calculation module. The granularity of the model can range from the single definition of surface areas (without explicit geometry) and construction assemblies to the parametrically defined full model including geometry and HVAC systems. At this point many external applications can provide an input such as BIM capable systems. There are four major modelling components described in the following.

2.2.1 *Geometry modelling*

This component provides the geometrical information of the model. In a simplified case, the geometry can be defined implicitly by determining surface areas for different types of building surfaces. In a more favourable case, the geometry is defined explicitly in a 3D space. This option supports the 3D representation of the model that can be further used for different LCA visualization options. A third option is the parametrical definition of the building geometry which further includes the optimization possibility.

We can distinguish between two different options for the structure of the geometrical model. The first is based on the practice of energy models, which is usually a surface model divided into thermal zones. The second approach is the exact geometrical modelling of the building elements which is closer to the BIM practice. The advantage of the former over the latter one is the direct input to the energy calculation, but on the other hand there are many simplifications in terms of the bill of quantities (described later). The inverse is true for the “BIM” type of model.

2.2.2 *Assemblies*

The “assemblies” component describes all composite structures used in the building including the inhomogeneous materials (e.g. masonry made from brick and mortar) as well as the layered constructions (e.g. wall structure). As a further extension, joints can be defined at this point which represent the connection between constructions, and additionally can include geometrical properties too.

2.2.3 *HVAC*

The last two components of this module are mostly used if an energy calculation is part of the assessment. The “HVAC” component is used to describe technical systems (heating, ventilation, air conditioning, etc.) installed in the building. The level of specification can range from a single general system (e. g. residential gas heating), to very detailed model including all pumps and pipes.

2.2.4 *Usage*

The last component of this module includes all user-specific information about the building such as occupancy schedules, door and window opening schedules, temperature setpoints, etc. (depending on the type of energy calculation) as well as life cycle related usage information such as renovation cycle, expected type of usage or expected lifetime of the building.

In most of the cases, all the information that is added to the calculation system in the modelling module can be described in a BIM model, however further attention should be paid to the exchange requirements between the database module as well as with the calculation module, an example is provided in the last chapter.

2.3 *Calculation module*

The calculation module provides the heart of the framework. This module is intended to perform all transformations and evaluations that provide all information which is not included explicitly in the model. The module includes three components described as follows.

2.3.1 *Quantity take-off*

For a building life cycle assessment, the amount of materials used in the building needs to be quantified in order to calculate the embodied impact as well as other related impacts (transport or disposal). Therefore, this component takes the model of the building as input and provides the bill of quantities (list of materials with amounts) for which the environmental impact can be assigned to.

The required calculations are highly dependent on the type of the model. For example, for the “surface” type of model the volume of material used at the joints needs to be added/subtracted depending on the reference line of the surface in the wall construction (innermost/outermost surface). Inhomogeneous constructions (e.g. wooden roof systems) serve as another good example, as the profile used in the construction may be described indirectly (e.g. beam size and axis distance) without explicit geometry.

The type of output can depend on the purpose and type of the result evaluation. For a simple calculation the list of all materials may be sufficient, but if the assessment aims to locate the surface of the model with the highest impact, the provided amounts need to include a placeholder (where it is located in the building).

2.3.2 Energy calculations

The highest impact related to the operational phase of the building is usually caused by the operational energy use. To include this in the assessment, an energy demand calculation needs to be done. The type of calculation can range from a simple seasonal steady-state method to a very detailed energy simulation with an hourly resolution. The type of calculation again highly influences the required input from the model. This component can take further external input that may not be included in the model, for example weather data for the specified location of the building.

2.3.3 LCA calculation

This component is used to allocate the impact to the materials and energy that is used by the building during its life cycle. Also, other life cycle specific calculations are performed here, such as the counting of replacement of the building components as well as the calculation of transport and disposal scenarios for each material. The required output of this component depends on the type of applied postprocessing. This component can include methodological options, for example static/dynamic LCA calculation or localized/general evaluation. A static calculation means that all input data (e. g. environmental impact of brick production per kg) is expected to remain the same during the life cycle of the building. On the other hand, in a dynamic calculation the environmental impacts of the unit products assumed to change over time (e. g. because of the change in the electricity mix), and therefore they need to be updated during calculation. Depending on the available information, the localization of the building may also influence the results of the assessment (through transport distances and available manufacturing technology).

2.4 Post-processing module

The structure of the framework implies that all manipulation of the raw output of the calculation module is processed in the postprocessing module. This module aims to provide a range of options to communicate and interpret the results of the assessment. In a simple case the output can be a simple aggregated number based on a corresponding environmental impact indicator. In a more detailed case further visualizations can be performed (in graphs or on the 3D model of the building), examples are available in the literature [12], [16]–[18]. In some cases (e. g. certification) a full report needs to be created based on the results of the calculation, which can be done with a designated component. These three components cover a good range of possible postprocessing options, but the list is not limited to them.

2.5 Optimization

In the favourable case of an automized model generation an optimization module can be introduced in the system. The module takes one or several well quantified outputs of the postprocessing module, they serve as objective(s). It modifies the designated variables of the modelling module which act as parameters in the optimization. This way any optimization algorithm can be implemented in the workflow that is independent from the type of problem (e.g. evolutionary algorithms or other derivate-free algorithms). This structure does not support the application of derivate-based optimization processes, because derivates are not available in the mathematical problem associated with building LCA, since many parameters are discrete and non-numeric (e.g. type of material).

3 Example application of the framework using existing software tools

While the aim of the previous chapter was to define the framework as general as possible, in the following we present a case study for the application of the concept where already available software is used for some modules.

3.1 Parametric modelling with building optimization option

The case study introduces a workflow where the focus is on the automatic model generation possibility (Figure 3). This means that manual input is only needed at the initial step, where the fixed parameters and the optimizable parameters of the model are defined. The entire framework is based on Grasshopper[1] environment. The Background Data consist of two components, a predefined custom database for material physical data (e.g. thermal conductivity) and lifecycle information (e.g. estimated service life) and an environmental database (e.g. ecoinvent) in OpenLCA[2]. The Modelling module is based on the Ladybug&Honeybee[3], and only the Geometry and the Assemblies components are used. In this case, default values are used for the HVAC systems and for the corresponding schedules. The energy demand is calculated with EnergyPlus[4] (through Honeybee). The results are visualized with Rhino3D[5] (the modelling tool that the Grasshopper environment is based on). Finally, the optimization is carried out with the Octopus[6] plug-in. In this case only three other custom components need to be created (e.g. using the python component of Grasshopper), the quantity extraction based on the model, the calculation of the environmental impact based on the inventory created by the previous component and the quantification of the selected results to provide numerical input to the optimization module.

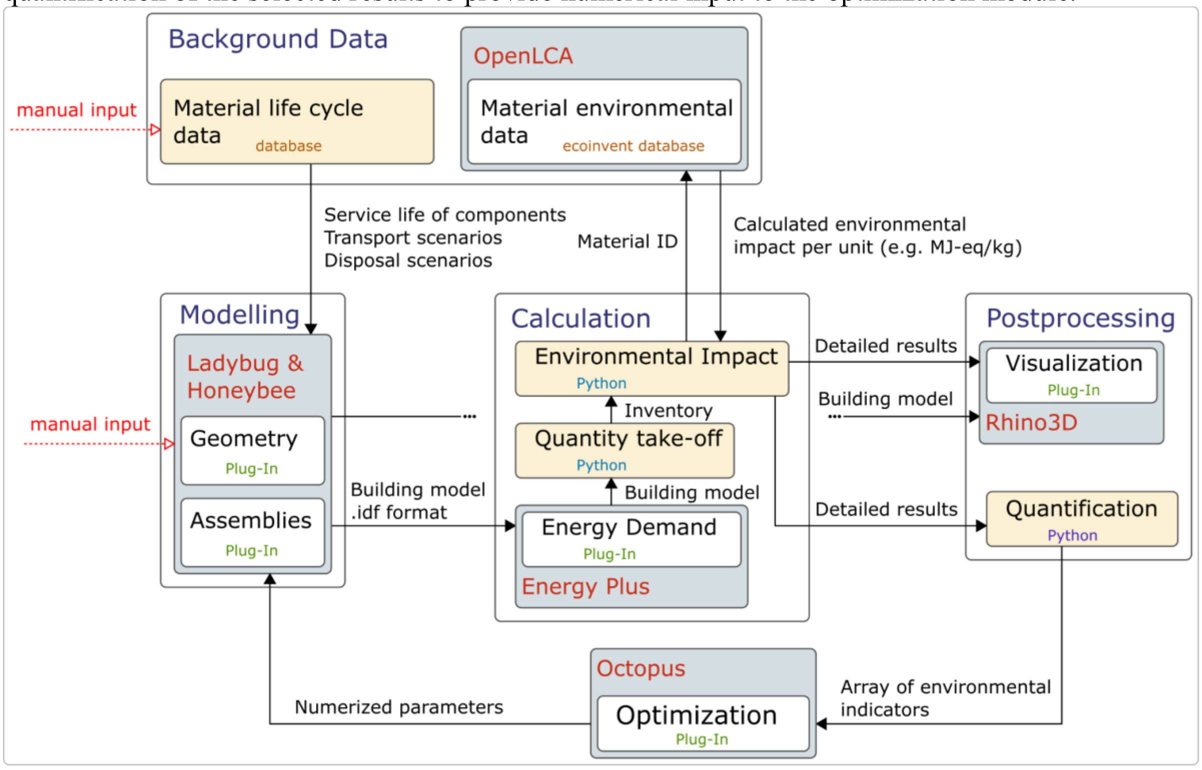

***Figure 3**. example application, setup of the framework and external software used.*

[3] https://www.ladybug.tools/honeybee.html
[4] https://energyplus.net/
[5] https://www.rhino3d.com/
[6] https://www.food4rhino.com/app/octopus

This application requires specific exchange information between the components. The modelling module takes additional input from the material database and extends the generated idf model (the standard input file of Energy Plus) with additional information needed for LCA (service lives, transport and disposal scenarios, and a reference ID to the environmental database). The output of the energy demand component is the same building model along with the calculated energy demand. The quantity take-off component uses the same model to create the inventory of the building (including the embodied materials and the operational energy use). The environmental impact is associated with the elements of the inventory based on the database ID. The impact of the inventory elements is provided by OpenLCA. Finally, the detailed results and the building model are passed to the visualization component to create views of the actual solution. In this case the quantification component is only used to extract (or aggregate) selected results to provide a numerical input (as objective) for the optimization component. This optimizes numeric parameters, which are translated into modelling parameters (e.g. different options for insulation material) and the calculation cycle is repeated until a specific criterium is met by the optimization component.

4 Conclusions

In this paper we presented a conceptual structure of a modular cross-platform framework for building Life Cycle Assessment. This approach aims to support interchangeability and interconnectivity of the different available software tools that are used for the specific aspects of LCA. We defined the conceptual workflow and illustrated the exchange strategies between the modules on a case study application. This also showed that for most of the modules existing software can be used by establishing the interface between them. High-level programming environments (such as Grasshopper or Dynamo) make the development of such interfaces easy and fast. During the development, the modules can be created and updated step-by-step so that the first simple version can be utilized from the very beginning. Also, fundamentally different components can be developed side-by-side (e.g. for simulation or steady-state methods for energy calculation) and they can be compared based on the same case studies. This structure also supports the parallelization of calculations that is very useful for the case of optimization especially if the calculations need high computational capacity.

The structure also aims to provide options for different levels of calculation, so that the framework can be utilized already in an early design stage with low information availability as well as at a late stage when detailed calculations can be done.

Acknowledgement

Project FK 128663 has been implemented with the support provided from the National Research, Development and Innovation Fund of Hungary, financed under the FK_18 funding scheme. This paper relates to ongoing research within the international project IEA EBC Annex 72, which focuses amongst other things on harmonizing the methodology for assessing environmental impacts in the life cycle of buildings as well as the integration of LCA in BIM-based design processes. The authors would also like to thank all participants of the IEA EBC Annex 72 project (http://annex72.iea-ebc.org). hildegund.figl@ibo.at

Abstract. By 2050, the building sector has to become nearly CO_2-neutral in order to achieve the climate protection targets of the Paris agreement. This tremendous challenge can only be met by taking the carbon neutrality into consideration from the early stages of the planning processes. The overall aim of the project is to provide a life cycle analysis throughout the entire planning and construction process of a building with a special focus on CO_2-neutrality. To this end, Building Information Modeling (BIM) is an appropriate method. The project aims to close the gap between specialist consultants and BIM applications. For that, relevant data for cost estimation, scheduling construction planning and management or sustainable building aspects, shall be added automatically to BIM elements. This data exchange shall be carried out using open BIM and IFC interface according to ÖNORM A6241-2 via a central platform, the "6D BIM Terminal". For more complex calculations the respective specialist planning software shall be made ready to exchange data in IFC format. Thus, life cycle analyses and life cycle cost assessment, as well as specifications for tender, can be performed on the basis of the building model. The expected results of the project are as follows:

- The prototype of a "6D BIM Terminal"
- Interface for existing specialist planning software to the 6D BIM Terminal
- Guidelines for planners
- List with the required properties (PSet's)

1. Introduction

1.1. Motivation

By 2050 at the latest, the building sector will have to become "largely" carbon-neutral if the climate protection goals of the Paris Agreement shall be achieved. Since carbon neutrality of buildings (Zero Carbon Buildings) is a major challenge, it must be part of the building design from early stages of the planning process and must not be ignored at any stage. At the same time, the CO_2 reduction should be affordable and should not be at the expense of other environmental aspects. Therefore, costs, as well as other life cycle indicators, are also needed for the overall optimisation of CO_2-neutral buildings.

Building Information Modeling (BIM) as a process of optimizing the design of buildings using an intelligent digital building model that can be collaborated by the whole planning team offers the best prerequisites for the continuous consideration of ecological aspects during the whole planning process. However, while in other countries (Great Britain, Norway) the 3D-BIM mode of operation has been anchored in planning practice for some time now, German-speaking countries have only recently begun to face up to this technology. In the further dimensions of time (4D), costs (5D) and sustainability (6D), there are hardly any applications throughout Europe. Hence, specialist planners and consultants who do not work on the basis of CAD programs operate predominantly outside the digital building model – also in supposedly BIM-based planning.

1.2. Objective

The overall objective of the project "6D BIM Terminal: Missing Link for the Planning of CO_2-neutral buildings" is the lifecycle analysis of buildings during the planning and construction phase with a special focus on the planning and construction of CO_2-neutral buildings. This shall be done by closing gaps between BIM-based design planning and engineering design. Data that goes beyond geometric and design information and is necessary for the consideration of costs, deadlines and sustainability aspects (4D, 5D and 6D) shall be supplemented as automated as possible with the help of predefined reference BIM elements. The data structure of these BIM elements shall be based on (inter) national standards (IFC, bsDD, ASI property server). The project focuses on the life cycle analysis of the building materials and technical building equipment used in the building, as there are still the essential barriers to the exchange of information between design software and specialist planner software.

In addition to planners and civil engineers, the process should also support procurers and calculators. Therefore, a further aim is to compile the BIM elements from items of the Austrian Performance Description for Building Construction ("Standardisierte Leistungsbeschreibung Hochbau", LB-HB) and thus to create tender specifications largely automated on the basis of the digital building model.

The process shall take place via a central platform, the "6D BIM terminal". Bills of quantities, LCA data, life cycle costs and the list of tender items shall be generated based on the digital building model.

The results are intended to support SMEs in particular. They should facilitate the entry into complex BIM planning, which is more than just a 3D planning. Since the results should be general and the SMEs shall not be forced to buy expensive software and training, the data exchange should be done using open BIM.

2. Methods

The work packages defined for the implementation of the "6D BIM Terminal" are:

- Development of process patterns – based on use cases (survey of software producers and users, analysis of processes, responsibilities, data interfaces, software components)
- Properties for building elements and HVAC: Definition of the property set (PSets), identification of missing or incorrect properties in the IFC standard and ASI property server, formulation of missing items in the Performance Description for Building Construction
- Conception and development of the "6D BIM Terminal"

Applied methods and standards for the calculation of LCA and cost data are:

- LCA according to ISO 14040/48, EN 15804 and baubook acceptance criteria
- Life cycle costs according to ÖNORM B 1801
  Note: In ÖNORM A6241-2, there is a concrete indication that the ÖNORM B1801-1 object construction is to be applied for time (4D) and the costs (5D); in the field of sustainability (6D), no information is given on the methods to be used.

3. Results

The expected results of the project up to November 2019 at a glance:

- Preparatory standardisation work: Identification of the properties required for the life cycle analysis (PSet's) incl. guide for planners and specifications for software houses
- Reference elements: Catalogue with 6D BIM components that can be used as a reference and adapted to specific projects
- The prototype of the "6D BIM Terminal" with a functional user interface, API interfaces and reference catalogue as a tool for cross-organizational collaboration that enables the exchange

of 3D planning programs with complex BIM systems for the specialist planning by generating complex 6D BIM elements from "simple" 3D elements.

3.1. Preparatory work: properties of building materials and building elements

3.1.1. Standards, References

For a planning team whose members usually use software programs from different distributors a neutral transfer format is required for the different data in order to work on a common building model. An internationally standardized database, model and file format are the Industry Foundation Classes (IFC). These have been an official ISO standard (ISO 16739) since the IFC4 was released [1]. The IFC standard is based on building objects, such as walls, columns, etc. for architectural planning; pipes, air outlets, heaters, valves, etc. for technical building equipment. The IFC does not only define the building objects, but also the properties for these objects.

The international reference database for IFC-based properties is the buildingSmart Data Dictionary (bSDD). The bsDD serves as an extension and namespace for the IFC data model. It allows the linking of terms and expressions, their dependencies and definitions (data type, units, value ranges, ...) across different languages.

For the national application of BIM technologies in Austria, OENORM A 6241-2 [2] was created by the Austrian Standard Institute (ASI). This standard regulates the technical implementation of a uniform, structured multi-dimensional, BIM-based data model. An important part of the ÖNORM A 6241-2 is the so-called ASI property server, which is unique in Europe. The online database (http://db.freebim.at) defines a multi-dimensional data model and exchange format for inter-disciplinary cooperation on the basis of the "IFC4 Add 1" standard. ÖNORM and property server are intended to create the basis for the "exchange of graphical data and related factual data" on an IFC and bSDD basis. All characteristics, materials and values defined in the data structure of the property server are identified by a unique identification number (GUID) assigned by bSDD and thus fixed once and unchangeable for Austria.

3.1.2. Matching the properties

Data required for 6D planning are costs, deadlines, LCC and LCA indicator values. The technical description of materials is based on building physics / structural properties and the positions of the Performance Description for Building Construction (LB-HB).

The building physics and building ecology properties and values for the reference elements in the “6D BIM terminal” come from www.baubook.info [3], an online database for ecological construction products. Cost data, dates and positions of Performance Description for Building Construction (LB-HB) are stored in the construction software ABK. At the beginning of the project, these characteristics were compared with the BIM standards and references (IFC, bsDD, ASI property server).

As a result, IFC, bsDD and the ASI property server turned out to provide a useful working basis, but needed a variety of revisions or additions:

- The existing building physics and building ecology properties lack clear definitions.
- The properties regarding the life cycle analysis of materials and elements are incomplete, obsolete or wrongly defined.
- The BIM properties are still largely missing for elements in the HVAC area.
- The BIM properties are practically not used in practice.

Hence, a key outcome of the project is the Property Set, which will be forwarded to the ASI standard groups and to the local group of bsDD (bsAT – building smart Austria).

3.2. 6D BIM Terminal

3.2.1. Principle idea

Currently, only 3D information is output by the CAD programs; the other features for the material and element description of the IFC4 format have not been supported by any CAD software yet. The CAD software tools are capable of exporting IFC4 compatible data, but in fact they are conversions of older IFC formats. Therefore, the 6D BIM-Terminal should enable specialist planners from the various disciplines to import 3D data via the IFC interface, to automatically supplement the data required for the 4D, 5D and 6D planning in the respective project phase and subsequently to export them in the appropriate format again. The 4D, 5D and 6D properties should be semi-automated assigned via matches with a reference element catalogue.

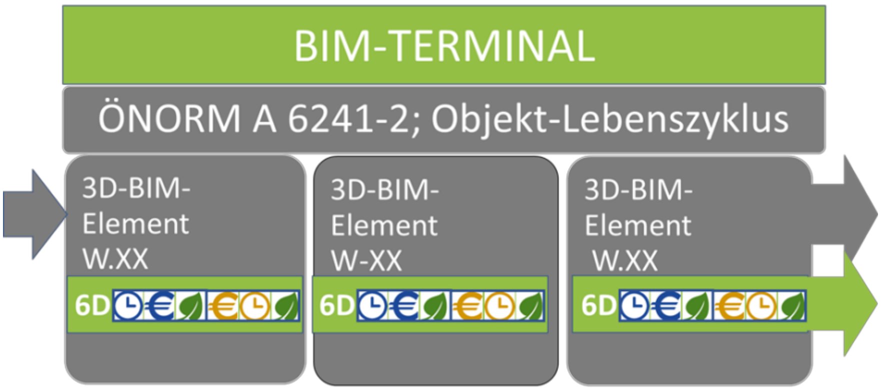

Figure 1: In the “6D BIM terminal”, the 3D information from the CAD programs is read in and supplemented with missing 6D information (4D: time, 5D: installation costs, 6D: LCA data, in each case for the construction and follow-up costs). Specialist consultants can read out the data they need, filtered from the BIM terminal.

3.2.2. Reference elements

One focus of the project is the creation of a reference element catalogue with prefabricated elements according to BIM standards. The composition of the reference elements comes from the “IBO Passive House element catalogue” [4]. These elements are available online in the www.baubook.info database [3] with building physics and life cycle assessmet data. The data is either used directly in baubook for LCA calculations or passed on to other software programs as energy performance calculation tools free of charge via an XML interface.

The existing XML interface has been used to transfer the baubook elements to the construction management software ABK. These elements include the material structure and formulas for the calculation of the life cycle assessment data as well as essential building physics properties such as the U-value. With the likewise imported baubook LCA data for building materials, the LCA indicators of the element can be calculated directly in ABK. More important, in ABK the cost data and the tender items from the Performance Description for Building Construction (LB-HB) were assigned to the elements. For the assignments, the corresponding properties (e.g., materiality, thickness, and height of an element) had to be aligned with the 26,000 tendering items of the LB-HB. If several matching positions were found, the entire item group was assigned to the element and the most ecologically and economically relevant items pre-selected as the default value. This tendering item is automatically activated as soon as an IFC object is matched with the reference element in the “6D BIM terminal”.

The reference elements shall be the main part of the functionality of the “6D BIM terminal”. Suitable models for regular updates and additions to the element catalogue are currently being developed.

3.2.3. Process flow (Figure 2)

In the current process description for the “6D BIM terminal”, the following roles are modelled:

- Designer (responsible for digital building model)

- Procurer (responsible for tender)

Both of them can start the process (has to be defined in the BAP (BIM Processing Plan)).

A central document for a project is the project element list (PEL). The basis of the PEL is a project element catalogue (PEC). The PEC can be derived from a general element catalogue.

Within the project element catalogue the designer has to provide the data the procurer needs in order to be able to determine (deduce) the corresponding tender items and masses. These data shall allow for the automated creation of the call for tenders, the life cycle costs and the life cycle assessment later in the process. In the further process, the catalogue will be exchanged between the designer and the procurer, since the procurer may add further elements or specify individual elements. Hence, it is important that the responsibility for the creation and maintenance of the project element catalogue is time-related in the hands of one role. The project element catalogue can also serve as a base document for requirement formulations to the BIM model as part of a BAP (BIM Processing Plan).

Finally, the designer creates the BIM model in a BIM-capable software using the requirements for objects and properties as described in the agreed project element catalogue. He converts the created model from the own modeling software into the IFC format and sends the IFC model to the procurer for further processing. The procurer checks with suitable software whether the model contains the required classifications and properties. The successfully checked IFC elements are imported into the “6D BIM terminal”. Within the “6D BIM terminal” the IFC elements have to be assigned to reference elements from the project element catalogue. These reference elements contain a rule set which activates the allocation of the appropriate tendering items to the corresponding IFC elements. In the “6D BIM terminal” prototype, initially only the predefined reference elements will be available. Subsequently, a wide variety of stakeholders (manufacturers, software companies, specialist planners) are to import further reference elements in the specified format. Format and workflow are currently being defined.

The generated project element list is the data basis for an AVA software to use this list (database) to generate a tender in the desired form (ONLV Format according to ON A2063 [5] in Austria).

Note: At this point, the BIM based pathway could be abandoned and offers could be obtained in a traditional, classic way.

For bidders, a data package is prepared that allows to identify in the BIM model for each bid position those elements that trigger a position or deliver the masses for a position. The data package contains the project element list (PEL), the associated IFC data and an ONLV file. As a result, the bidder will be able to identify the structural conditions for positions more clearly and to be able to calculate prices more precisely. The bidder returns a priced offer in the classic ONLV data format. After examining all offers, a classic awarding documentation will be created in the ONLV data format. This is in turn transmitted to the bidder by means of a data container consisting of the project element list (PEL), the associated IFC data and the awarding documentation.

LCA and LCC data can be produced as a by-product of the tendering process when the project elements are mapped with the reference elements. In early planning stages the LCA&LCC data can be generated using the same logic as described in the process flow for the tendering process above. In this case the role of the “procurer” is taken by the LCA and/or LCC consultants.

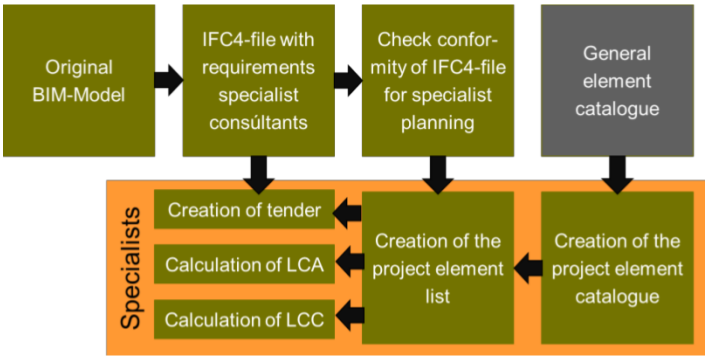

Figure 2: The designer creates the BIM model in a BIM-capable software using the agreed requirements for objects and properties and converts it to the IFC4-format. The conformity of the IFC file is checked and then imported into the "6D BIM terminal". Within the "6D BIM terminal" the IFC elements are linked with reference elements from the project element catalogue. These reference elements contain a rule set which activates the allocation of the appropriate tendering items, LCA and LCC data to the corresponding IFC elements.

4. Conclusions

The "6D BIM terminal" will provide a tool for cross-organizational collaboration. The "Cooperation Tool" enables the exchange of existing 3D planning programs with complex BIM systems. The prerequisite is that the data is transferred via IFC4 to the BIM terminal. The tools will be operated by the project partners as a platform and provided to other software houses and stakeholders after the end of the project. Thus, the "6D BIM terminal" should also support for specialist software solutions outside the project team.

The main hurdles of the project An essential aspect of the project is the data exchange via open BIM. The biggest hurdles in the project therefore lay in the underlying standards, since relevant properties are incomplete, obsolete or wrongly defined, are largely missing as for the HVAC and are practically not used in practice. Hence, a key outcome of the project is the Property Set, which will be forwarded to the ASI standard groups and to the local group of bsDD (bsAT – building smart Austria).

The project results will be finished in November 2019.

Abstract. Building Information Modelling (BIM) supports construction processes by dealing with the variety and complexity of design in a single virtual model. The model may also be complemented by the static and energy performance of buildings. Facing the growing demand of sustainability strategies in the construction sector, the consideration of environmental information within the planning process influences the decision making of planners and stakeholders. Nevertheless, the life cycle assessment of buildings has been so far excluded in BIM, due to the high variety of accurate information and time required. In this paper, a systematic framework is presented and applied to a case study. BIM-LCA assists actors along the planning and designing phase, from the building conception as a whole, up to the elements' details and materials' definition. BIM and LCA intertwine in an application scheme of seven phases for integral planning and four levels of structural composition of a building. With respect to these, involved actors examine potential solutions through a tool which exploits alternative specifications in order to assess the environmental impacts. The goal of this paper is to demonstrate the application of a BIM-LCA model regarding decision making for reliable values of environmental impact in a given structural level of the building. The main findings of this framework are due to the multitude of actors and information orchestrated, namely to uncertainties which characterize the whole planning process and data handling. Through BIM-LCA, actors are assisted by ensuring flexibility of models and consistency of results throughout planning and designing.

1. Introduction

The construction sector is responsible for 50% of global greenhouse gases and roughly 40% of the total raw material consumption: as one of the main contributors to global environmental impacts, it is in the last years under particular attention in order to achieve a substantial change. [1]

For the environmental improvement of the building's lifecycle the LCA method is well established and gained importance, mainly as basis of the building certification labels and building product declarations. Its procedure consists in the calculation of a building-LCA by collecting materials and products over the whole life cycle. On the basis of the analysis, information can be selected and all relevant environmental impacts are calculated [2][3]. Even if LCA results depend mainly on materials, it is possible to gather more and more specifications on component or whole final product level within comprehensive building LCA tools and databases. This is justified from the variety, complexity and interconnectedness of the products which do not allow for simple solutions for complete building LCAs: the design of the building shell, for instance, is important for the energy consumption, the location of the building can define transport distances and users' habits determine resource consumption during use and the maintenance and refurbishment activities [3].

Such observations lead to a paradox: a comprehensive LCA can be only carried out after the final design on the products through a detailed ex post data collection but the buildings impact is strongly defined during its conception, namely in the first stages. When the environmental impact is not only to be assessed but to be optimized, the LCA has to be applied in these early stages already. However, differently from technical and economical dimensions, the environmental value of a construction is yet hardly included during the early decision making process.[4] In addition to this, discussions about the current decision making approaches are ongoing: with the rising of building performances and complexity, the ordinary organizing and planning procedures are getting demanding in terms of costs and time; for such reasons, they are considered no longer suitable and further more integrated and dynamics strategies are investigated [5][6].

As solution to this matter, informatics entered in daily practice of the last 20 years and several tools became essential instruments for planner and technicians [6]. Among this variety, BIM (Building Information Modeling) realizes an integrated design starting from early stages, with a set of interacting policies, processes and technologies and facing the main issues, i.e. information fragmentation during lifecycle, building performance prediction and automated assembly [7][8]. Process efficiency studies report up to 40% elimination of unbudgeted change and 80% reduction in cost estimation time with almost 7% reduction in project time [9].

In conclusion, BIM and LCA methodologies are the key for a new approach of planning and design: by technical point of view, the implementation of LCA in BIM, thanks to informatics development and availability of libraries, is within range. However, environmental impact evaluation during the early decision stages and its significance for integrated design is still a strongly debated topic.

2. State of art

When the building is not well defined, technicians are involved in order to take decisions about the overall design and select available alternatives.

As demonstrated by Basbagill et al. (2013), postponing material and thickness decisions during the design development stage is not a successful strategy in terms of environmental impact. On the other hand, an aware and timely choice of materials can significantly reduce the total GWP emissions, avoiding designers' effort on inconsequential decisions during the critical early design stages. The knowledge of material properties, building shape and orientation, for instance, can be the basis for the optimization of final energy performance [10].

In literature, several approaches and tools for LCA in BIM are available but however not all issues have been so far solved or new challenges arose. By technical point of view, the creation of such tools as support instrument for decision-making showed problems, such as the missing interoperability between BIM interfaces and environmental databases, the import of BIM information into LCA software, the complexity for many actors of treatment of a BIM model [11]. The use of IFC format has proven to be advantageous, by facilitating building description and construction industry data exchange through an open file format and neutral platform [12].

Differently, the methodological aspect is more discussed. Antón and Díaz (2014) suggest a "material-oriented" approach: the BIM library can include relevant environmental information coming from previous analyses, so that the designer will consider such performance within the ordinary material choice procedure. As disadvantage of this approach, besides the low results accuracy (e.g. transport distances measurement), LCA database implementation showed problem in terms of efficiency [13].

An alternative to this may be an environmental impact assessment during the whole planning and design process: a more accurate approach, which avoids data reentry, and realizes a real-time assessment through a three-dimensional object. Most of existing applications in literature use 3D-Cad models to be connected to an LCI database, which, in comparison to a BIM Model, are not capable to include relevant information such as recyclability, reuse and construction life span, together the with material collection [14][15].

Even though the huge potential, the combination of a BIM interface with this approach is not always effectively feasible. It has been observed, that not many standards and guidelines address demolition and aspects of refurbishment in the BIM [16]. A quick and accurate estimation of waste due to the demolition is possible only by calculating all material quantities of a building which has exhausted its service life but, even for existing buildings, this is not a direct calculation, which is a lack of accurate information that practitioners and clients face in daily practice [17].

As result of this discussion, it can be claimed that, BIM-LCA approaches, even if acknowledging the relevance of early stages, intended their application only from the early *design* phase. This because at the moment there are not available enough synergies between stakeholders, technicians and clients and none of these have achieved a full automation for calculations or information transfer between software [11][18]. As noticed by Röck et al. (2018), such application provides results and conclusions which cannot be generalized, since they depend on the quality of input data from both BIM and LCA model completeness and data accuracy [19][20].

3. Method

Within a research project "BIM based integrated planning", supported by the German Federal Ministry for Economy and Energy (BMWi), a procedure for the definition of planning and lifecycle phases has been developed [21]. As results of this, a model of concretization made of 7 phases has been realized for each of them, the information depth of BIM level and the required specifications have been collected, with particular attention to the data necessary for LCA [23].

The detail of such information depends mainly on the considered building levels: whole building, functional system, element system and component layers (see Figure 1).

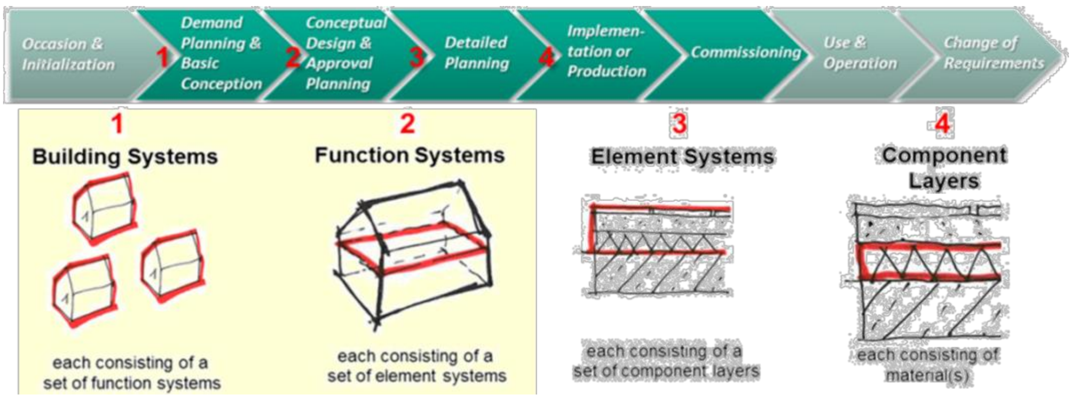

Figure 1. Building levels with reference to a model for concretization phases of planning and design process. [22]

In this section, basing on the above mentioned research project and further works [23] [24], a methodology is presented with focus on the early planning stages (phases 1-2 from the Figure 1), the involved actors and the information which is within required.

The information is *step-by-step* fragmented, reduced to the most detailed value, and converted depending on its characteristic (descriptive, quantitative, and boolean) in order to set up a full automation through informatics instruments.

3.1 Occasion and Initialization

The project starts after the initiative of an individual, who is following own personal, political or entrepreneurial goals. The main activities regard evaluation of the solution sets, basing on a series of implicit and explicit decisions and conditions. In this context, after the comprehension of the main issues and possible contributions to the project, specific solutions are considered, depending on the personal past experiences and knowledges. Such alternatives concern the whole building system, e.g. building type and construction methods (Figure 2).

The first and most important decision concerns the realization or postponement of the project, by taking into account relevant problematics (social and political) and the own experience. The functions addressed to the initiator are the research of information, the designation and experts and their corresponding commitments.

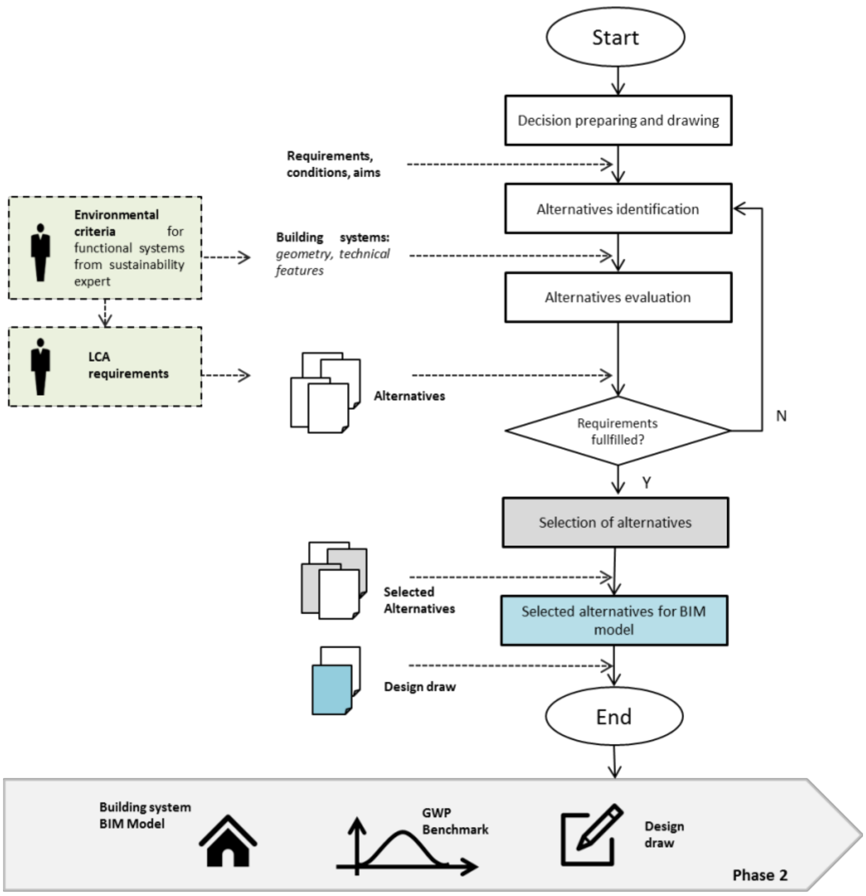

Figure 2. Stage 1: Process details and information needed [22]

The established project managers group provides general features, such as the usage type (office, residential, industrial …), category (single- or multi-family dwelling, school or university …) and location. This leads to first quantitative specifications, i.e. number of dwellings, offices, rooms, and consequently to the first evaluation of minimal using surfaces and volumes, such as mean floor area, net floor area (see f.i. ISO9837 or DIN277 standards). The plot of land location enables roughly to a hypothetic floor plant and building orientation. Furthermore, construction technologies can depend on design preferences and workforces experience as well as material availability of the neighborhoods.

As shown here, on this level, essential information is already available and a first environmental value of the whole building system can be estimated. However, this occurs *indirectly*: in fact, due to a still low workforces' awareness, sustainability problematics are not particularly taken into account unlike economic, technical and social aspects. As support during the whole project management, figures with particular sustainability expertise as wells as tools can be exploited and aims (with volunteer characters) and requirements (compulsory or guidelines suggestions, e.g. EEG for Germany) may be provided [23]. On the basis of those, alternatives can be assessed and their choice can be supported with help of environmental *Benchmarks* derived from a tool which gather in its database either available other LCA results or normative regulations. A first design draw is lastly processed, which roughly represents the building system and describes technical features only in qualitative terms, and accompanied by overall environmental impact estimation.

3.2 Demand planning and basic conception

While the first phase is focused on the building technical and geometrical specification, the following one is centered on management of financial resources and evaluation of the investment risk. The actors are called to prepare and secure a project with outlook to an upcoming investment decision. Through the involvement of the real estate industry, capital and ideas are merged and developed into a project.

Information coming from the first phase are here processed, such as plot of land, location (to be linked to permissible land for construction), infrastructure supply, permissible main use, intended real estate market and users, and further technical specifications (building structure, storeys, building orientation). In comparison with the previous stage, alternatives may be assessed by means of *function systems* level (Figure 3).

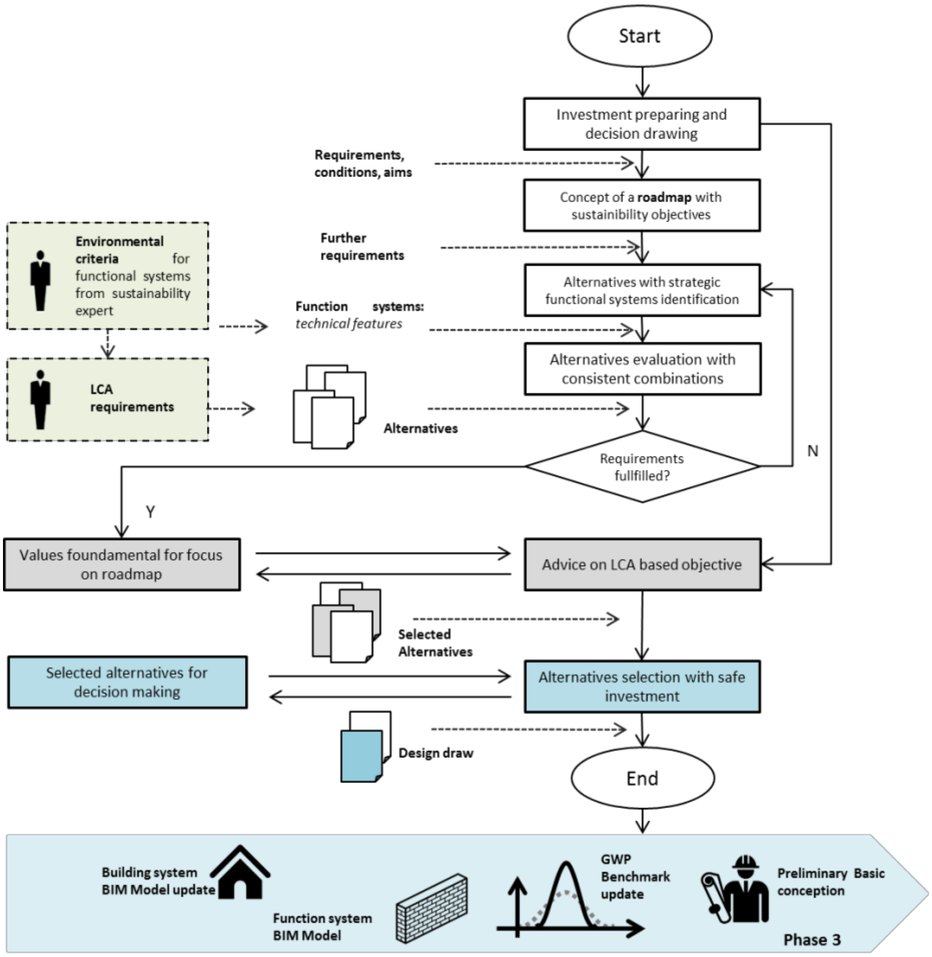

Figure 3. Stage 2: Process details and information needed [22]

Consequently, the whole building is differentiated in functional systems such as external walls, floors or roof and for each of them qualitative technical requirements are addressed (i.e. EnEV for Germany) and then connected to the already given geometry. As well as the initialization and ground concept, environmental requirements and guidelines are provided and included in a so called "*roadmap*" [21][22].

The alternatives deemed consistent with the abovementioned requirements are then evaluated and the one which guarantee a safe investment selected. As results of this process, for each functional system a BIM model is generated, the tool calculates GWP benchmarks through its database and the previous models are updated with more accurate results. The first preliminary concept design can be then presented.

4. Case study

The presented framework is applied on an exemplary multi-apartment building in Germany. With help of the online tool SBS for building sustainability evaluation, total GWP impacts have been calculated for building and functional system. An Excel tool has been set up for results collection and benchmarks calculation for alternatives comparison. The building and functional systems examples are derived from previous works and projects available in the SBS-onlinetool (www.gabi3.com) database and exploited as statistical values in order to derive Benchmarks based on typological standard. [25]

4.1 Building systems evaluation

For the initialization, the selected information cover general building features such as construction type, using type, energy standard and installation standard. Such features are the ones considered relevant for LCA and therefore their variation leads to different GWP value feedbacks. Each characteristic has been defined as specified in Table 1.

By fixing, for instance, the building use type and energy standard, different installation standard and construction types may be considered. As shown in Table 2, installation standard on this level has no relevance on the resulting GWP Benchmarks; on the other hand, the construction type can be relevant for the total potential emissions and this reduction is due to the production phase. Hence, for a multi apartment building with KfW55 energy standard, a light construction has been chosen [26]. By comparing the results with the DGNB reference for new constructions [27], the total GWP seems to be underestimated.

Table 1. Stage 1: Information needed, sources and selected example

Building system	Info	Reference	Example
General information	Building Type	Use type in according to	Multi- apartment building - Fixed
	Energy standard	EnEV, KfW, Passive house, Plus energy building	KfW55 – Fixed
	Installation standard	Low/high	Variable
	Construction type	Massive/Light	Variable
	Net surface		**707,4 m²**

Table 2. Stage 1: Benchmarks results [kg CO2/m²net surface year] [25] [27]

GWP [kg CO2 eq./m²y]	Massive Building/ Low installation standard	Light Building/ Low installation standard	Light Building/ High installation standard
Production CG 400+300 + EoL CG 300 + CG 400	5,59	1,26	5,59
Use phase KfW55	22,94	22,94	22,94
Total	***28,53***	***23,2***	***28,53***
	DGNB Reference value [NWO15(V16)] [26]		***53,11***

4.2 Functional systems evaluation: external wall

For the definition of a functional system different standard solutions of external and internal walls, floors, roofs and installation sets have been derived by simplified BIM models belonging to SBS database (see Table 3). For each of them, LCA analyses. For this case study floors, roofs, and internal walls have been fixed and external walls and installation sets varied, by taking into account that the previous analysis suggests a light construction technology for a multi apartment building and finally a new total impact due to production and end of life is calculated (see Table 5).

Table 3. Stage 2: Information needed and benchmarks

Functional system – Cost group [DIN 276]	Example	Amount [26]
Basement – CG320	Basement with overlying insulation – Fixed	294,4 m²
External walls – CG330	1) Wood Walls 2) Wood fibers	776,8 m²
Ceiling – CG350	Wood ceiling with structural beams- Fixed	588,8 m²
Roof - CG360	Slope Roof- Fixed	294,4 m²
Installation set – CG400	1) KfW55:Domestic water distribution stainless steel, Ventilation system, Composite pipe, Buffer storage ***Underfloor heating***, 2) KfW55: Domestic water distribution stainless steel Ventilation system, Composite pipe, Buffer storage***, District heating station.***	707,4m²

Table 4. Stage 2: Information needed, sources and selected example on functional system (Standard systems from previous projects [25])

Cost Group DIN276	Construction	GWP [kg CO2 eq./m²] [25]	Specification Unit [m²]
CG 320	Basement with overlying insulation	148,55	Basement surface
CG 330	1) Wood ext. walls	3,38	Ext. walls surface
	2) Wood fibers ext. walls	17,96	
CG 350	Wood ceiling with structural beams	-19,60	Ceiling surface
CG 360	Terrace Roof-	139,10	Roof surface
CG 400	KfW55:Domestic water distribution stainless steel, Ventilation system, Composite pipe, Buffer storage		net surface
	1) with *Underfloor heating*,	56,73	
	2) with *District heating station*	28,78	

Table 5. Stage 2: Information needed, sources and selected example on building system

GWP [kg CO2 eq./m²y]	Wood walls/ underfloor heating	Wood walls/ district heating	Wood fibers walls/ district heating
Production + EoL CG 400+300	3,28	2,72	3,04
	DGNB Reference value [NWO15(V16) Construction] [26]		**3,98**

Differently from the previous analysis, on this level the installation sets are more relevant for the final results, which are now provided in a more comprehensive form. The calculated benchmarks towards the DGNB reference value provided for the construction of a new residential building (NWO15 Profile) [26]: this prove the good accuracy of the results provided by SBS-onlinetool database.
On the other hand, due to a lack of comprehensibility regarding simulation data, specific installations and auxiliary energy, any further information about use phase is not given and therefore results cannot be yet enhanced.

5. Conclusion and future outlook

With the presented framework, environmental impact results can be provided already during the first decision making process and before the early design stages. Peculiarity of such framework is the necessity of sustainability expertise and respective tools supporting the project manager and providing construction alternatives and GWP values starting from the early stages. As shown in the case study section, such tools have to handle issues due to data requirement and inaccuracies. Most of them are caused by missing information about specific energy consumptions as well as refurbishment or renovation measures, which depend on the user's habits and choices and are all considerable sources of uncertainties for LCIA analyses.[18] These uncertainties have to be included in the decision making process to provide the practitioner both the sustainability feedback and the robustness of this value. Even on completion of final building design and data collection, environmental impacts cannot be still depicted by a single trustworthy value, but better by a range of values of which width or distribution depends strongly on uncertainties. [29]
Finding a solution to this matter represents indeed the next challenge: in terms of results robustness, an improvement of SBS-onlinetool can be realized in a first instance by enrichment of the available database and provision of statistical records to keep constantly up to date. Moreover, with regard to the overall methodology, more dynamic and probabilistic approaches are nowadays still on investigation. Such approaches aim to reach an environmental impacts prediction by considering of a multitude of variants and factors. Among them, the German Excellence Cluster "IntCDC" establishes research networks called to investigate innovative integrated Co-design including predictive Life Cycle Assessment, in order to achieve a real-time decision support and robust statements during the early design stage with limited environmental information basis and uncertain boundary conditions. These forthcoming improvements on LCA methodology aim to provide and to successfully communicate robust statements on environmental performance already in or before early design. Hence, through addressing the data quality and availability related issues not only in early design for LCA, some of the current implementation issues in BIM-integrated LCA may be overcome. [30]

Connecting BIM and LCA: The Case Study of an Experimental Residential Building

Veselka J, Růžička J, Lupíšek A, Hájek P, Mančík Š, Žďára V, Široký M

Czech Technical University in Prague, Czech Republic

jakub.veselka@fsv.cvut.cz

Abstract. The aim of this paper is to present application of BIM models for the complex quality assessment and environmental analysis based on LCA. An experimental two storey building of TiCo Project representing a full scale part of a real multi-storey residential building has been used for this case study. The presented BIM model contains all relevant environmental characteristics and it will be used for environmental analysis, coordination, and operation (e.g. real-time data analysis from the sensors). Theoretical part covers development of the methodology for data transfer from BIM model to assessment scheme based on SBToolCZ, which is a national tool for building sustainability certification in the Czech Republic. Next step will be focused on describing connection of LCA and the BIM model databases and mapping data between them. Case study is focused on utilisation of BIM model with all relevant environmental characteristics for LCA analysis. All changes during construction phase and their impact on environmental analysis and LCA will be monitored and assessed.

1 Introduction

1.1 Current situation at the BIM market

Building Information Modeling (BIM) has already been widely spread and established during last couple of years at the European markets [1] [2] as well as in the Czech Republic. Markets and legislation start to be mature and ready for the BIM. In the most developed countries there is a plan of implementing BIM on the national level. For example in the Czech Republic the usage of BIM is mandatory from 2022 for the over-limit public tenders financed by the Public sector [3]. Although mentioned data [1] [2] seems positive, it is necessary to dive deeper into data. Study from the Boston Consulting Group (BCG) [4] company points out fact that with revenue of almost $10 trillion (6%) of global GDP makes AEC industry of Architecture, Engineering and Construction (AEC) one of the most important.

Another study of the McKinsey&Company [5] points out that “the world will need to spend $57 trillion on infrastructure by 2030 to keep up with global GDP growth” and also presents 5 trends which will shape construction and capital projects. Three of those trends directly contain the BIM technology (Next-generation 5-D BIM, Digital collaboration and mobility and The Internet of Things and advanced analytics respectively). The same document also says that the Construction industry is currently one of the least digitalized industries ever (worse position in the digitalization has only Agriculture and hunting).

Next important topic for further development is Facility Management (FM) perspective which also has high impact to the environment. Review of 3 Case Studies [6] from the Czech market summarizes current market development and shows possibilities of future focuse.

All mentioned analyses bring us to the conclusion that AEC industry needs a real evolution and BIM is one of the key factors on the way of digitalization.

2 Theoretical Part

2.1 BIM and LCA

Important chapter which is not yet entirely described is implementation of environmental parameters into the BIM model. This topic is widely discussed across the industry, on many various platforms e.g. Annex 72, working group under the International Energy Agency's Energy in Buildings and Communities Programme [6].

The key part always related to the model is its detail. In terms of BIM there is widely used term Level of Development (LOD) [7], standard developed by the BIMFORUM [8], the non-profit organization consists of The Associated General Contractors of America (AGC), The American Institute of Architects (AIA) and American Institute of Steel Construction and its also part of the BuildingSMART[1], the international organization developing international standards related to BIM (e.g. openBIM, Data Dictionary or data exchanging format The Industry Foundation Classes (IFC)).

The LOD in terms of incorporating environmental data can be divided in two parts:

2.2 Aggregated Data Method

Simplified method of modeling which can be widely used for comparing different material bases (e.g. load bearing system, façade etc.). The model follows LOD 200-300 and environmental data are aggregated according the whole structure (e.g. environmental values for timber wall with inserted insulation between studs is recalculated according volume of all parts). Elements which are not in the model (e.g. hangers, veneers etc.) are neglected.

2.3 Element Data Method

Detailed method of modeling which can be used for precise calculation of building's environmental impact. The model itself has to be developed in LOD 350-400 which means that it contains detailed geometrical data of the building (e.g. concrete rebar, wall studs, veneers etc.). This method is highly accurate but also time consuming. It is also necessary to keep a wide database of environmental data of used materials. Due to high detail of the model there is only minor elements neglected.

2.4 SBToolCZ

SBToolCZ is a Czech national sustainability certification scheme similar to BREEAM or LEED with focus to Czech building industry and standards. It is applicable for residential buildings, offices, schools and kindergardens. It is based on complex evaluation of environmental, social, economic and location-related quantitative and qualitative indicators. The received scores from each indicator are normalized and weighted, and the resulting score is translated into bronze, silver or gold certificate, which is awarded by independent certification bodies [9]. Schema of the SBToolCZ and its connecting with BIM models will be used in the future research.

3 Case Study

3.1 The Case Study Description

The main project objective is to develop a flexible construction system for a new generation of multifamily residential buildings capitalizing on synergy of non-bearing light timber-based structures and with a light bearing structures from high performance concrete with maximal utilization of advanced prefabrication technologies. The structural system from high performance concrete is characterized by a high bearing capacity, long lifetime, fire resistance, and favorable acoustic and heat accumulation parameters.

Timber-based structures guarantee a low carbon footprint of production, lower weight, and excellent thermal insulation of building envelope. Key issues that project addresses are development and

[1] https://www.buildingsmart.org/

optimization of both types of structures, their interfaces and coordination of prefab production of the elements and concerted fast assembly on site. Optimization in terms of environmental impacts, energy efficiency and economic feasibility is also part of the project. Load bearing system from high performance concrete and non-bearing timber-based elements fill be produced and its function will be tested per parts on special research equipment at UCEEB CTU and as a whole on a small experimental structure. Based on experience from pilot the design of all elements will be improved and verified by production of prototypes. The experimental building will be built in spring 2019 at University Centre for Energy Efficient Building (UCEEB) of Czech Technical University (CTU) in Prague. The resulting building system will become a part of portfolio of RD Rýmařov, which will sell it to developers of residential buildings in Central Europe.

3.2 The BIM Model

The digital model itself has been developed in software Autodesk Revit. This software has been chosen according the internal research which confirmed it as a leading product of the BIM world with the most advanced tools for many different trades and stakeholders on AEC market.

The case study consists of the following tasks:

- Design model in LOD 300 with applied Aggregated Data Method (described in 2.2),
- Construction Model in LOD 400 with applied Element Data Method (described in 2.3),
- As-built model in LOD 500 with incorporated all parameters needed for Facility Management (FM),
- Dashboard showing real-time data from the incorporated sensors.

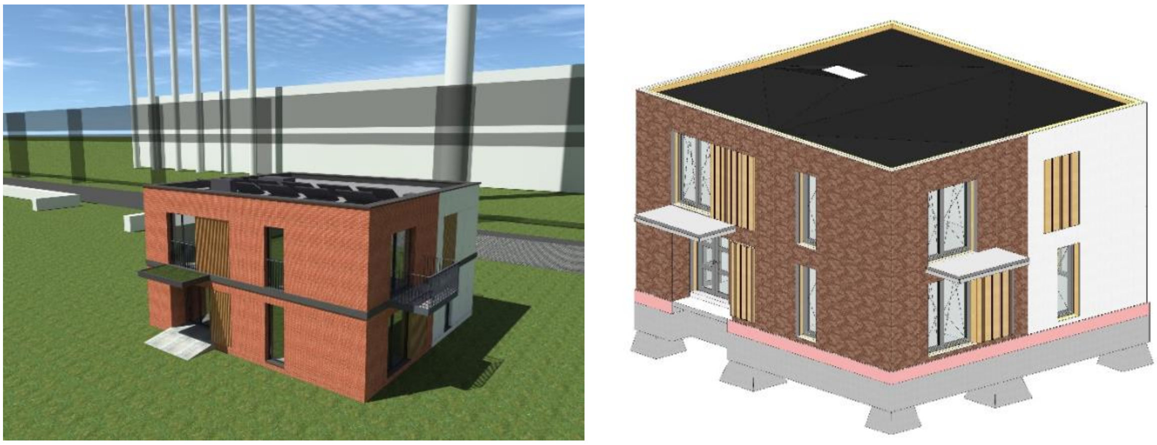

Figure 1 – Project visualization and the BIM model

Current situation described in previous section creates a perfect condition for creating the "Real BIM model" which contains all related data important for design, construction and operational phase of the project. Thanks to the TiCo project the real building will be built anyway. With the current market situation and proper knowledge there is a room for this Case Study.

3.3 Current status of the model

Currently the model is developed in LOD 300-350 and it contains all the relevant structures with relevant environmental data: Primary Energy Input [MJ] and Global Warming Potential [kg CO_2,ekv]. The environmental data has been taken out of the Envimat[2] database, the Czech catalogue of the environmental parameters of building materials.

Figure 2 - Environmental impact of the building elements

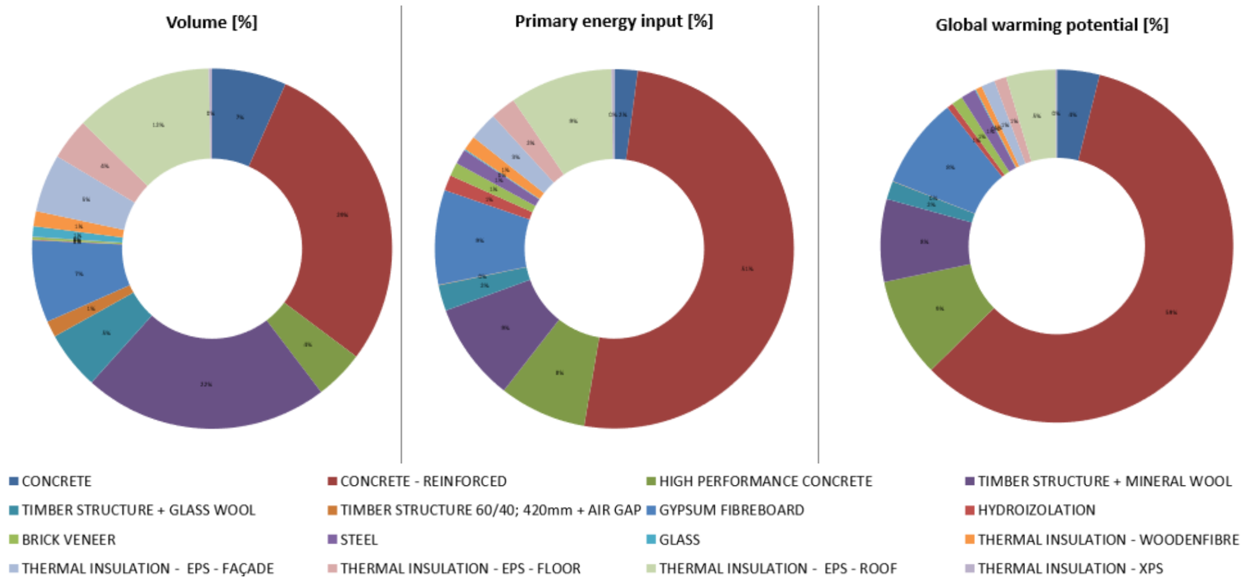

Figure 3 - Environmental data of the model

3.4 Challenges of digital model

During the modeling the team has always dealt with the following obstacles:

- Quality of the model and its LOD,
- Environmental data quality and consistency,
- Software limitations (e.g. volume deviation)..

The idea of this project part is to implement all the related date important for the operational project phase. Due to delay of construction phase this part has not been implemented yet.

4 Conclusion and the future focus

Experimental building TiCo has not been erected by the time of writing this paper yet, so only the Design Model with Aggregated Data Method of implementing the environmental data is applied. This method confirmed a wide benefit of using BIM for similar purposes because it allows simple comparison of different material bases.

Even though there are several lessons learned applicable for each project:

- Incorporating the basic environmental data is a simple process which can be replicable.
- Missing methodology and legislation describes the process of implementing environmental data into the BIM model.

4.1 Future Focus

- Incorporate the sensors data into the BIM model.
- Follow the SBToolCZ scheme and incorporate all environmental data into the BIM model.
- Create the methodology which allows replicability of gained knowledge across the market.

Abstract. The construction and building sectors are one of the highest consumers of resources and energy. Literature evidences the potentialities of the design phase towards the improvement of environmental, economic and social performance of buildings. Thus, the Life Cycle Sustainability Assessment (LCSA). approach is recognized as suitable method. It is based on the "triple bottom line" principle, to calculate environmental, economic, social impacts produced by buildings during its life cycle. The present paper aims to present a methodological framework based on an LCSA, used during design stages of buildings and integrated into a building's design technology such as Building Information Modeling (BIM). A conceptual approach to conduct the data integration and a possible workflow to integrate the LCSA into BIM is proposed. The value of the present approach is the possibility to conduct quantitative environmental, economic and social assessment of buildings to guide designers to measure and predict the building's performance.

1. Introduction

The building sector is responsible, from cradle to grave, of significant environmental impacts [1]. In the European context, for example, the use and construction stages of buildings consume half of the extracted materials [2]. Moreover, it is also recognized as one of the most important waste producers, by generating one-third of the total amount [3]. Regarding this situation and given the growing demand for reducing environmental impacts of cities and buildings, the building sector also produces economic benefits [4–6] and positive impacts for the society.

The design stages of the buildings are considered as relevant in order to reduce their impacts among their life cycle [7,8]. Consequently, over the last decades there has been developed several assessment tools for design stages, mainly based on environmental aspects. The Life Cycle Assessment (LCA) is considered one of the most appropriate method to analyzes the impacts produced by buildings, mostly focused on environmental aspects [9]. The utility of LCA-based tools compared to existing Sustainable Building Certification (SBC) or Green Building Rating Systems, such as LEED [12], BREEAM [13], Living Building Challenge [14], is based on the possibility to bring quantitative assessment of building's sustainability [15] through the stages of the building's life cycle. Existing SBC are mostly based on the assessment of qualitative environmental aspects of sustainability, generally related to energy [16]. That fact evidences the scarce incidence of other sustainability dimensions, for example socio-economic aspects, such as their contribution to the employment creation in certain region or city. Furthermore, literature [7] recognizes the potentialities of the use of LCA-based methods to be integrated in building design stages. However, the main barriers over the use of LCA methods applied to buildings are related to the time-consuming process and the wide amount of data required [17], especially during the phase of Life Cycle Inventory (LCI). In this sense, several works demonstrate the viability of applying simplification strategies for buildings LCA [17–21]. It is recognized that the feasibility of using environmental assessment tools and methods, lies in the simplicity and effectiveness to verify and calculate the impacts. Malmqvist et al. [17] show the possibilities of simplifying the method without the results being substantially affected. Soust-Verdaguer et al. [22], through the analysis of simplification strategies of LCA case studies (single-family houses), underline that one of the feasible strategy to reduce effort during the LCI phase is the integration of BIM models. The strategy allows to integrate LCA into BIM methodology and helps to visualize impacts during the decision-making process. The potentialities of the integration of LCA into BIM through the development of methods and tools are demonstrated in several works [23–39]. Despite of the great amount of developments that integrate BIM and LCA, they are mainly focused on the use of Life Cycle Assessment method to assess environmental aspects. However, current situation based on "complex systems with extended and durable effects on the society" [40], requires more comprehensive and extensive strategies. Thus, the Life Cycle Sustainability Assessment (LCSA) approach aims to go beyond the limitations of the traditional LCA approach [40], by integrating environmental, economic and social dimensions. Literature review evidences that the application of LCSA into building sector is still scarce, and especially during design stages. To fulfil research gaps on this area, the present paper aims to describe a methodological framework based on an LCSA approach, used during design stages of buildings and integrated into a building's design methodology such as Building Modelling Information (BIM).

2. State of the art

This section presents a definition of the main aspects and a review of studies that integrate the LCSA approach to building products and buildings, and the implementation of LCA-based method into BIM technology.

2.1 Life Cycle Sustainability Assessment (LCSA) approach

The Life Cycle Sustainability framework aims to integrate environmental, social, and economic dimensions of sustainability and to guide the decision-making towards a life cycle perspective [41]. It is based on the formula proposed by Klöpffer (2008) [42] which introduces the application of the three techniques: (Environmental) Life Cycle Assessment (LCA), Life Cycle Costing (LCC) and Social Life Cycle Assessment (S-LCA). Guinée et al. [43] understand the LCSA as a "transdisciplinary framework for integration of models rather than a model in itself" [43]. The UNEP/SETAC Life Cycle Initiative to LCSA [44] recognizes that the three techniques are based on the ISO 14040 [10] and they have similar perspectives and aims (Phases 1, 2, 3 and 4).

Previous literature review [45] evidences that its application into building sector is still scarce. However, several examples have been detected and summarized in Table 1. An example of the application of LCSA to a building product (marble slabs) is performed in Capitano et al. [46]. The study determinates in parallel the environmental, economic and social impacts produced by two existing companies' producers of marble in the Sicilian region. The authors have collected and used primary data for the impact calculation [46]. The LCA includes five impact categories: Human Toxicity Potential; Acidification Potential; Eutrophication Potential; Photochemical Oxidation and Global Warming Potential [46]. The LCC includes: Costs of extraction and production, Fuel costs (diesel and natural gas), Waste disposal costs and Electricity costs [46]. The social impacts analyzed are: total employees, women in administration, immigrants, limited contracts, unlimited contracts, health insurance, annual health check and monthly salary of employee [46]. The results obtained are reported on a desegregated manner, presenting in parallel environmental, economic and social impacts. This is due to the fact that the authors aim to acquire a transparent procedure to support decision-making into a sustainability perspective [46].

Table 1. List of LCSA studies.

References	Year	Functional unit definition	Scope of the assessment Design /Product	Data sources
Capitano et al. [46]	2011	m^3 of marble	Existing product	Primary data
Dong et al. [47]	2016	building construction project	Existing product	Primary data
Hu et al. [41]	2013	ton of materials from the EOL building	Design stage	Generic data
Onat et al. [48]	2014	national level	Existing product	Primary data
Traverso et al. [49]	2012	1m^2 of modules	Existing product	Primary data
Zheng et al. [50]	2019	1-km long pavement with one- lane (3.5mwidth)	Existing product	Primary data – secondary data

Analyzing previous studies in this field [41,46–50], one of the main barriers over the application of LCSA to buildings and building products are related to the data collection, especially for economic and social aspects. Moreover, limitations on the definition of a common functional unit for the three methods is highlighted by Zheng et al. [50]. The study considers that the "social impacts are assessed using management behavior, rather than physical quantities", due to that social impacts are not linked to the functional unit. Most of case studies [41,46–50] are based on existing products or buildings, extracted from site-specific sources (local companies or suppliers). This means that the application of LCSA requires additional efforts in data acquisition. Thus, Dong et al. [47] underline that in spite of LCSA being a relatively new technique, the S-LCA is especially the most limited part of the method. Specific research on S-LCA [51,52] underlines the difficulties on data availability about social impacts. Moreover, there is no consensus on the specific or consistent S-LCA method [52]. Regarding detected difficulties, Guinée et al. [53] highline the need to develop quantitative and practical indicators for S-LCA.

Another difficulty was found over the communication of results and the effective integration of environmental, economic and social impacts in the assessment process. Difficulties on weighting and calibrating indicators in order to support the decision-making stages have been identified in [46–50]. Moreover, it is concluded that the use of LCSA frameworks is still infrequent in building sector, especially focused on guiding the design stages and assessing scenarios for sustainability. Most case studies [46–50], based the LCSA application on existing products or buildings, excepting Hu et al. [41]. Considering this context, the development of tools and methods focusing on design stages of buildings is becoming an opportunity. However, this type of tools should deal with uncertainty, underlined by Guinée et al. [53] as one of the three most crucial challenges to be addressed by the LCSA, along with variability and the feasibility to obtain reliable results.

2.2 BIM methodology and LCA integration

During the design stages of buildings, it is expected that the BIM methodology can integrate a great amount of information about the building, guide designers on a user-friendly way, and reduce time and effort during design process. Regarding the integration of LCA and BIM, it is expected to be automatic, user-friendly, useful during the design stages, and provide reliable results [38]. Considering previous research on this field [38], it may be concluded that one of the most relevant challenges of the integration of life cycle perspective into BIM methodology is the interoperability [25]. This means that the ideal workflow should provide the most automatic interaction between the BIM model and the data about environmental, economic and social impacts. Several examples on how it can be conducted are detected. Röck et al. [31], for example, to calculate embodied environmental impacts, solved the link LCA and BIM as a simple product between the total area of building element obtained from the BIM model and the environmental impact values from the LCA database. Soust-Verdaguer et al. [54] proposed a BIM-based LCA method to compare the environmental performance of envelope alternatives during the life cycle. The workflow is based on integrating the automatic bill of quantities (extracted from the BIM model) with various documents of supplementary data, before conducting the environmental impact calculation. Furthermore, Shin et al [24], to conduct simultaneously LCA and LCCA during design stages, required several design documents to conduct the existing two-dimension-based quantity calculations. The authors evidenced that the process requires a large amount of time and errors occasionally result [24]. Case studies analysis conclude that the more complete and complex data structure and information provide, the more difficult to automatize the integration of LCA and BIM.

Table 2. List of LCA-based studies integrated in BIM technology.

References	Year	Design stage	TBL (environmental, economic, social) dimensions of sustainability
Basbagill et al. [34]	2013	Early design stage	Environmental
Peng [55]	2014	Detailed stage	Environmental
Röck et al. [31]	2018	Early design stage	Environmental
Shin et al. [24]	2015	Detailed stage	Environmental and Economic
Santos et al. [56]	2019	Early design stage and Detailed stage	Environmental and Economic
Soust-Verdaguer et al. [54]	2018	Detailed stage	Environmental

Previous research on this field [38] recognized that one of the most important uses of BIM models in the LCA application is to obtain the bill of material quantities. This means that exists a direct relation between the material quantification of the building and the environmental impacts that those materials and process produce. However, regarding the integration of social aspects other difficulties are identified. Specific S-LCA literature [51] recognizes that one of the most relevant difference between LCA and S-LCA is that LCA mainly focuses on collecting physical aspects of a product, and the S-LCA needs to collect additional information about organizations aspects along the chain of production.

Moreover, literature review (see Table 2) evidences the scarce existence of tools or methods, that develop LCA-based studies integrated in BIM technology, nor based on "triple approach" (environmental, social and economic) neither based on the quantification of impacts produced by buildings during their life cycle, that can be used to guide decision-making during the design stages. Considering detected gaps on literature, this paper presents the first steps towards the definition of a conceptual framework based on LCSA of buildings integrated to BIM methodology. The paper proposes methodological considerations to use BIM models to conduct LCSA, by combining LCA, LCC and S-LCA methods.

3. Description of the method

This section aims to provide a general description of the main methodological aspects to be considered to conduct LCSA during design stages of buildings, and a possible workflow. It also aims to identify the main difficulties and challenges towards the interaction of LCSA into BIM methodology.

3.1. Methodological considerations in LCSA

The proposed conceptual method was based on UNEP/SETAC Life Cycle Initiative to LCSA [44], which includes the ISO 14040 phases (1) goal and scope definition, (2) inventory analysis, (3) impact assessment, and (4) interpretation. The approach also complies with the standards on environmental, economic and social assessment of buildings ISO 21931-1[57] and ISO 21931- 2 [58], LCA of buildings EN 15978 [9] and EN 15804 [59], LCC of buildings ISO 15686-5 [60] and UNEP/SETAC Guidelines of S-LCA [51].

Goal and scope definition: Considering previous research on this field [49], the proposed LCSA approach integrated the implementation in parallel of the three methods (LCA, LCC and S-LCA). The use of a "common goal and scope" [44] was proposed. The method considered the UNEP/SETAC recommendation for the definition of a functional unit and the system boundary definition. The functional unit was performed describing the technical utility of the product and the product's social utility [44]. The system boundary comprised relevant unit processes, at least for one of the methods (LCA, LCC, S-LCA) [44].

Life Cycle Inventory: The inventory analysis phase was supported using the BIM model and the interaction of environmental, economic and social data about the building. Following the recommendations of UNEP/SETAC [44] the LCI "compiles exchanges between unit processes and organizations of the product system and the external environment which lead to environmental, economic and social impacts". Thus, it was suggested that the "unit process" has a direct correlation between environmental, economic and social aspects, such as shown in Figure 1.

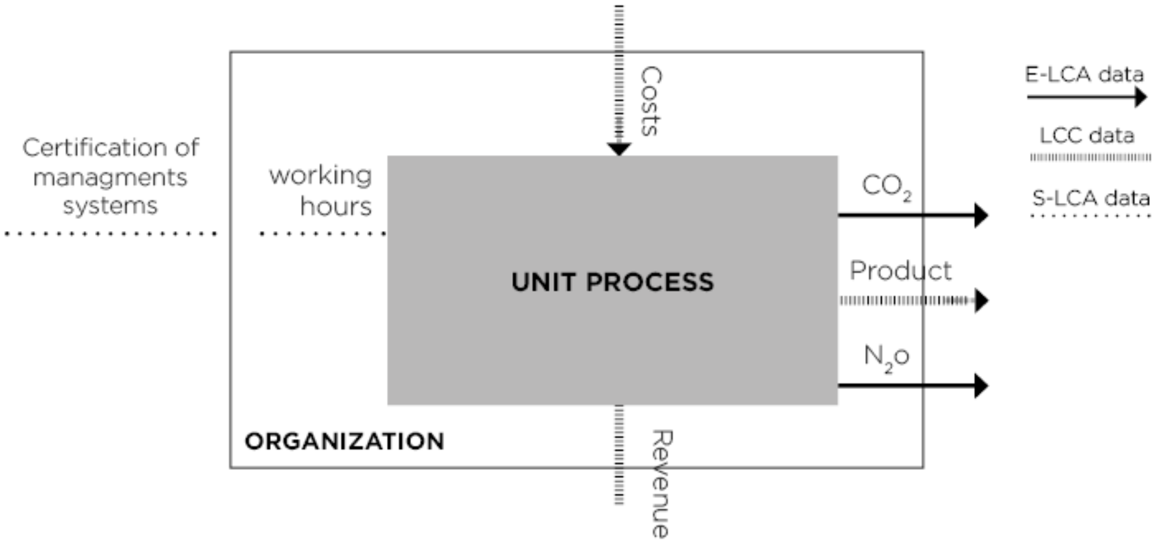

Figure 1 Scheme of the interaction of environmental, economic and social aspects of unit process. (Source: based on [22]).

Life cycle Impact Calculation: The classification and characterization steps were developed following UNEP/SETAC [44] recommendations. Thus, to deal with possible differences in characterization models of impact categories and impacted environments, a combined framework for impact assessment based on the individual S-LCA, LCC and LCA was performed [44].

Interpretation: The method follows the UNEP/SETAC [44] recommendation of combining environmental, economic and social aspects. This strategy can provide designers a sustainable assessment of the building and help decision-making during design stages.

3.2. BIM model to LCSA

The present conceptual framework aims to get the most out of the BIM model (geometry and information) to conduct the LCSA calculation, in order to reduce user manually entering data and reduce effort in data acquisition. Regarding that one of the underlined limitations of BIM to conduct LCA is the limited database [55], the proposed structure integrates a *TBL / sustainability* database about the building with the BIM model. It was founded on previous research [54,61–63] based on the integration of LCA into BIM methodology and the design process of buildings in BIM.

3.2.1 Phases of the method. Following, a possible three steps workflow (see Figure 2) to conduct a LCSA linked to BIM methodology is presented.

Step 1: BIM model. The proposed method started by defining the template, which "helps designers to derive standardized information and outcomes in a consistent work environment" [64]. This step aimed to provide a reliable and normalized structure to build up the BIM model. This step also aimed to provide designers the possibility to integrate different alternatives or scenarios in the model.

Step 2: **LCSA calculation.** This stage was based on the **interaction** between the **normalized BIM model** with *TBL / sustainability* database, which contains the environmental, economic and social impacts data following the Guidelines of LCSA [44] (Figure 1).

Step 3: Communication of results. This step was focused on the visualization of results, according to a normalized structure which aims to organize results and help designers to optimize the model. To provide an automatic optimization of the BIM model, a simultaneous interaction between the first step and the last one was performed.

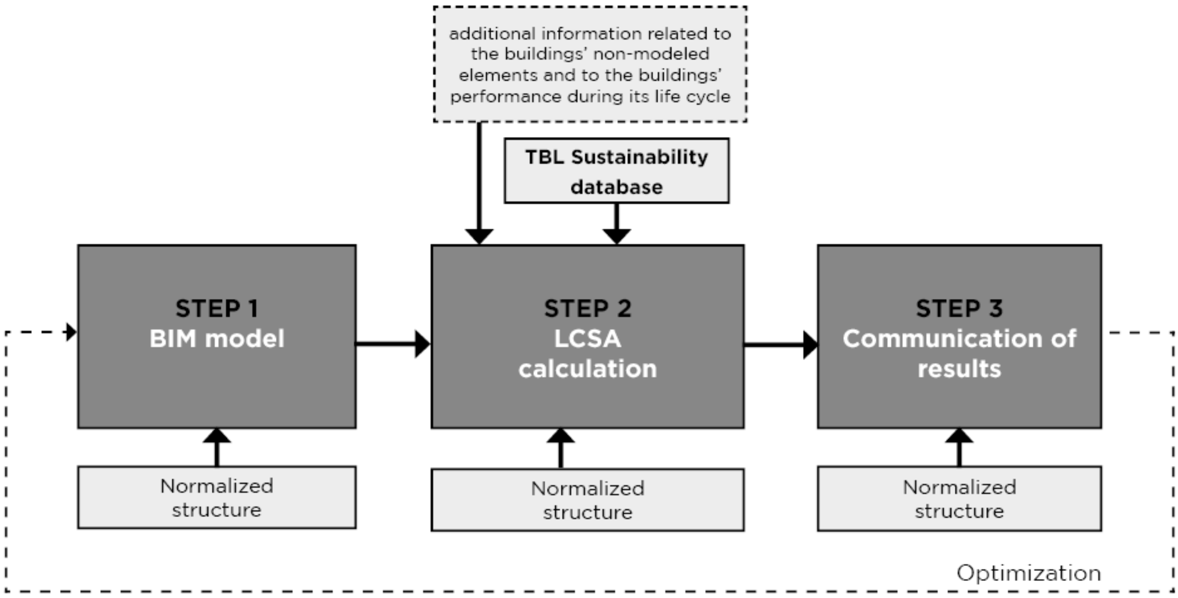

Figure 2. Scheme of the proposed workflow.

4. Discussion

From the literature review and the proposed framework, the following limitations, challenges and resulting research gaps have been detected.

4.1 Limitations on conducting LCI and LCIA

Regarding the integration of the BIM model (bill of quantities) and the implementation of LCI using the structure based on the LCSA unit process approach (Figure 1), it can be problematic in the terms described by Hu et al. [41]. The correlation between environmental, economic and social dimensions of the unit process can neither be linked with the unit process nor with the functional unit [41]. Hu et al. [41] underline that not all the costs (e.g. overhead, profit and loss) can be directly linked with the unit process as well as the qualitative SLCA indicators. The incapability to link the S-LCA assessment to the functional unit is also discussed in the S-LCA specific literature [52]. A possible solution to address the underlined difficulty could be to limit the use of the unit process and the selection of indicators to those that can be integrated in the triple approach (environmental, social and economic), and verified for the case of building design.

4.1.1 Data availability and design-oriented benchmarks. The lack of available S-LCA data is an underlined limitation [47]. Dong et al. [47] propose as a possible solution, to establish a sector-based database of S-LCA, to collect primary data. Moreover, it is also noted that the emerging use of this type of sustainable assessment tools and methods (integrating environmental, economic and social dimensions) can be a powerful tool to improve the performance of buildings, thus the development of benchmarks for guiding designers is recommended. Recent research [116] examines the need of benchmarks and reference values to guide and support decision-making on building design stages. In this sense, the present method also considered the integration of benchmarks and reference values adapted to regional and national scenarios.

4.1.2 Communication of results. The difficulties of integrating environmental, economic, and social aspects in the communication of results were detected. Finkbeiner et al. [65] underline that LCSA requires appropriated multi-criteria evaluation strategies. Life Cycle Sustainability Triangle and the Life Cycle Sustainability Dashboard are proposed as approaches to address this challenge [65]. Thus, it is needed to verify them into building design stages. It is also needed to establish effective strategies focused on helping designer during decision-making.

5. Conclusions

This paper presented the first steps towards the development of a method to automatically perform LCSA calculations during design stages and that uses the potentialities of the BIM methodology to quantify and reduce environmental, economic and social impacts of buildings. In future work, this LCSA framework will be verified in building applications, in order to determine its accuracy and reliability for decisions-making during building design stages.

Acknowledgments

The authors would like to thank the Spanish Ministry of Economy for support the research project (Grant BIA2017-84830-R). The work presented here has a partial financial supporter of the National Research Plan. Thanks to the IEA EBC Annex 72 (http://annex72.iea-ebc.org) experts which provided (directly or indirectly) a fruitful input that enriched this study. Also, thank to Prof. Alexander Passer for the rich contributions. The authors acknowledge the reviewers for the constructive suggestions.

Digitalization of building LCA and international activities – in the context of German assessment system for sustainable building

Brockmann T

Head of Division II Construction and Environment, Federal Institute for research on Building, Urban Affairs and Spatial Development BBSR, Germany

tanja.brockmann@bbr.bund.de

Abstract. In this paper it is shown how digitalization and the establishment of an online infrastructure for life cycle assessment (LCA) in the context of the assessment system for sustainable building (BNB) by the German government forms starting point for an open international data network, as brought forward by the activities of InData ("International Open Data Network for Sustainable Building"). The establishment of the ILCD+EPD data format for EPD, the provision of interfaces, the development of workflow structures, guidelines and rules, which are openly published, internationally allow to access data from several databases. All these aspects are subject of the InData activities, and are decisive for a harmonization of LCA for sustainable building. With this concept of digitalization the propagation of the use of environmental product declarations (EPD) in building LCA was enhanced, and also new applications for using EPD data are offered, e.g. in BIM or other context.

1. Introduction

Nowadays the climate change is widely recognized. It is the motivation for manifold international, European, and national policy strategies regarding CO2-reduction, energy and resource efficiency, all of these are aspects of sustainability. As a consequence, building certification systems for sustainable building have been established worldwide (Figure 1).

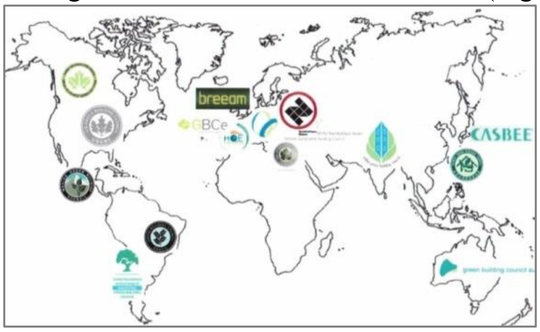

Figure 1: Building certification schemes for sustainable building worldwide.

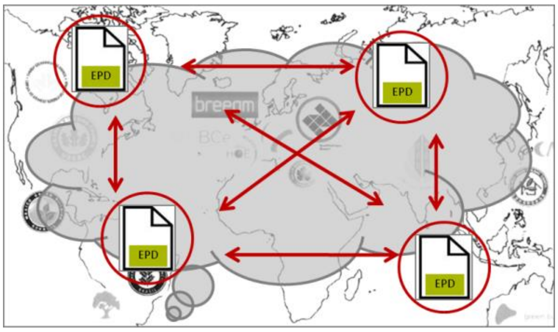

Figure 2. Integrated communication of EPD data via digitalization.

In Germany, Sustainable Building is part of the National Sustainability Strategy with the Guideline for Sustainable Building and the Assessment System for Sustainable Building (BNB) being most essential for the construction sector. The government takes the responsibility and brings forward sustainability by establishing BNB as a binding instrument for federal buildings. All information and tools are offered with a high transparency in order to diminish barriers. Political programs and support is considered as very helpful, also for the definition of responsibilities. Experience in Germany has shown that the centrally bundled provision of data and tools by the government is a valuable instrument for a wide application of LCA at building level and the realization of sustainable buildings.

2. BNB

The sustainability of a building under the BNB principles takes into account Ecological, Economic, and Socio-Cultural aspects in equal parts, additionally regarding Technical and Process Quality for buildings. Particularly with respect to ecological quality, that is, when considering the impact on the global environment, LCA forms an essential part of the overall assessment (Figure 3). The primary energy demand and effects of the building on the global warming, ozone depletion, photochemical ozone creation, acidification and eutrophication potential are determined, taking into account the life cycle over the chosen time period of 50 years.

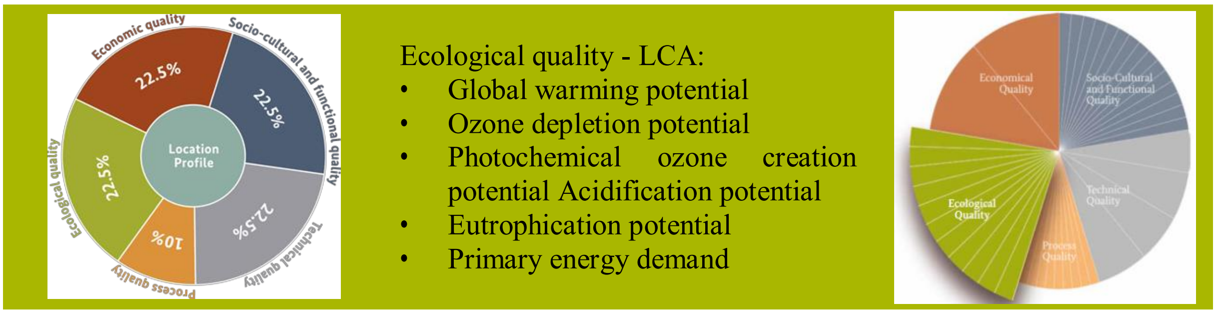

Figure 3. Considered dimensions of sustainability within BNB.

2.1. BNB tools

For choosing suitable building products and constructions BNB provides ÖKOBAUDAT with basic data for life cycle analysis at building level with the online tool eLCA. All provided tools are web-based, cost-free, open-source based, and publicly available; for all of them an English version (or other information) is given. The tools are initiated and maintained by the Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR), a research Institution under the portfolio of the Federal Ministry of the Interior, Building and Community (BMI) [1, 2].

2.1.1. The ÖKOBAUDAT platform. It is a platform with data, information, and links related to the LCA of construction works. At the platform's core is the online database with LCA datasets on building materials, construction, transport, energy and disposal processes. ÖKOBAUDAT is provided already since 2009, and it is available for everybody interested in an ecological evaluation of buildings with a consistent database. Search- and filter-functionalities allow browsing relevant data for chosen materials or products directly in the online database.
Currently, ÖKOBAUDAT provides more than 1,200 datasets (about half of them are generic data) on all important construction product groups. Since 2013, it comprehensively meets the demands of European Standard EN 15804.
ÖKOBAUDAT data are used nationally and internationally by other certification schemes, LCA tools, BIM applications, or other. All ÖKOBAUDAT data are quality checked. The *ÖKOBAUDAT Manual* [6] contains technical and formal information on the ÖKOBAUDAT database.

2.1.2. eLCA software for building life cycle assessment. With the online tool eLCA the environmental effects of buildings can be easily determined taking into consideration the entire life cycle [7]. The basis is the calculation rules of BNB which are linked with the ÖKOBAUDAT data.
The core of eLCA is the component editor ("Bauteileditor"). The users can model their building

components in a very user friendly way. The dynamic graphic displays the building components with its material layers and enables the user to visually inspect the input data (Figure 4). The results can be directly compared with the benchmarks of BNB. eLCA presents the calculations transparently, and thereby enables detailed analysis of the results (Figure 5).

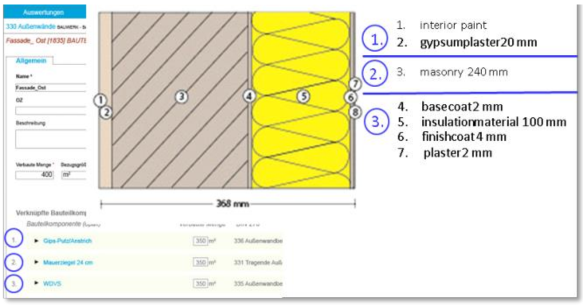

Figure 4. Dynamic graph – visual check input parameters.

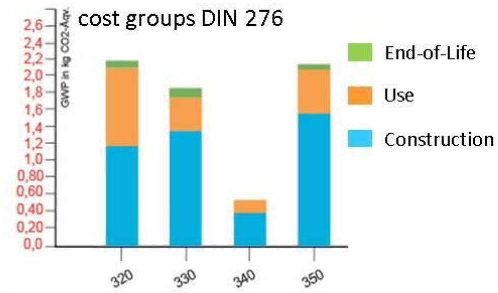

Figure 5. Analysis of eLCA results.

eLCA is a central instrument in the digitalization process as there is internal and external data transfer to and from the tool. Besides LCA, the instrument is used for other BNB criteria, like life cycle costing (LCC), transport calculations, and waste/recycling with digital data exchange.
It also imports building components from external software applications e.g. used for German (bindingly required) energy performance certificate for buildings ("Energieausweis"), and exports data/results to subsequently used applications.
Data transfer to/from BIM applications also is possible, and will be further developed in ongoing (research) projects.

3. Digital LCA infrastructure within German BNB

Reasons to digitalize the LCA infrastructure within the context of BNB were to improve all data related workflows, assure independency, and reduce cost for the production of building LCA.

In earlier stages ÖKOBAUDAT consisted of zip.files, and LCA sometimes was based on excel calculation routines. With a growing amount of data and data providers suitable workflows had to be developed. Also, the BMI/BBSR decided not only to offer online data transfer via ÖKOBAUDAT, but also to publish an independent building LCA calculation tool, eLCA.

Also, there already was the vision of an open international data network and to establish an integrated communication of EPD data and information. Standardized EPD were produced internationally, but due to the format (often pdf.file) they could not be used directly e.g. for LCA calculations.

A digital data format and interfaces were the precondition for these online structures. Within the digitalization process, most decisive was the development of a machine readable data format for EPD, i.e. the ILCD+EPD data format. This forms the basis for most other related activities.

3.1. LCA tool chain

BNB established a complete digitalized LCA 'tool chain'. It starts with the basic material data from EPD, which are imported in the online database ÖKOBAUDAT, exported from there to eLCA, which results are used for the final evaluation with bronze, silver, or gold sustainability certificate (Figure 6).

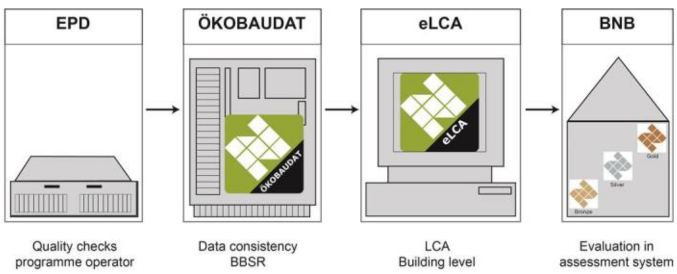

Figure 6. Digitalized tool chain LCA German BNB.

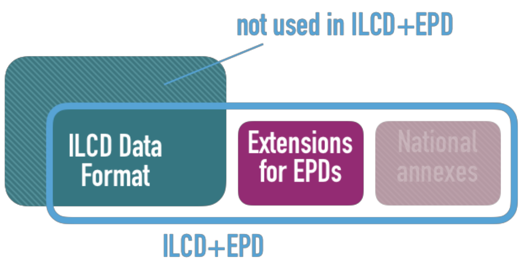

Figure 7. ILCD+EPD data format.

3.2. Technical Aspects
For a better understanding of the digitalized LCA structures the technical aspects are described.

3.2.1. Data format
The ILCD+EPD data format (short for 'ILCD data format with EPD extensions') is a technical means for transporting information associated with an EPD in a structured way. It is based on the established ILCD data format created by the European Commission [8]. It does not use the entire extent of the original ILCD format, but only those parts which are necessary and suitable for describing EPD data, complemented by additional EPD specific information that was not foreseen in the original ILCD format (Figure 7). The information is published in the *Table of Definitions ILD+EPD data format, CPEN2018* and corresponding *FAQ-document* [6]. The format structure allows for national annexes, where e.g. metadata can be integrated. Data format as in ÖKOBAUDAT is fully compatible with InData (Table 1).

3.2.2. Databases. In technical terms, the ÖKOBAUDAT database is based on the software soda4LCA [9].

3.2.3. Interfaces. The ÖKOBAUDAT is equipped with a standardized interface (API – application programming interface) for data exchange with other applications and software tools with the corresponding authorisations. The API documentation is provided in HTML and PDF formats in the zip.file *Developer documentation* [6].

3.2.4. Data supply for ÖKOBAUDAT. One of the decisive advantages of the digitalization is that now for all data providers an online data transfer into ÖKOBAUDAT is possible. There are essentially several ways of data import.

Import via EPD Editor
The currently published open source software, the EPD Editor [10], was developed on behalf of and financed substantially by BMI/BBSR. On the basis of existing EPD (e.g. pdf.format) with this software EPD datasets can be transformed/modelled in the ILCD+EPD data format with manual input, and then imported into ÖKOBAUDAT. A special feature of the tool is that datasets can be created in several languages and then offered in bi- or multilingual version. Currently the EPD programs ift Rosenheim, Bau EPD, kiwa, and Thünen Institut with representative average datasets, use the EPD Editor for data creation and transfer. For the *EPD-Editor manual* [6] and other support see website ÖKOBAUDAT/downloads.

Direct import via an interface
Data supplier can import their EPD/LCA datasets directly into ÖKOBAUDAT online from their database systems via the interface. Currently, the EPD program IBU and thinkstep with generic data use this option.

Validation tool
Before datasets are imported, which way ever, data providers must check their data with the validation tool [11]. Data are validated regarding data format, completeness, and product category allocation. The tool was developed for BNB and is regarded as highly user friendly and intuitive. It runs on a standalone, cross-platform basis. Instructions are given in *Technical Validation of datasets* [6].

3.3. Data quality management - ÖKOBAUDAT

While EPD programs publish several EPD types, e.g. differing in referenced standards (EN 15804, ISO 21930) [3, 4], background database (Gabi, ecoinvent), and depth of information (core EPD, program EPD), addressed location etc., the specific aim of ÖKOBAUDAT is the provision of data for building LCA. The results are related to benchmarks and are used for evaluation and comparison within certification schemes. For this application a high level of data quality and consistency is decisive. Therefore, the data quality management is an essential part of the LCA infrastructure. It comprises requirements regarding data format **and** data quality, in terms of EPD programs, processes and workflows.

3.3.1. Process of data acceptance. The process of data acceptance is as follows:
1. Send *Application form* [6] including self-declaration about compliance with requirements
2. Check of data provider (program and provided documents) by BMI/BBSR
3. Approval of data provider
4. Data supply to inbox of ÖKOBAUDAT
5. Plausibility checks (e. g. sample testing of data)
6. Full approval (data provider + data)
7. Publication of data in ÖKOBAUDAT

3.3.2. Requirements data provider. To ensure data quality in ÖKOBAUDAT, the data providers are checked in terms of meeting the requirements. Hence, they are asked to provide the following information / documents:
- Self-declaration stating conformity with relevant standards (e.g. EN 15804) and *Principles for acceptance of LCA data in ÖKOBAUDAT* [6]
- Access to program rules and PCR documents
- List of the members of the PCR review panel
- List of verifiers, description of the requirements for the verifiers and verification process
- Consent of the owner of the datasets for use in ÖKOBAUDAT

3.3.3. Requirements data format. To ensure compliance with the data format the following criteria need to be regarded:
- Delivery of data in ILCD+EPD data format
- Use of validation tool before data delivery
- Delivery of data for plausibility checks (sample testing)
- Validity of data

3.3.4. Quality aspects eLCA

The eLCA calculations are in line with quality assurance as the application of eLCA offers high transparency and consistency of calculations. Pre-configurations of data (e. g. if EPD datasets only offer production phase information, i.e. modules A1-A3, datasets for use phase and end-of-life scenarios need to be assigned), construction element templates, frontend for data input, and graphic presentation of results contribute to quality. Also, interfaces allow using synergies by importing building components from other (energy) calculation software, which also minimizes sources of errors by avoiding manual data input. Another aspect is ongoing optimisation by users' feedback.

3.4. BIM

As already mentioned data format and digitalized LCA structures allow to connect with BIM applications. BMI/BBSR currently is analysing suitable workflows, and further developments in ongoing (research) projects. As BNB has to be applied for federal buildings in general, relevant developments need to be aligned. As a public institution usually predominantly open source and regulations applicable for all stakeholders will be supported. BBSR is involved in national and international standardization works regarding BIM. As being part of InData which co-operates with

ECO platform, which both aim at digitalization and use of EPD for BIM, BBSR will support international harmonization of these processes.

4. International activities

International activities of BMI/BBSR aim at supporting sustainable building. For this reason, it is involved in national and international standardization works. It organizes sessions during (SBE and WSBE) conferences. In respect to building LCA, from beginning on, there was the vision of digitalization for an integrated international communication of data and information to enhance application of building LCA (Figure 2). This is an important motivation for the engagement in InData.

4.1. InData

InData was initiated after important talks/sessions at WSBE 2014 in Barcelona, and is chaired by the BBSR. The mission of InData is to establish an open web based international data network structure for EPD/LCA data using a common data format and open source software, as formulated in the *Decalogue* [6]. Within this network, data for specific purposes shall be identified by filters and easily implemented in applications. InData is an informal, non-profit working group of interested stakeholders who support the stipulated mission. It aims at establishing best practice for providing digitalized EPD as a quality source of verified EPD/LCA data for BIM, as for building LCA and other relevant applications.
With the participating members it represents important EPD programs and covers a significant amount of EPD (Figure 9). From 2014 with about 1,000 globally registered EN 15804 conform EPD it grew to about 6,000 in January 2019 [12]. With this, the interest in using digitalized structures is growing. Another reason for interest in InData is the growing amount of BIM applications in the construction sector which implies a strong demand to connect EPD data with BIM based building models. As InData is offering a platform for developing digitalization and harmonized structures, more stakeholders get involved. Starting with 6, now 12 nations are involved.

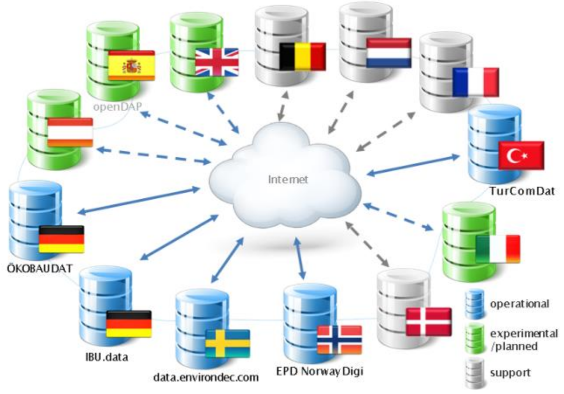
4.1.1. Open Network. InData bases its activities on the already existing ILCD+EPD data format, as this offers a high flexibility for possible adaptions, and allows open access to data, while maintaining individual ownership. Anyhow, the use and development of the format as such is to be seen independent.
The idea of InData is to represent defined data quality and consistency. Thus, it decided to define a InData compliance. Within the open data network only InData compliant data will be published. This means that most participants probably will only share certain parts of their databases within the InData network, (e.g. only English is compliant). Only those members who commit (by self-declaration) to meet InData compliance will be allowed to share data within the InData network.

4.1.2. InData compliance. InData compliance comprises common commitment about the data format **and** rules. Currently, it refers to construction products and European Standard EN 15804 (CPEN2018), but it is flexible for development and definitions of compliance for other products and standards. Actually, InData already is defining a compliance level for the amendment EN15804:A2. [5].

a) *Technical*
   In Data defined a common core of information, i.e. the list of addressed elements of the data format, the definition and explanations of these, and stating mandatory data fields (Table 1). These commitments of harmonization between the international stakeholders are published in the *Table of Definitions ILD+EPD data format, CPEN2018* and corresponding *FAQ-document* [6].
b) *Compliance Rules*
   The compliance rules *InData compliance – core rules and requirements* [6] address the data quality, which is mainly used in the sense “fitness for purpose”. With a high transparency and

given information about the delivered data the users will be enabled to filter the adequate data for their specific purposes. Anyhow, common basic rules are described, for EPD data (data format, standard EN 15804, verification, language, validity of data, product category structure, background databases, life cycle modules, and scenarios), data providers (responsibility on datasets, acceptance criteria, validation of data), and EPD programme operators (e. g. verification aspects).

4.1.3. Currently in use. Following BMI/BBSR with ÖKOBAUDAT, InData participants brought ideas to practice and now, are ready to contribute to the data network: IBU Germany with IBU.data, EPD International Europe with data.environdec.com, Metsims Turkey with TurComDat, and EPD Norge Norway with EPD-Norge Digi (Figure 8). It is a great success that these stakeholders were able to set up these databases structures on basis of the openly published information and the given open source structures, with only very little additional support from experienced experts. Further stakeholders are currently setting up further databases and corresponding structures.



InData = member, permanent guest, interested stakeholder.

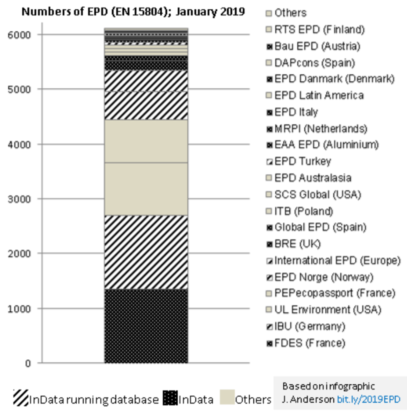


Figure 8. InData Network - participating stakeholders. **Figure 9.** Represented EPD by InData.

4.1.4. Website. The InData website offers general information about InData, but the core element will be the browsing of InData compliant data, offered by the participating international stakeholders. Data and technical structure are ready for the publication of the data. As compliance rules are still on the way, the data will be published in a next step, after approval of these rules. Then, the data will be accessible in a table with user friendly search and filter functionalities (Figure 10).

Search results License conditions of the individual data providers apply. Data resale prohibited

4.1.5. International co-operations. As InData committed to base its activities on already existing methods and standards it co-operates with ECO platform, the umbrella organization for EPD program operators. ECO platform offers a coherent framework, and it harmonizes activities on EPD, like e. g.

verification procedures and other processes. Harmonized rules will be regarded within InData. Also, ECO platform support InData with digitalization and thus, use of EPD for BIM and other applications. Exchange of both initiatives is given by joint international meetings.

5. Summary and Outlook

With establishing the digital infrastructure for building LCA the German government offered the basis and starting point for international activities which support the propagation of sustainability in the construction sector. The open access to quality-checked data and tools diminishes barriers and enhances harmonization. Decisive was the digitalized EPD format ILCD+EPD. Workflows, tools, user friendly features, and rules are further developed and enhanced continuously within multi-lateral co-operations, nationally and internationally. Digitalization not only improves quality, but also it allows for manifold further developments in future, especially as being open source based. Further developments for the optimization and use for BIM will be the issues in the coming working process, at national and international level. Anyhow, the participation and provision of already running databases according to offered data format and open source structures is considered as a great access for both, German LCA infrastructure as a national forerunner, and InData initiative as an international platform, and distributor of the ideas.

Acknowledgements

The mentioned developments were carried out in research projects within the research program Zukunft Bau run by BMI, in which amongst others, thinkstep, IBO, KIT, greendelta, okworx, and Online Now!, were involved. Especially to acknowledge are the valuable contributions to this paper by Hildegund Figl (IBO), and Oliver Kusche (okworx).

Computer-aided supporting tool for LCA evaluation of energy efficiency of the buildings – assessment method and case studies

Domjan S, Arkar C, Medved S

Laboratory for Sustainable Technologies in Buildings, Faculty of Mechanical Engineering, University of Ljubljana, Aškerčeva 6, 1000 Ljubljana, Slovenia

suzana.domjan@fs.uni-lj.si

Abstract. In the paper methods and the development of computer tool for the comprehensive life cycle assessment evaluation of the new or renovated buildings is presented. To support decision making process, computer tool was developed and consists of two computational units: the building description unit (BDU), and the life cycle assessment tool (Etool). BDU enables the determination of energy needs and final energy demand for the operation of EPBD systems. For the purpose of environment impact assessment, the life cycle inventory database is integrated into the BDU. Data are exported to LCA evaluation tool E^{tool} that include two assessment modules: life cycle environmental impact module for mid-point and end-point assessment taking into account impact groups and damage factors from IMAPCT2002+ and ReCiPe methods and life cycle costs assessment module for evaluation of costs optimal values of energy efficiency measures for nearly zero energy buildings (nZEB). In the paper case studies are presented and discussed. The results show that energy use has dominant influence on buildings' environment impacts and that life cycle cost analysis show optimal thermal insulation thickness higher than required in current regulative.

1. Introduction

The Energy Performance of Building Directive (recast) (EPBD recast) [1] introduced targets for nearly Zero Energy Buildings (nZEB) in the form building minimum energy efficiency criteria. Directive also required that minimum energy efficiency criteria must be required in the way to be cost-effective. The experts involved in building planning and renovation encounter this challenging task in the early stage of planning. In addition to the relevant multidisciplinary knowledge on life cycle assessment (LCA), a simplified computational tool to verify the early phase decisions is needed to meet the requirements of EPBD [2]. Such computer tool is presented in this paper

2. LCEA, LCIA and LCCA computer tool structure

Computer tool for life cycle energy efficiency (LCEA), environment impact (LCIA) and life cycle cost assessment (LCCA) has two calculation units: the building description unit (BDU) and LCA evaluation unit (E^{tool}) as it is shown in Figure 1. The BDU is based on the national building labelling software tool KI Energija [3] developed by Knauf Insulation company and authors of the presented article, meanwhile the E^{tool} was custom made in MS Excel environment.

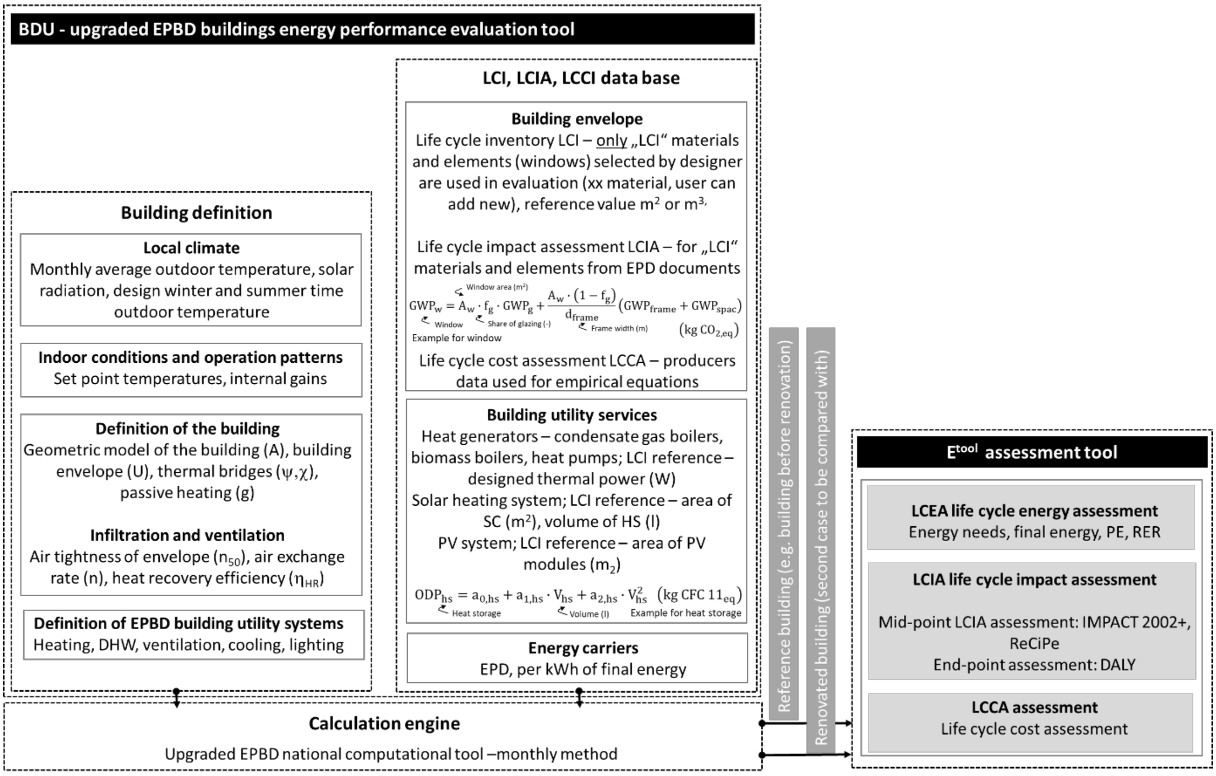

Figure 1. Structure and interactions between BDU (upgraded EPBD national certificated software tool) and life cycle assessment tool (E^{tool}).

2.1. *Upgrading the BDU for life cycle assessment*

EPBD evaluation software tool was upgraded by creating additional database files marked as “LCA” that includes life cycle inventory (LCI) data. If the designer chooses the material, the building structure or the building service system component from “LCA” database, additional inventory data for LCIA and LCCA is created in the BDU.

2.1.1. Life cycle energy assessment (LCEA). Monthly method is used for determination of energy needs for heating and cooling [4], [5], and other EPBD supporting standards were used for final and primary energy evaluation. Yearly value of energy demand is used to determine non-energy related variables such as emissions of pollutant equivalents or energy carriers’ costs.

2.1.2. Life cycle environment impact assessment (LCIA). The environment impact indicators were chosen according to the public available data sources. Because of that, basic indicators presented in Environment Product Declarations are used. Data from public open database like Ökobaudat [6], Environdec EPD Database [7], Eco-Platform [8] and IBU [9] and manufactures data (i.e. Knauf Insulation [10]) were used to create data that are integrated in the BDU. LCIA is performed in three phases – through classification, characterization and normalization. In the classification phase material and energy flows as well as emission of pollutants equivalents related to “LCA” marked building elements and energy carriers, are summarized during user selected assessment calculation period into seven pre-selected impact categories. Values are presented as physical quantities (e.g. kg, MJ). In the characterization phase sum of environmental impacts expressed by equivalents (e.g. AP or EP) are weighed by impact factors (e.g. global warming potential GWP_{100} of particular greenhouse gas) and classified into several damage categories. As most common used, damage categories included in IMPACT 2002+ [11], [12] and ReCiPe [13] method can be evaluated in E^{tool}. By normalization, impacts of analysed building (reference and designed one) are compared to the total environmental impacts in the reference system (e.g. European Union) and total impacts are normalized to total number of inhabitancies in the system (410×10^6 in EU). By grouping and weighting, end-point in form of single score environmental impact can be evaluated by Eco Points per year (PT/y). All indicators are presented in the way that show contribution of each group of "LCA" elements (energy carrier, materials, and building service systems).

2.1.3. Life cycle cost assessment (LCCA). The important requirement of the EPBD recast is that EC Member States must set minimum requirements for energy performance of buildings in such a way that a cost-optimal solutions are provided. In order to assess the cost-effectiveness of measures, life cycle cash flow is shown in E^{tool} determined by discounting costs and savings. Guidelines accompanying Commission Delegated Regulation [14] that suggested macroeconomic annual discount factor (3%) and predict the annual increase in energy carrier prices (2.8% for natural gas and light heating oil prices, 2% for coal and 9% increase of electricity price) for the period until 2030 were taken into account. Annual cost of maintenance of technical systems is assumed to be between 2% and 5% [15]. The residual value of the measures is determined on the basis of the expected lifetime of the measures [16].

2.2. *LCA evaluation tool E^{tool}*
Data determine in BDU needed for LCEA, LCIA and LCCA life cycle assessment are automatically transferred in form of inventory database to E^{tool} for two project, one of which is selected as a reference. Among others, E^{tool} display LCA metrics shown in Fig. 2 (LCEA), Fig. 3 (LCIA) and Fig. 4 (LCCA).

Figure 2. LCEA metrics displayed in E^{tool} shown nZEB indicators, energy carrier demand, embodied energy and emissions of greenhouse gasses; two project can be compared at the same time.

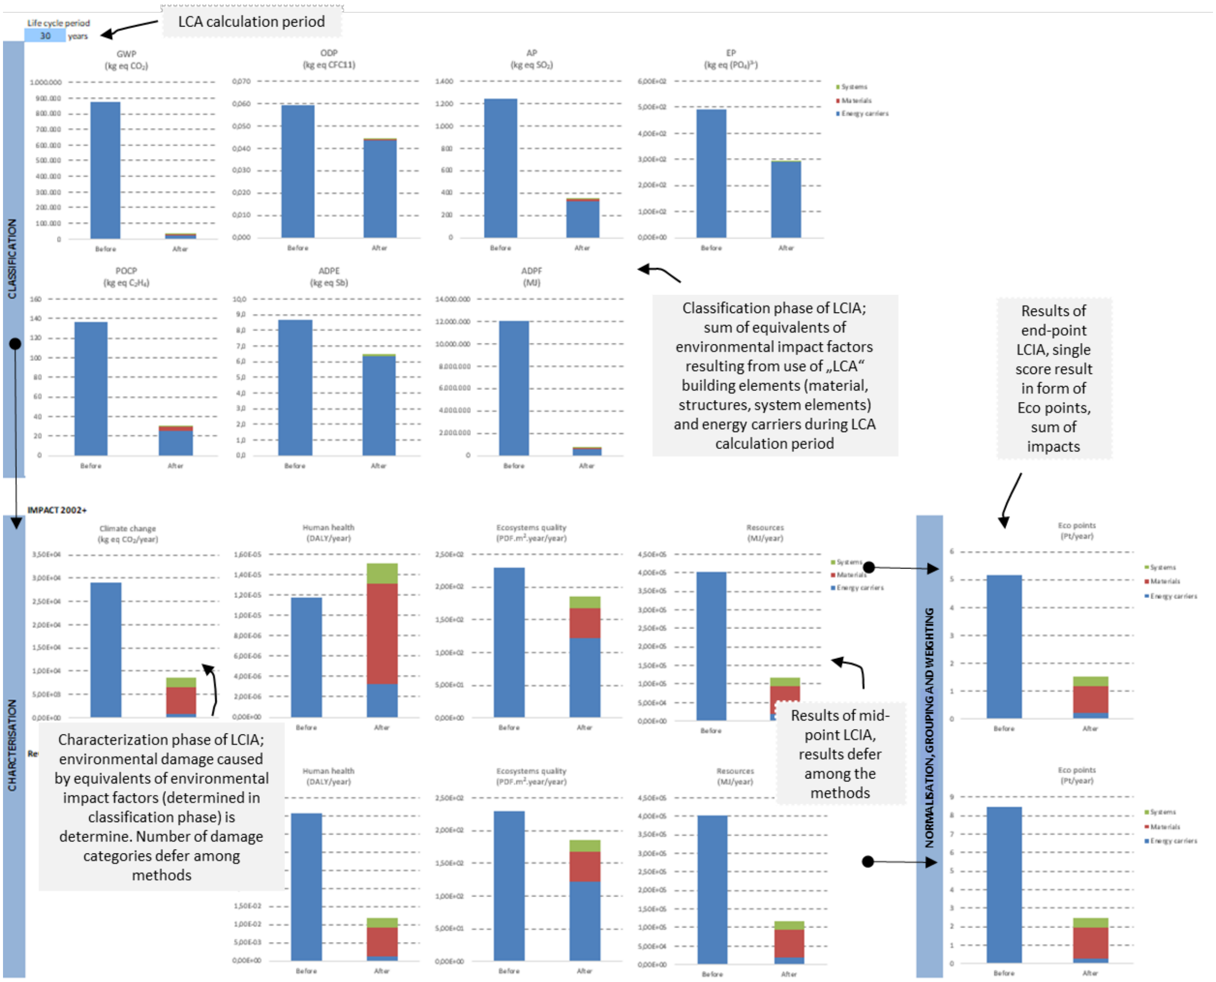

Figure 3. LCIA metrics displayed in E^{tool} as mid-point and end-point assessment.

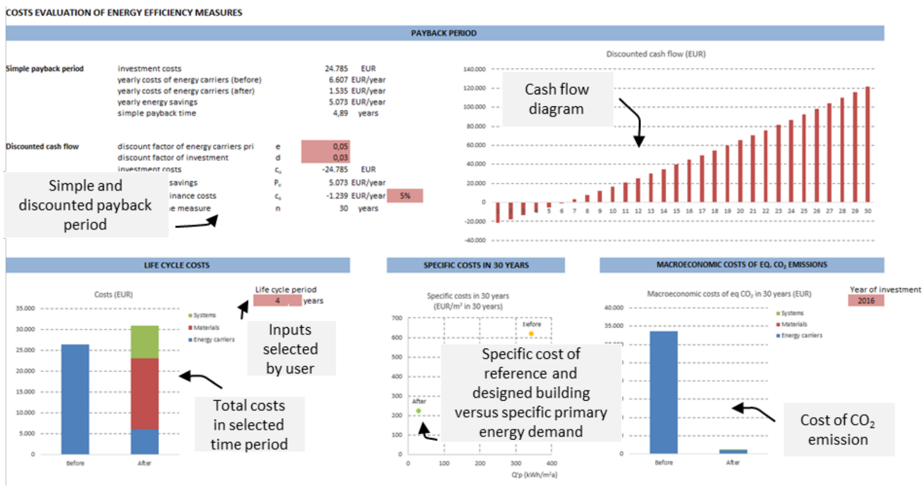

Figure 4. LCCA metrics displayed in E^{tool} showing cash flow diagram, LCC and cost of CO_2 emissions.

3. Study Cases

3.1. *An integrated assessment of the effects of energy retrofitting of a public building*

An example of an analysis of the energy retrofitting measures of a larger hospital in Ljubljana is presented (Fig. 5). The facility is heated by district heating system. District heat is also used for the DHW. Conditioned area of the building is 7405 m^2, energy needs for heating Q_{NH} 1.195,457 kWh/a and primary energy needed for operation of the building Q_p 1.865,362 kWh/a. Proposed and analysed measures are replacement of windows (U_w 3 W/m^{2}K → 1.1 W/m^{2}K), thermal insulation of the facade (U_{wall} 1.3 W/m^{2}K → 0.168 W/m^{2}K), and thermal insulation of the ceiling to unheated attic (U_{roof} 0.957 W/m^{2}K → 0.094 W/m^{2}K).

Figure 5. Hospital building in Ljubljana.

After the energy retrofitting, the specific energy needs for heating will be reduced by 75% (Q'_{NH} 161 kWh/m^{2}a → 39 kWh/m^{2}a), the final energy by 68% (Q'_f 220 kWh/m^{2}a → 70 kWh/m^{2}a) and the required primary energy for the operation of the building by 58% (Q'_p 252 kWh/m^{2}a → 107 kWh/m^{2}a). With a lower use of district heat (coal fired, 1,380 MWh/a to 320 MWh/a), CO_2 emissions will decrease by 345 tonnes per year, meanwhile emissions of $CO_{2,eq}$ will be lowered by 85 tonnes in the first year and by 270 tonnes every year after (Fig. 6).

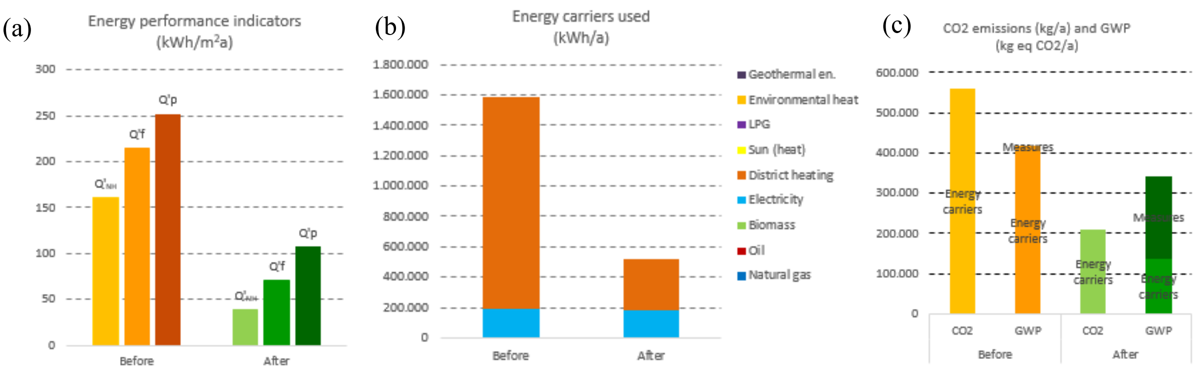

Figure 6. Results of LCEA: energy performance indicators (a), energy carriers (b) and CO_2 and GWP emissions (c) for reference project (before == existing) and retrofitted building (after).

The embodied energy of all energy efficiency measures (760 MWh) is lower than decried yearly energy demand (1040 MWh/a) for operation of the building indicating short "energy payback" period.

The operation of the reference building causes 0.58 DALY, while the retrofitted building will cause 0.48 DALY the first year, and 0.19 DALY/a in the following years. The number of Eco Points after retrofitting resulting from the use of energy carriers will be reduced from 68 Pt/a to 59 Pt/a in the first year and to 24 Pt/a in the rest of the calculation period. The investment payback time will, taking into account discount factors, d 3% and e 2.8%, and maintenance costs of approximately 0.5% per year, approximately 16 years. The cost of district heating and electricity for the operation of heating systems, DHW, ventilation and lighting will be reduced from the current 391 €/m^2 to 268 €/m^2 of the conditioned building area.

3.2. *Selecting technologies for nearly Zero Energy Building (nZEB)*

Passive reference building (A_u = 92 m^2, Q'_{NH} 11.9 kWh/m^{2}a) with pellet boiler and 600 l storage for heating and 300 l for DHW will be compared with following options: case 1: heat pump (A-W, 5 kW, heat storage 300 l), case 2: NG condensing boilers and solar heating system (SC 7.5 m^2, heat storage 300 l), case 3: NG condensing boiler for heating and DHW and 1.75 kW$_p$ grid connected PV power plant. Amount and structure of energy carriers is shown in Fig. 7.

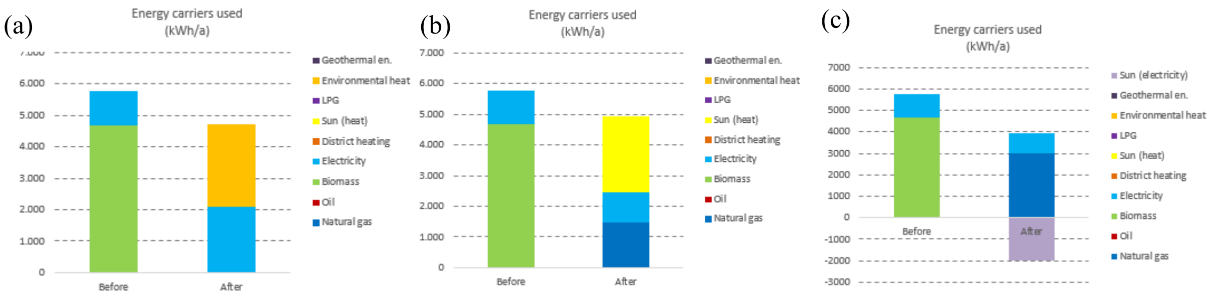

Figure 7. Amount and structure of energy carriers for reference case (before) and for the case 1 (a), the case 2 (b) and the case 3 (c).

Annual CO_2 emissions, calculated by the factors defined in Slovenian national legislation [17], are highest for the case 1 (1150 kg/a), and the lowest for the case 2 (750 kg/a). In all three cases, CO_2 emissions are higher than in reference case (as biomass is CO_2 neutral). Comparing GHG emissions (GWP) shown that the case 1 is the best solution due to the lower use of energy carriers and the high share of RES in the electricity mix in last years in Slovenia (Fig. 8).

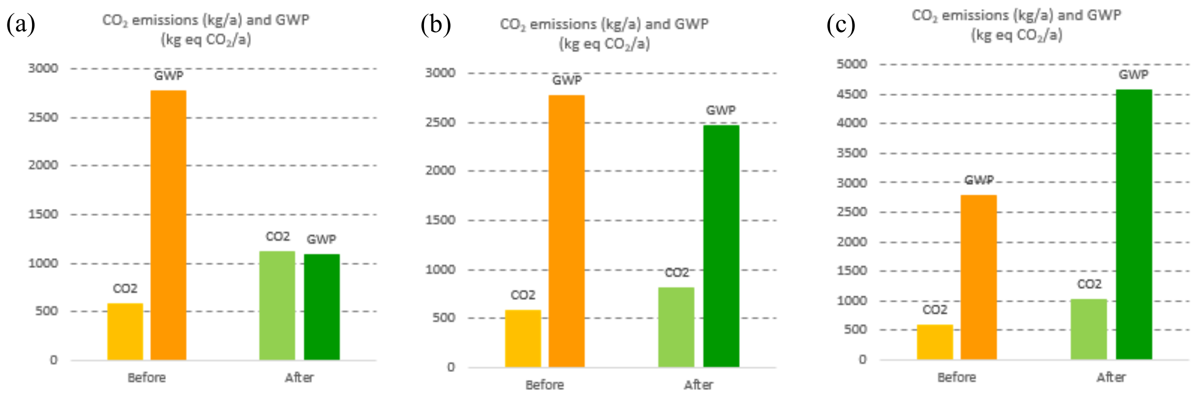

Figure 8. Annual CO_2 and GWP emissions for reference building, the case 1 (a), the case 2 (b) and the case 3 (c).

In comparison with the reference case (0.445 Pt/a), Eco Points in the first year of operation of the building would be more than a half lower for the case 1, approximately the same for the case 2 (0.425 Pt/a) and significantly higher for the case 3 (0.88 Pt/a), which is predominantly influenced by the environmental pressures caused by the use of materials and the production of system elements (Fig. 9). After the first year of operation, damage to the environment is caused only by the use of energy carriers, and the relationship between the cases is changing. The lowest number of Eco Points is typical for the reference case (0.075 Pt/a), the environmental impacts of the case 1 and the case 2 are quite similar (0.11 Pt/a, 0.12 Pt/a), while the number of Eco Points for the case 3 is almost doubled (0.19 Pt/a).

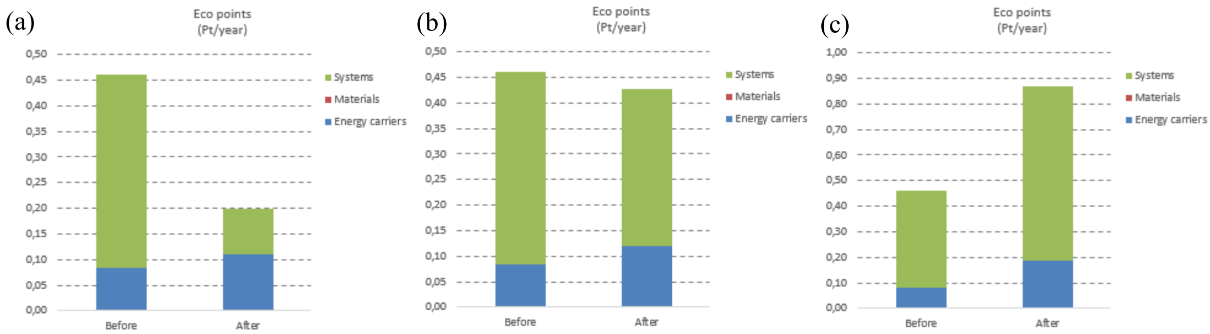

Figure 9. Eco points for the first year of operation for reference building and the case 1 (a), the case 2 (b) and the case 3 (c).

LCCA shown that costs are almost identical for the reference case (€ 18,200), the case 2 (€ 18,100) and the case 3 (€ 18,200), meanwhile life cycle costs are lower by 17% (€ 15,200) in case of the case 1. The total costs of the investment and the energy costs are roughly equal for the case 1 and 3, whereas for the case 2, the investment cost is 2/3 of the total cost of reference case over a 30-years period.

3.3. *Envelope energy retrofitting optimization of a multi-family building*

Study case of energy retrofitting of the envelope of multi-family building in Ljubljana with conditioned area of 1950 m^2 (Fig. 10). Building is connected to district heating system. As a reference project we took existing building, without thermal insulation and with old wooden frame windows (U_w = 3.0 W/m^{2}K). Energy needs for heating are 147.7 kWh/m^{2}a.

Figure 10. Multi-family building in Ljubljana.

Thermal insulation thickness was optimized on the basis of cost-effectiveness in the 30 years calculation period. The optimum thickness of 25 cm results in maximum specific cost saving 52 EUR per m^2 of useful area. Macroeconomic costs of $CO_{2,eq}$ emissions are lowest at much thicker thermal insulation layer, from which it follows that common practice to limit the grants with the thickness of the thermal insulation or with the U-value of the building structure is not adequate (Fig. 11a). LCA cost optimization of windows replacement shows that windows with double glazing are more cost effective and provide the same decrease in specific primary energy needed for the building operation (Fig. 11b). Macroeconomic greenhouse gas emissions costs indicator also gives priority to this technology.

(a) (b)

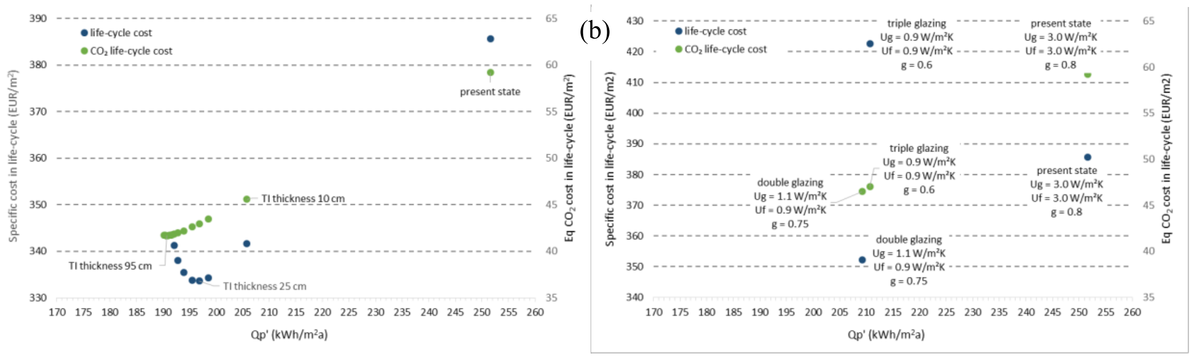

Figure 11. LCA thermal insulation thickness and window technology optimization on the basis of the life cycle specific costs.

4. Conclusions

Complex LCA evaluation computer tool was developed at the Laboratory for Sustainable Technologies in Buildings at the Faculty of mechanical Engineering (University of Ljubljana). Tool is divided into two connected units that enable life cycle energy efficiency (LCEA), environment impact (LCIA) and life cycle cost (LCCA) assessment. As life cycle environmental impacts assessment methods are not widely used, even sense of EPD is difficult to explain and number of assessment modules are more or less limited to A1-A3 and because life cycle assessment is accompanied by a number of prediction uncertainness, the authors of this article see the importance of a developed LCA computer tool primarily in education and learning assessment methods and sustainability of buildings. This is easier when methods are introduced through case studies and effect of the design decisions are promptly compared.

Abstract. Ensuring sustainability for real estate is subject - among other aspects - to building related information. This information needs to be stored and updated continuously throughout the life cycle of a building. A delivery to buyers, tenants, consultants or other actors must be possible at any time. However, in most cases transactions cause significant loss of information while the issues associated with the "building passport" approach remains unsolved to date. Considering the long service life of buildings, various questions arise: (1) How to support data generation and storage within the life cycle and how to encourage actors to compete? (2) How to assure a high data quality and how to store it over a long period of time? (3) How to assure that all data users can track down the data owners at any point of time to manage compliance and legal issues? (4) Are there any new business models or new scopes for designers or other service providers? Information needs of actors along the life cycle are analysed and new information technologies (e.g. blockchain) are discussed. A relation to Building Information Modeling (BIM) is shown. Potentials of enhancing existing approaches regarding documentation retracing and accessibility of building and life cycle related information by using new technologies and IT are discussed; benefits of using a blockchain based system is pointed out by referring to existing pilot projects and first examples. Solution approaches for building passports are shown.

1. Introduction

The implementation of principles of sustainable development in design, construction, and use of buildings requires that the economic, environmental, and social impacts of each decision are taken into account. This demands a reliable and comprehensible basis for decision-making. The collection, processing, interpretation, transformation and communication of suitable information that supports decision-making thus becomes an essential prerequisite. In particular, the increasing adoption of life cycle analysis with its quantitative methods of life cycle assessment and life cycle costing, which is used to support design and investment decisions, requires a considerable amount of data. This also applies to the economic valuation, risk assessment and due diligence of buildings, which incorporate sustainability aspects to a greater extent than in the past. This requires the exchange of information between actors, the configuration of information flows along the value chains, appropriate information management and the application and further development of data processing systems. Indeed, information forms an essential basis for decision-making, but also legal and economic consequences are associated with it.

The "value" of information is growing, as is the risk of dealing with false or incomplete information. At the same time, it is a special feature of buildings that information must be stored over long periods of time and partly updated or supplemented. This raises a number of questions: (1) How to support data generation and storage within the life cycle and how to encourage actors to compete? (2) How to assure a high data quality over a long period of time? (3) How to assure that all data users can track down the data owners at any point of time to clarify on compliance and legal issues? (4) Are there any new business models or new scopes for designers or other service providers. These questions are explored in the present article.

2. Current trends in the demand for building-related data

At present, several developments can be identified that will lead to an increase in the demand for building and life cycle related data. These are among others:

- The introduction of level(s) [1]: The European Commission (EC) has developed the basis for a reporting instrument which serves to present and communicate sustainability-relevant features and characteristics of buildings. This is currently being tested. Among other things, the instrument deals with the effects of sustainability-relevant features and characteristics on the value of real estate and its development as well as the associated risks. For the first time, through the introduction of an indicator dealing with value creation and risk factors – namely indicator 6.2 – an attempt is made "to provide information on the reliability of the underlying data and calculation methods on which a reported performance is based."[1] This points to the need for a transfer of information from sustainability assessment to valuation and risk analysis with simultaneous quality control.

- The development of a taxonomy to record and evaluate the contribution of real estate projects to sustainable development [2]: The EC has launched an initiative on "Sustainable Finance." One sub-aspect is "green finance". The aim is to channel financial resources towards projects that contribute to sustainable development, particularly in the area of climate protection and resource conservation. This implies that in future banks will need reliable information on whether and to what extent a to-be-build or to-be-renovated real estate has an above-average environmental performance for project financing. This is to be achieved by means of a taxonomy that summarizes sustainability-relevant information in a form that can be interpreted by banks.

- New approaches for the development of lifecycle-accompanying object documentation in the form of building passports or building files [3]: In a current Global ABC initiative, an attempt is once again being made to agree on a format for the collection, administration and communication of building data that is required during the lifecycle by owners, administrators, experts or third parties. This is a continuation of efforts, in some cases lasting decades, to introduce building passports, which have not yet led to a result so far.

- The results of BAMB [4]: One of the main proposals resulted from a recent research project funded by the EU is the documentation of the material composition of buildings in the form of material passports. Further research projects go in a similar direction. There is a close connection with the goals of a circular economy.

- New guideline for waste audits before demolition and renovation works of buildings [5]: The guideline plans the compilation of information on the type and quantity of materials used in the building and on recycling possibilities in preparation for dismantling or conversion work. This can be facilitated by taking over information from the design phase of buildings.

It becomes clear that the requirements for object data are currently growing, not only in terms of type and scope, but also in terms of quality, reliability and traceability. Thus, the following requirements for building- and life cycle-related data can be formulated. In particular, data should

a) meet the information needs of actors on selected occasions in the life cycle of buildings,
b) be extracted/processed to the extent possible from information already generated during design, construction and management processes in order to save time and money,
c) be permanently available - here in terms of lifecycle support -, including their history,
d) be updatable / overwritable and expandable, with the respective history,
e) be clearly assigned to a data source/author who vouches for the correctness of the information and assumes a corresponding liability,
f) be machine-readable / processable (e.g. BIM-compatible / BIM-able), and
g) be (globally) accessible when access conditions are met.

The listed requirements are important for different types of information. These are presented in Table 1 including a distinction between static and dynamically generated data.

Table 1. Selected types of information to manage in the life cycle of buildings (Lützkendorf)

Type of information	static	dynamic
Information on location and land	X	(x)
Excerpt from the land register	X	(x)
Approval documents (e.g. building permit)	X	(x)
Planning documents incl. drawings - new building/updated (a)	X	(x)
Image documentation		X
Expert reports (e.g. subsoil reports)	X	(x)
Participants in planning incl. contracts - New construction	X	
Participants in the execution incl. contracts - New construction	X	
Acceptance protocols and warranty periods - New construction	X	
Bill of materials – New construction/ updated	X	(x)
Cleaning, maintenance, repair instructions (e) – New construction/ updated	X	(x)
Energy performance certificate (always latest version)	X	(x)
Information on environmental and health compatibility (b)	X	(x)
Information on technical quality (c)		
Other certificates (e.g. sustainability certificate) - New construction	X	
Insurance documents		X
Usage data (Energy, Water)		X
Usage costs		X
Status of the maintenance reserve		X
Documentation of maintenance activities		X
Indications of possible pollutant inputs from use (d)		X
Documents for reconstruction, (various, see new building)		X
If available, Leasing contracts (e.g. green lease)		*X*

(a) Incl. references to won competitions
(b) Incl. risks to local environment and health, with regards to the carbon footprint
(c) In particular with respect to stability, sound insulation & room acoustics, fire protection, moisture protection, thermal comfort in winter, thermal comfort in summer, visual comfort, accessibility, flexibility, rebuildability, deconstructability, recycling friendliness.
(d) e.g. for the use of buildings for chemical cleaning, industrial buildings, etc.
(e) *Incl. indication of cycles*

From Table 1 it becomes clear that some documents created during the design phase must be updated and supplemented during the further use of the building. On selected occasions (e.g. lending, insurance, valuation, transactions), the information contained is passed on to third parties (e.g. valuers, insurance brokers, buyers) and used by them. Figure 1 shows examples of such information flows.

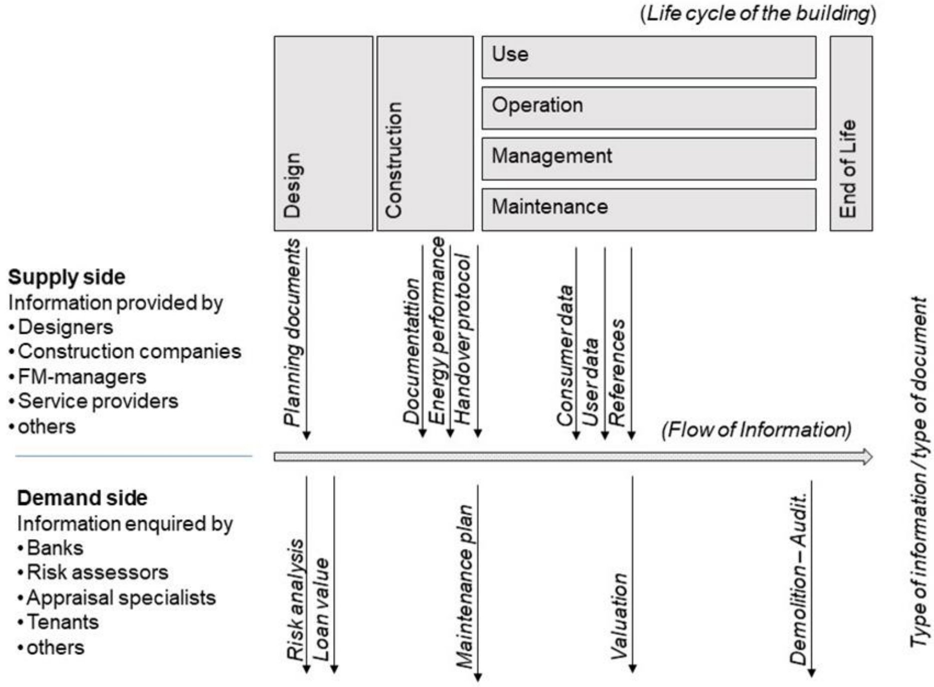

Figure 1. Selected types of information flows in the life cycle of buildings (Lützkendorf)

"*Globalization*" also leads to transactions in the real estate industry that are far away from traditionally known submarkets and thus to the need for reliable data on properties and market conditions at other locations. Ultimately, the trend towards "*Digitization*" offers solutions. To answer the above-stated questions, the possibilities offered by current IT solutions, such as BIM, databases/clouds and blockchains are discussed in the following.

3. Brief introduction of solutions

3.1. Building information modelling (BIM) and BIM Level

BIM – a virtual model as the digital twin of a building – is an approach to support documentation and information flows during the entire real estate life cycle, from the early stage of conception through the more detailed design stages and the construction process (where it enables all parties to work on a shared model) and up to the operation and management of the complete building and its final deconstruction. The concept has been around for years; however, it had a major focus on the design and construction phases [6]. Since all building- and material-related information is stored in a central location from the start of the design phase, BIM shows great potential for embodied and whole life carbon calculations, especially in the early design stages [7]. To speed up and support the process of implementation during all phases of a real estate life cycle, the so-called BIM Levels were introduced to give an assessment of the current implementation status of a model (referred to as maturity of a model). While Level 0 indicates that there is no collaboration and most information exist in printed or electronic printed 2D drafting, Level 1 includes first 3D CAD concept work, CAD standards, and file sharing over a common file sharing system. Level 2 is the first system with advanced knowledge and information transfer with implemented workflows between serval parties. The final level, Level 3, which is not fully defined yet, is considered as being a fully digital knowledge and information transfer characterized by full transparency and based on a single model shared between all participants.

In addition to the introduction of the above-mentioned BIM-Levels to describe the maturity of a model there are seven, so called "dimensions", which describe how the included data is linked with each other. While all dimensions up to dimension 4 relate to data about the construction object and the construction sequence (compare to "design" and "construction" in figure 1), dimension 5 to 7 add additional information (everything following the construction phase in figure 1). Particularly dimension 5, the cost analysis, and dimension 6, the sustainability evaluation, are relevant when it comes to taking BIM further than the construction phase towards lifetime documentation and facility management. Existing literature shows benefits of using BIM as a facility management tool [8] but they clearly indicate that there are some open issues, as stated in section 2 of this paper. A lot of data such as energy consumption, maintenance or leasing contracts is dynamically generated and must be therefore frequently updated during the life cycle. This requires clear roles and responsibilities among the different involved actors.

3.2. Clouds and databases

The concept of a database is nothing new, however, new possibilities of storing information globally accessible in clouds, including change histories, made it an attractive solution to storing information over the entire life cycle. Cloud based offers for real estate documentation are already available, including features such as valuation, data transfers to other users and active real estate management. Cloud and database solutions are the most popular solutions these days. However, it is important to distinguish between the stored data types. Some use digital databases for storing electronic print documents which are not (or only partly) machine readable, while others use it to store data, which is fully machine readable and ready to be processed. The later solution is the more advanced and complex solution, as it enables data-driven analysis without any human interaction. In order to get to this point, it is a key success factor to reliably transfer print information such as paper scans into machine readable data. There are a few solutions in the market already, but they all include manual support and are not very reliable yet [9].

Since BIM models can also be managed on servers or in clouds, it is difficult to make a clear distinction between these two technologies.

3.3. Blockchain

Thanks to the strong development of Bitcoin [10], there has been a lot of attention to the topic of blockchain. A blockchain can be understood as a decentralized database whose entries are immutable [11]. Blockchains can be categorised in two major categories: "*Public Blockchains*" where everyone can compete, validate, and look at all transactions, and "*Private Blockchains*" where an invitation is required to contribute to the network. During the past year a new category has been forming called "*Hybrid Blockchain*." Hybrid Blockchain consists of private ledgers which are all registered in a public blockchain. This joins the benefits of both, full transparency and immutability from public ledgers and data privacy from the private ledgers [12].

The major benefit of this technology is the possibility of performing transactions without any trusted parties or middle man. Object of a transactions can be anything from cryptocurrencies like Bitcoin to properties or simple data. Once a transaction is validated, it is consolidated with other transactions to build a new block. To ensure that manipulation in the blockchain is prevented, a process called "hashing" is used compressing the content of the block into a string of a set length. The major benefit of hashing is that the output of the algorithm changes entirely, if a single character of the input is changed. As the hash of every block also contains the hash of its predecessor, it is assured that, if a block is manipulated, the error will cascade down through all blocks which have been added after it, revealing the fraud. In order to manipulate a transaction, one would therefore have to manipulate every single copy of the ledger at the same time, which is impossible.

To finally add the new block to the existing chain and distribute it across the network, a consensus protocol is used. There are different implementations such as the proof-of-work or the proof-of-stake, all having in common to achieve a consensus between all users across the network about what the truth is and whether a block can be added or not [13]. In the current market, there is only a limited offer of solutions based on blockchain. The current development is mainly driven by two types of companies, on one hand, big software enterprises and, on the other hand, small startups with a major focus on real estate.

4. Discussion

The discussion addresses the questions raised in the introduction. Among other things, it is discussed whether and to what extent job-sharing approaches between different IT solutions can be developed.

4.1. How to support data generation and storage within the life cycle of the building and how to encourage actors to compete? (1) Addressing data requirements a) and b) in section 2 of this paper.

Data generation, as the start of the data life cycle, is one of the most crucial points of data management since this sets the base for all further activities, such as data interpretation and data transfer.

When it comes to the question of where and when to register a property in a blockchain or a cloud, a potential link to BIM can be seen. As BIM is currently mainly used during the design and construction phase – the start of every real estate life cycle – this could be a promising entering point. BIM up to Level 2 and dimension 4 covers all relevant information, such as plans, materials used and contractors involved in the construction process. Once the construction process is completed, the BIM Model could - from the point of view of the authors - be transferred into a Blockchain assuring that no information gets lost. At the same time, it builds a framework for future information flow (compare figure 1) within the remaining life cycle of the real estate. To ensure a smooth transition, industry standards like the IFC (Industry Foundation Classes) [14] are of great help. To assure the usage of a format like this, political support in the form of setting requirements for minimal information which must be provided when transferring an object would be of great use. A further potential tool to assure information content and format standards could be based on the building passports, a certificate which is used to describe all relevant properties of a real estate. To support that data security during the construction process, it is also possible to link the blockchain to a BIM model as a backbone. [15] shows an interesting approach where all new information of a model update is consolidated in a new block, which is then added to the blockchain. This would lead to two major benefits: 1) The transition process from BIM to blockchain will be easier and more efficient and 2) data security can also be assured during the construction phase of a real estate.

Once the information is stored in a blockchain, an open question is how to convince property owners and property users to compete on keeping and updating all relevant information in a blockchain. For both sides, the most important requirement will be an easy-to-use and intuitive interface to make it as simple as possible for all users to compete. This is a very crucial point as this will be the first hurdle to take for users. The second major requirement is the verification process. Standard concepts such as the proof-of-work or proof-of-stake are based on monetary incentives for the miners to validate the added information [16]. When applying this concept to real estate documentation, the question of who will be the actor paying out incentives arises. In an ideal case, which assumes that a buyer is willing to pay a premium for a property if the data is complete and of good quality, the property owner could have this interest to pay for up-to-date information. However, looking at the current market situation, there are a lot of unexperienced actors who are not aware of the importance of good documentation. A lot of transactions are based on incomplete information with further data loss. Hence, one must find another compelling way to convince owners to compete. Only if banks and insurance companies demand consistent data more than before and make conditions more dependent on it, as it is intended with the new approach of taxonomies, the "value" of information will become clear and the willingness to pay for good information will increase.

For data transfer from BIM to a cloud the transition is a lot easier to realize as no incentives or validations are required. In some cases, the original BIM model is even created and stored in a cloud environment right from the start [17]. Depending on the database structure, the BIM model could be included as the main structure of the data set or as part of additional information.

4.2. How to assure a high data quality over a long period of time? (2) Addressing data requirements c) and d) in section 2 of this paper

Data quality is one of the most important requirements when it comes to storing information along the life cycle of properties. Blockchain and its characteristics mentioned in section 3.3. can be a key success factor to improve the data quality of real estate information. Once information is included into a block of a blockchain, it can neither be changed nor deleted or lost leading to assured data consistency and quality. As an actor, who requires information, it will therefore be possible to search the blockchain for the information he/she needs, knowing that there is no risk of losing any information which has been added.

Depending on how a database or cloud is used, it could also lead to high data quality under the precondition that a change history can be stored, showing when information has been changed and what the initial value was. The major problem is that in these systems there is always an administrator who has full access and change authority. Therefore, the scenario of an actor manipulating information, e.g. in order to achieve a higher selling price, is something to keep in mind. In other words, it is not impossible to change information or delete change logs. Nevertheless, if industry standards such as the building passport would set the minimum information requirements which have to be documented this technology provides a solid data quality. The data quality of BIM is strongly dependent on the different models and the implemented dimension. Since there are no industry standards or minimum requirements yet, the data quality can be different in every model. In existing literature such as [18] the authors propose an interesting data standard as a combination of GIS proven data quality standards and ISO/TS 8000-1:2011 with focus on data provenance. By focusing on data completeness, metric accuracy, thematic accuracy, temporal accuracy and logical consistency the stored data would meet the required data quality over a long period of time. However, this would need to be ensured on a technology level, allowing to add information only if all standards are fulfilled. As of today, the current systems still do not have such capabilities and bear the risk of manipulation through the system administrator.

4.3. How to assure that all data users can track down the data owners at any point of time to clarify on compliance and legal issues? Addressing data requirements e) and f) in section 2 of this paper

Another useful characteristic of the blockchain technology is that at every point in time information can be tracked down to its owner/adder. In terms of compliance issues, this is a significant benefit when it comes to storing real estate information. A common issue is that there is no clear ownership for existing information. This causes problems when it comes to wrong information or bad decisions based on wrong information. Using blockchain to store all information would overcome this issue, always allowing to reach out to the data owner to clarify in case of uncertainty [19].

In most of the current cloud solutions an owner tracking including a change history is possible. Usually the history is even part of the user interface ensuring great visibility of the data ownership.

According to the data standards for BIM proposed in 4.2., a data owner and change log tracking is also possible in BIM models, given that it is supported on the technology level.

In all three cases, an open question which would need further investigation and research is how to handle the data ownership during transactions. As of now it is not clear whether the data ownership and data responsibility will be transferred to the buyer or stick with the actor who added the information to the blockchain in the first place.

4.4. Are there any new business models or scopes for designers or other service providers?

Thanks to the immutability of blockchain, a potential use case for blockchain is the creation of a blockchain based land registry. Sweden has been running a successful trial since 2016 with the target to extend and fully cover all properties in Sweden [20]. Furthermore, blockchain enables the tokenisation of properties which opens the opportunity to invest in pieces of properties, making it more affordable for everyone and not only actors with major liquidity [21]. Together with smart contracts, blockchain can also be used to manage properties and automate processes like maintenance work, rental payments and even contract management [22]. For designers and architects, it will be increasingly important to adapt to the current technology standards and build up expertise with the new tools. Design models should be offered as integrated solutions in currently existing industry standards to remain competitive.

The answers to the questions raised show that the IT fundamentals are available for improving information management throughout the lifecycle. Furthermore, a division of labour between the use of BIM in the design phase and systems for managing data over the life cycle are emerging. In the competition between these systems, it remains to be seen if this division of labour will succeed or if individual IT approaches will develop into complete solutions for the generation and management of "life cycle data", a term which was characterized in the context of a major project [23].

5. Use case and recommendation for action

For providers – e.g. prefabricated house manufacturers, who already hand over a house file to their customers today – there is the possibility of a permanent administration and provision of information. Using solutions available on the market (e.g. see [24] or [25]), the information types shown in chapter 2 can be stored with clear structure in a blockchain. In this case, the blockchains primary function is a database, which is forgery-proof and loss-free. Data such as information on materials used or the exact position of cables and pipes, which are often lost, are thus reliably stored. If a building is sold at a later date the buyer can see which materials were used in the construction and where pipes or cables are located for possible reconstruction work. Furthermore, a documentation like this is the starting point for blockchain-based real estate transaction [26] where the asset works as a digital security unit (DAI) [27].

Section 2 of this paper showed that the demand for building-related life cycle data is currently growing. This applies not only to new players (e.g. banks) on the demand side and the growing urgency and relevance (effects on property value and financing), but also to new occasions (deconstruction planning) and additional topics (bill of materials, life cycle assessment). Sections 3 and 4 demonstrate that suitable IT solutions are available. So, what is currently holding back the progress? The extremely heterogeneous construction and real estate industry has so far failed to clearly articulate the data needs of relevant actors on selected occasions. This is not a technical problem but a problem of content. Only if the demand for information can be clearly described approaches such as building passports can be developed further in a sustainable way. Therefore, an industry standard for structuring the exchange of information on buildings between involved actors in the life cycle of buildings is proposed. Available literature, including preparatory work by one of the present authors, provides initial approaches in this respect [28 – 32].

6. Summary and Outlook

Emerging technologies like blockchain and BIM have a great potential to support information management during the life cycle of real estate. Blockchain has a major benefit on the data security, however, one needs to carefully consider in which cases an implementation of a blockchain is beneficial. Thanks to the current development of BIM and databases/cloud computing it is also possible to secure information with its history. If there is a way to control the system-administrators it is the easier solution as of today. Still, blockchain will be a technology to keep in mind during the upcoming years and actors should have plans ready to quickly adapt to the technology if it becomes a new standard. Further business models such as making a real estate "blockchain-ready" or evaluating existing properties on the blockchain based on the stored information could be very profitable for actors who are quick to adapt.

frank.hilbert@tu-dresden.de

Abstract. The planning and construction of buildings and structures is based on collaborative building information processes. The information supply of these processes is characterized by the exchange of heterogeneous domain-specific information. For the treatment of most problems in the construction industry, the information involved is rarely considered in isolation, but rather elements from different information models are linked with each other. The concept of the information space has established itself for the persistence of such linked information models. For sustainable building, the continuous use of existing information models or information spaces is indispensable. Various implementation approaches exist for information spaces in civil engineering. One approach that is currently in the initial phase of standardisation and will therefore spread further in the construction industry is the multimodel approach. For large construction projects or more complex buildings, multimodels become very large and often contain information that is unnecessary for the respective processing situation. This makes the handling of such multimodels cumbersome and slows down the acceptance. One approach to reducing multimodels is to adapt them to the information needs of the respective information process. Information processes are embedded in a task context that essentially determines the information requirements of the process. In order to anticipate such situational information needs, this paper presents a method to define context-adaptive multimodel templates based on a formalization of the context dependencies of the information requirements. These can be evaluated at the time of application towards situation-specific information requirements and form a basis for the creation of situational information spaces for the realization of a context-oriented information supply.

1. Introduction

1.1. Interoperability in Construction

In construction projects, various organizational and functional information must be processed together. This information describes architecture, engineering and management aspects for both, the representation of physical and functional properties of a building and for its construction and is bundled by various model-based domain-specific information models (e.g. cost models, time models or construction models) or as unstructured project information (e.g. catalogs, examples, contract bases).
For the construction industry the information formats are established and can therefore not be changed without great effort. The processes for generating and using digital information models for the planning, construction and operation of buildings during their entire life cycle are dealt with by the Building

Information Modeling (BIM)[1]. Digital information models form the basis for a common effective information logistics for all parties involved in the construction process.

1.2. Applications and Collaboration Platforms

The information models are created and processed by specific software applications (e.g. CAD, FEM or planning software). Their native exchange formats are highly heterogeneous. However, the special applications that are customary for different application areas have reached such a high degree of maturity that their use is indispensable. The collaborative processing of these information models takes place within cross-model, cross-format, cross-domain and cross-organizational building information processes. In order to achieve project-wide interoperability of the information models, adaptations or new developments would be necessary, which are too expensive for the mostly small-structured companies in the construction industry. Instead, the concept of integrating existing applications via cooperation platforms is favored for collaboration [2][3]. The collaboration platforms frequently used in construction projects offer different components and services depending on the level of integration and often contain their own information logistics components that enable data exchange between heterogeneous software tools of the project partners without the need for special coordination. The approach proposed in this paper for the context-oriented provision of information for building information processes is based on such a platform architecture. The structure of the platform and the composition and use of contextual information is only briefly presented in this paper for reasons of space. More detailed information on the proposed context-aware collaboration platform can be found under [13]. For more detailed information on the use of context, please read [16].

1.3. Information spaces

However, for most problems in the construction industry, the individual information models are rarely processed in isolation. Often elements of different information models, which are separated by the data technology, refer to same aspects and must be linked together for the treatment model and format-spreading. In particular, building-specific 4-D and 5-D software applications (e.g. iTWO, Navis-works, Synchro or Visco Office Suite) connects building structures with elements of planning and control models. The dependencies of the model elements are usually mapped into the data structures of the respective specialist application and are stored in a proprietary data format after the information process or are even discarded altogether. To avoid having to recreate this link information each time, it makes more sense to save the dependencies together with the information models concerned. The term information space has established for such a networked information model. [4]. The use of linked model elements in an information space comprising formats, models and domains leads to an increased information potential compared to originally separate information models, which is indispensable for the processing of many tasks in the construction industry. If, for example, the positions of a bill of quantities are linked with the operations of a preliminary model and elements of a building model, time, quantity, geometric or cost-oriented statements can be derived relatively simple. Two essential approaches exist for the exchange of information spaces in the building industry.

One approach is the generic multimodel [5]. This approach makes it possible to model the relationships between unchanged information models by linking their elements externally in a special link model. The links are multivalent, which means that more than two elements can be linked and these elements can come from more than two different information models. In addition to the domain-oriented models and the Link Models, a multimodel contains additional meta-information describing the general properties of the whole multimodel as well as the properties of the Link Models and the interlinked information models. For the exchange of information, multimodels are serialized as multimodel containers (MMC) with project-wide unique annotation vocabulary. Figure 1 illustrates the structure of a multimodel container on the left. Two linkmodels (left) combine the logically connected elements of different subject models for different intentions. The exchange format is published as MMC 2.0 container by BuildingSmart [6]. The multimodel approach is standardized by DINSPEC 91350 for BIM-

LV containers (IFC + GAEB). There are currently efforts to define further specialized containers (e.g. ecological construction data containers, fire protection containers, etc.).

In addition to these approaches from Germany, an interdisciplinary container for the exchange of information in construction projects was also developed in the Netherlands as part of the COINS research project [7]. The goal of the project was the standardization of a flexible information container for the connection of the entire building data set with networked data approaches.

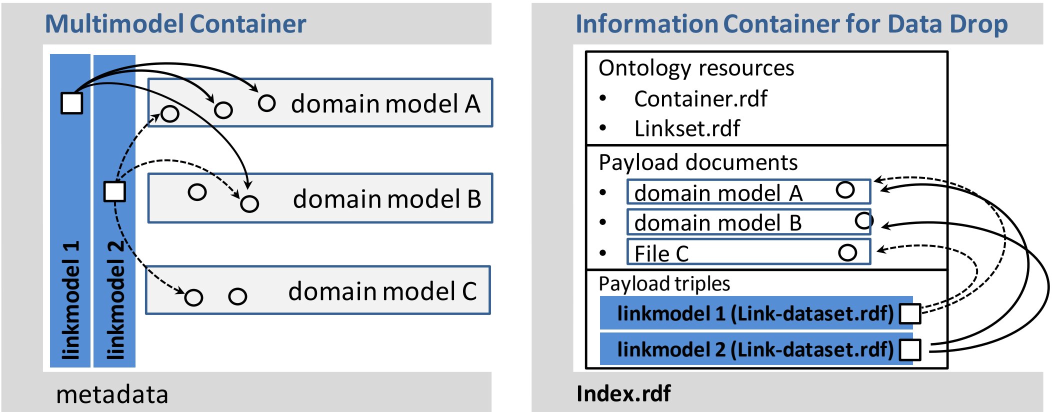

Figure 1. multimodel container structure vs. ICDD container structure

For this purpose, two versions of an information space container were published in 2010 and 2014. These versions are the predecessors of the Information Container for Data Drop (ICDD), which, similar to the multimodel, are intended to establish semantic interoperability between data or information with different data formats and domain affiliations. The main difference to the multimodel is the use of ontologies. Interdependencies between data elements are formulated as triples within the XML-based format RDF. The standardization of the ICDD takes place in two parts by the ISO, whereby ISO/CD 21597-1 describes the contents of the container format and ISO/CD 21597-2 contains the description of the semantic ontology. Both parts were accepted by ISO and CEN at the end of 2018 and ISO certification is expected in 2019 [8]. Since DINSPEC91350 is technically compatible with the ICDD-ISO on a .xml basis, multimodels can be expressed and transformed into the ICDD format. Figure 1 shows the Structure of the ICDD Container on right.

1.4. Information space enabled collaboration platforms

For the exchange of information spaces in construction projects the information logistics of the involved collaboration platforms must be upgraded accordingly. A corresponding service platform, which connects the software systems used by the construction project partners and provides the infrastructure for the collaborative use of multimodel containers, was presented in the Mefisto research project [9]. As an example, the existing GRANID specialist applications were prototypically linked with the platform services of gibGREINER GmbH (for use by the customer) and the RIB iTWO of RIB Software AG (for use by the contractor). The structure of the cooperation platform, its functionality and its use as a virtual organization of a construction project is described in [10].

1.5. Information space issues

With the increasing complexity of the building and the construction project as well as the increasing number of actors and domains involved, the quantity, scope and granularity of the information models used are increasing correspondingly. In the planning phase in particular a large number of information models are created, which, in addition to the building itself, also affect the building permit or the organization of the later realization phase. Depending on the type and size of the construction project, different types of construction plans, documents and CAD files are exchanged between the parties involved in the construction. This can range from 2000 documents (shell construction) to up to 4000 (turnkey construction for shopping center) (see Figure 2). The reason for this development, in addition to the increasing complexity of construction projects and buildings, are the increasing quality requirements placed on the used information models as a result of the extended scope of tasks. In addition to the changed legal regulations, new, more complex production processes, special work steps and a number of new requirements must be taken into account, which concentrate on specific questions such as of energy efficiency, sustainability or additional life cycle considerations and areas of responsibility.

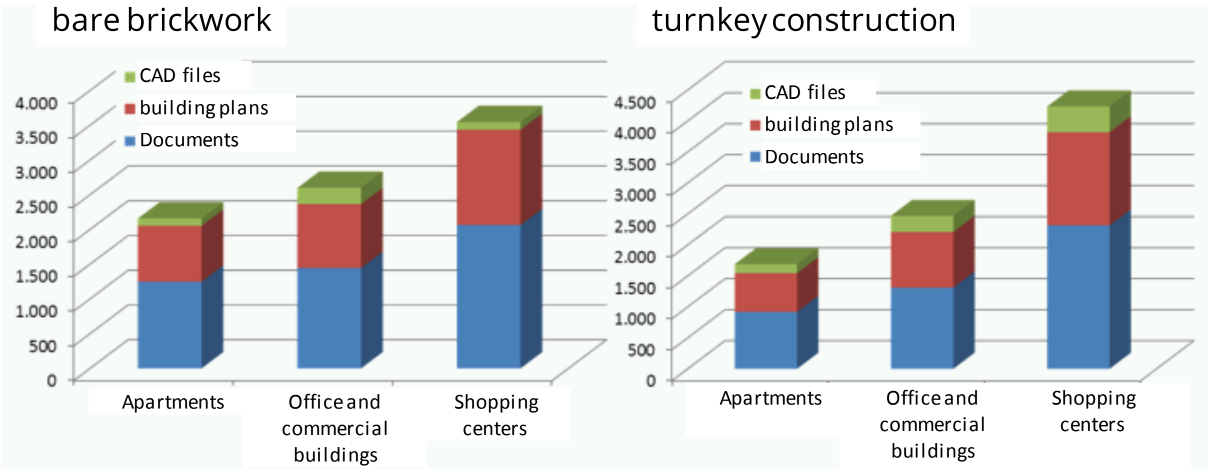

Figure 2. Average number of document types for construction projects, (source: planConnect GmbH Dresden)

With the information models, the resulting information spaces also grow and hinder the effective cooperation between the project partners. Especially in large, complex data structures the orientation effort is increased and a targeted search for required partial information as well as the tracking of model dependencies becomes more and more difficult. In addition, the semantic interpretation of the model contents is also a major hurdle for laypersons and machines. Therefore, it is difficult for those involved to estimate which parts of the information space are relevant for a current task. Against the background of this initial situation and the expected further increase in the volume of data, the targeted provision of precisely tailored information is becoming increasingly important for project success [11]. Such a provision requires intelligent information logistics that reduce the scope and complexity of the information models to be exchanged and thus ensure that the information processes are provided with information that is appropriate to the situation

2. Approach

Many tasks in the building industry require specific model sections, model qualities and model interrelationships. Often only, certain building parts, corresponding properties and allocation units or individual dates and time windows are considered. For the determination of precisely fitting information spaces for construction information processes an estimation of the information requirement is therefore necessary. Here a context dependence of the information need can be recognized. In this different aspects of the respective processing context determine the concrete extent and the quality as well as the linkage depth of the currently needed information spaces. For this reason, it is necessary to take a close look at the processing situation in order to anticipate the expected need for information. Building information processes are embedded in a processing context, which is primarily determined by three main elements: Process, actor and resource. In order to represent this processing context in a machine-readable way, a context model is required that formally represents the processing situation in a hierarchical structure [12]. Such a context model is presented under [13]. This model bundles the three main aspects and the associated sub-aspects (see Figure 3).

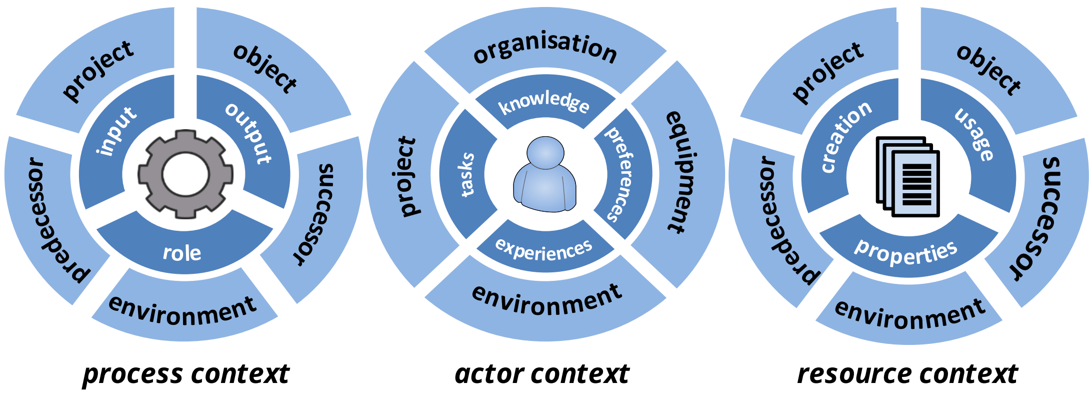

Figure 3. Context Areas [16]

There are two main points to consider when using contextual information. On the one hand, the individual context aspects have a different influence on the information requirements and on the other hand, the information logistics context information differs in relation to its update rate. Thus the relatively static actor context differs from the more dynamic resource context and from the highly dynamic interaction context. Therefore, not all context information can be determined in advance, but must be considered at the time of application. Only the selection of the context information relevant to information requirements and the type and scope of its influence on the information requirements can be estimated in advance.

In order to describe information needs in this work, the multi-model approach is preferred to the ICDD approach, since the former offers the possibility of formulating specific information space templates. Therefore, the multi-model approach is used and extended in the following to describe a situational information need.. In order to make multimodel-based information spaces accessible for automatic processing by information systems, the multimodel approach offers a comprehensive semantic description of the information models and link models involved [14]. The semantic description of the multimodel can also be used prescriptively for the specification of required information spaces. In this way, requirements for a multimodel-based information space can be formalized as so-called multimodel templates (MMT) without embedded or referenced model instances (as also defined in DINSPEC 91350). Descriptive properties of the information models involved are specified, which define their model qualities (e.g. excerpts, granularity and specialization). Figure 4 illustrates a multimodel template for the tendering of construction works and the corresponding multimodel container.

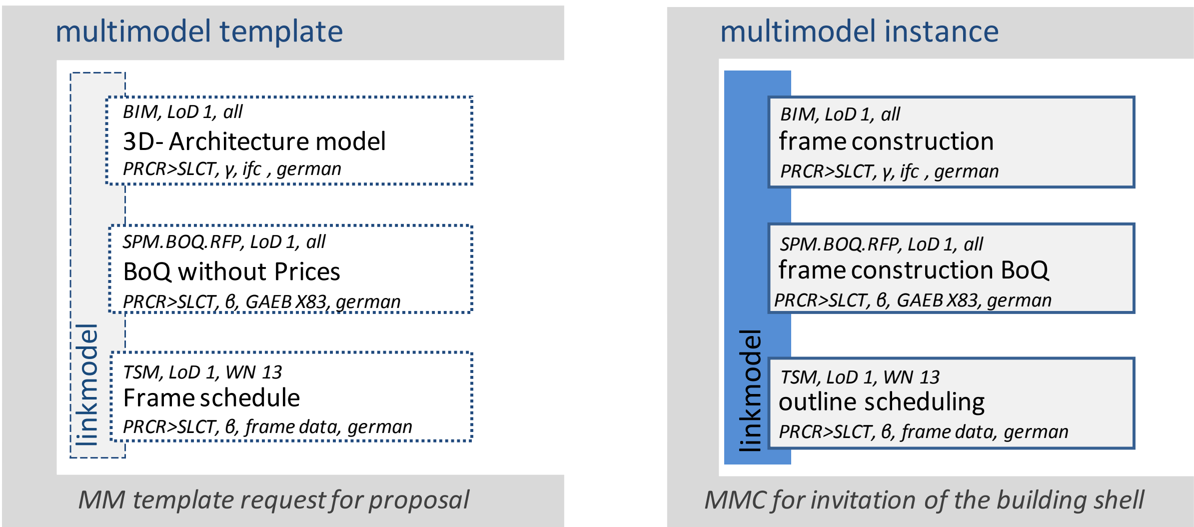

Figure 4. A multimodel template and corresponding multimodel container [16]

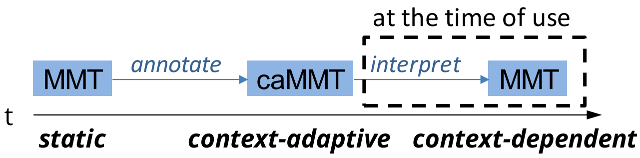

Figure 5. Creation of Context-compliant multimodel templates

The multimodel template shown here requires a multimodel that combines the logically connected elements of a 3D-Architecture model (building objects), a quantity list (BoQ items) and a general plan map (frame schedule). Static constraints describe the requirements for the quality and detail of the information models involved (e.g. model domains, project phases, levels of detail and processing status). The link depth is described using the metadata of the link models. In order to formulate the influence of context aspects on the design of situational information requirements, this static multimodel template is to be extended to a context-adaptive multimodel template. In a first step, the context-dependent components of the information requirement must be identified.

In order to formalize the influence of context attributes on the information requirement as contextual relationships, the static template attributes must be exchanged for context-adaptive attributes for the context-dependent components. Information logistics context dependencies of the context-adaptive attributes can be described by contextual relationships. In [13] the scripting language ContextScript for formalizing context relationships was introduced, which enables mapping between interacting context factors and affected information space parameters. At the time of execution, the context transformations can be evaluated with current context values in these context-adaptive multimodel templates, resulting in a context-based multimodel template. Thus, a context-dependent information need can be anticipated. Of the basis of this need a context-oriented multimodel can be created, which corresponds to the situational information requirements of the respective information process. Figure 5 illustrates the procedure: A static multimodel template (MMT) is provided with ContextScript annotations and creates a context-adaptive multimodel template (caMMT). The contextScripts of the template are evaluated at the time of execution according to the current context values and processed to a context-dependent multimodel template (MMT) (see Figure 5).

2.1. Context gathering and Integration

The prerequisite for evaluating the context dependencies is that the relevant context information is determined at the time of application. HENRICKSEN ET. Al. identified in [15] five essential phases for the integration of context information in context-related applications and distinguishes between context gathering, context reception, context management, context query and context adaptation. These five phases of operational context integration are preceded by the conceptual phase of context modeling (see Figure 6). The context gathering phase deals with the management of context sources and the insertion of recorded context information into the context model. Context information is not only collected and stored, but also further processed in order to determine high-quality context information. The context management phase organizes the administration and distribution of the available context information.

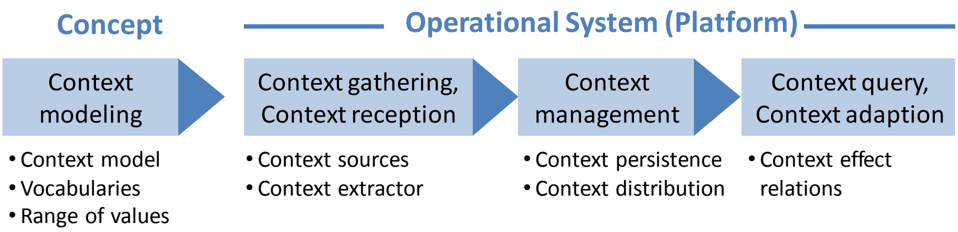

Figure 6. Phases of the operational context integration of a collaboration platform

For this purpose, the various context information obtained by the context determination must be maintained persistently and consistently. In the context usage phase (context query, context adaptation), the context model is a prerequisite for adapting the application behavior to the current context. For this purpose, the applications are provided with context information by answering context queries.

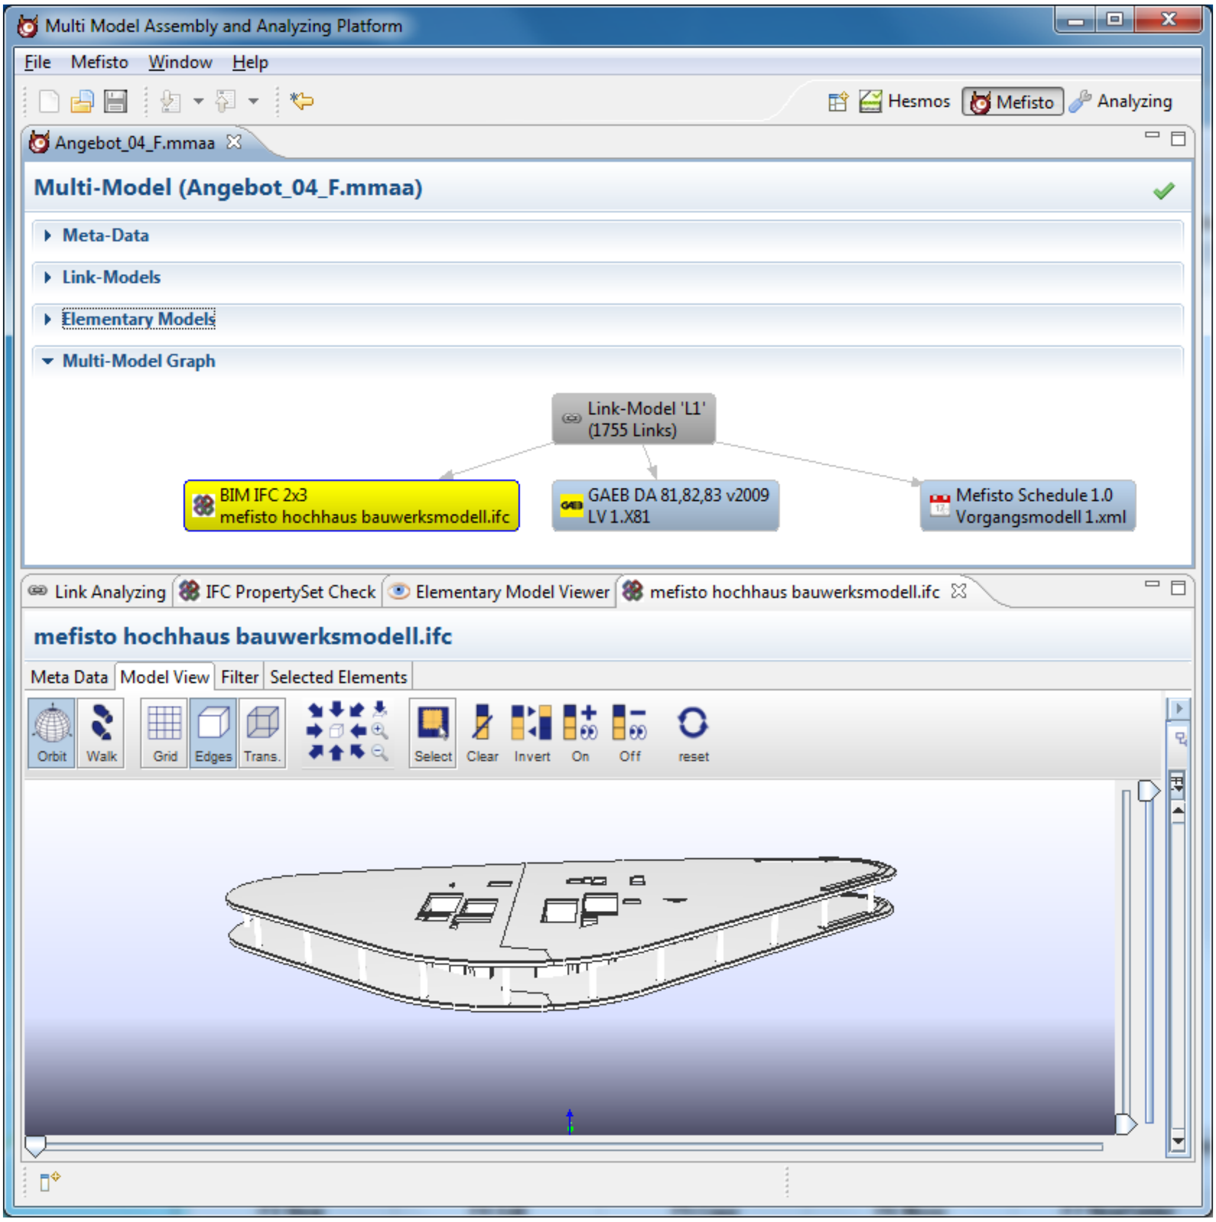

Figure 7. Evaluated multimodel container for the section of a building shell

2.2. *Context aware platforms*

For the implementation of context integration it is necessary to enable the collaboration platforms used in construction projects to become context conscious. In particular, information logistics must be expanded and the phases of operative context integration must be integrated into the elements of the platform. Depending on the level of integration, collaboration platforms already offer various components (e.g. content management system, user administration, workflow management system). These typical platform components can be used to collect context information. To do this, their functionality for integrating context information must be extended accordingly. For example, a workflow management system can determine the operational context by using the control data of the managed processes and the corresponding information resources as context sources. A document management component can be extended to determine the resource context by using the metadata of the information resources exchanged on the platform. A user management component can provide the actor context. During the usage phase of the context (context query, context adaptation), the adaptation of the application behaviour to the current context is realized. This requires additional components for contextualizing the multimodel templates. Context-dependent information spaces are generated in three stages. In the first step, the contextual relationships of the multimodel templates are evaluated on the basis of current context information. Than a context-specific information request is created as a multimodel template (see [16]). In a second step, suitable information models are determined from the project information space of the platform and adapted via adaptation services (e.g. multimodel filter services) (see [17], [18]). Finally, a multimodel generator service combines the adapted application models and generates a context-related multimodel (see [19]). In [13] a platform architecture is proposed in detail, which realizes a context-related provision of information. In Figure 7 an example of an evaluated multimodel container for the section of a building shell is shown. Table 1 shows the reduction of the information space size of the corresponding multimodel container and a coarse excerpt from the underlying context aspects.

3. Conclusion and Outlook

It is indisputable that the use of information spaces leads to an increased information potential compared to separate and unrelated information models. However, due to their growing size and complexity, comprehensive information spaces quickly become unwieldy and rarely meet the situation-related information requirements of building information processes. For the generation of precisely fitting information spaces, a multi-stage approach for the generation of contextually appropriate information spaces was developed in this article. In a first step, a method was presented to formalize the influence of context attributes on information requirements as contextual relationships in multimodel templates. In addition to the ContextScript language, a context model was introduced that covers the information-relevant aspects of the editing context. In a second step, the situation-related information requirement is anticipated on the basis of the current processing context only at the time of application. In a third step, the project-wide information pool and multimodel filter services are used to generate context-specific information spaces. For this approach, this paper outlines a context-conscious collaboration platform as a conceptual framework for the implementation of an information logistics system that implements the context-oriented information supply for information processes in the construction industry. Since this contribution focuses only on the use of context-related information for the derivation of a multimodel-based information requirement, the remaining (context-invariant) system functionality of the collaboration platform was only outlined (e.g. domain model adaptation and multimodel generation). For detailed information on the outlined context-conscious collaboration platform, please refer to [13].

In particular, the approach of an extended virtual project information space is highlighted and its application for the determination of usable and producible information models is shown. For sustainable building, a continuous use of information is indispensable. However, due to the increasing size and complexity of the information models used, this is only possible through context-specific views. The integration of context information for the situational determination of information needs and the targeted provision of context-specific multi-models presented in this paper provides a basis for this.
For the future, we must expect a steady increase in the volume of information in the construction industry. According to this trend, the importance of demand-oriented information supply will increase, because only in this way can efficient information processing be achieved by the actors. For the future, we must expect a steady increase in the volume of information in the construction industry. According to this trend, the importance of demand-oriented information supply will increase, because only in this way can efficient information processing be achieved by the actors. The approach presented in this paper is a step in this direction. However, until the methods of context processing can be established as an integral part of future application systems, some hurdles still have to be overcome and details have to be optimized. Starting points for further research include automatic model links. A manual linking of interdependent model elements is complex and error-prone. There is still a lack of methods for automatic link generation, e.g. with the help of reference link models. MAZAIRAC AND BEETZ [20] as well as FUCHS AND SCHERER [17] present first approaches for automatic link generation with multimodal query languages. On the other hand, the context-specific adaptation of domain-specific domain models was only described very abstractly. For a practicable application of the described concept, suitable model filters are required for the adaptation of the domain-specific models with regard to quality, granularity and detail. Initial work in this direction comes from [17] and [18].

A design integrated parametric tool for real-time Life Cycle Assessment – Bombyx project

Basic S[1], Hollberg A[1], Galimshina A[1], Habert G[1]

[1] Institute of Construction and Infrastructure Management, Chair of Sustainable Construction, Swiss Federal Institute of Technology (ETH Zurich), Stefano Franscini Platz 5, 8093 Zurich, Switzerland

basic@ibi.baug.ethz.ch

Abstract. Life Cycle Assessment (LCA) has become a widely accepted method for environmental assessment of buildings, but is still not commonly applied in design practice. The biggest potential for optimization and reduction of GHG emissions lies in the early stages of the design process. Therefore, a design-integrated approach for LCA is needed. The goal of this paper is to describe the development of a parametric LCA tool for application in early design stages in the Swiss context. The envisioned users of the tool are primarily architecture and engineering students, but also practitioners. The integration of LCA throughout the design process is solved through a modular strategy. In the early stage, pre-defined components are selected to model a complete LCA. In the following design steps when more information is available, individual materials can be input with higher level of detail. The Bombyx tool is developed as a plugin for Grasshopper based on Rhinoceros3D and includes an SQL material and component database. Users are able to choose different materials and building systems and quickly modify the building's geometry while continuously receiving the calculated environmental impact in real-time. Visualization of the results, e.g. colour code indicate how the design performs in relation to a benchmark or optimization potential. The project is developed in open source to broaden the user and developer community and foster new ideas, designs and implementations in Bombyx.

1. Introduction

The built environment is responsible for more than one third of global greenhouse gas (GHG) emissions and has the largest potential for delivering long-term, significant and cost-effective GHG emission reductions [1]. Until now, the efforts to reduce GHG emissions mainly focused on the use phase of buildings. These measures have successfully reduced the operational energy demand for new and existing buildings and the limits for energy optimization in the use phase have mostly been achieved [2]. For new residential buildings, the so-called embodied GHG emissions related to material production, construction, maintenance and end of life of buildings account for half of the total emissions within an assumed life cycle of 50 years [3]. Therefore, the whole life cycle of buildings has to be evaluated. Life Cycle Assessment (LCA) has become a widely accepted method for environmental assessment of buildings in a scientific context, but is still not commonly applied in design practice. In the rare case that it is applied, LCA is used as post-design evaluation as a mandatory part of sustainability certification schemes. However, post-design evaluation through LCA is not sufficient on its own, as it does not improve the environmental performance of the design [4].

In general, decisions made in the early stages of the design process, have the greatest influence, as they set general conditions for the subsequent design process [5] (see Figure 1). As such, the early design phase has the highest influence on costs [5], operational energy demand [6] and the environmental impacts [7]. Therefore, the biggest potential for optimization and reduction of GHG emissions lies in the early stages of the design process. LCA needs to be applied in early design stages to allow for holistic environmental optimization of the building.

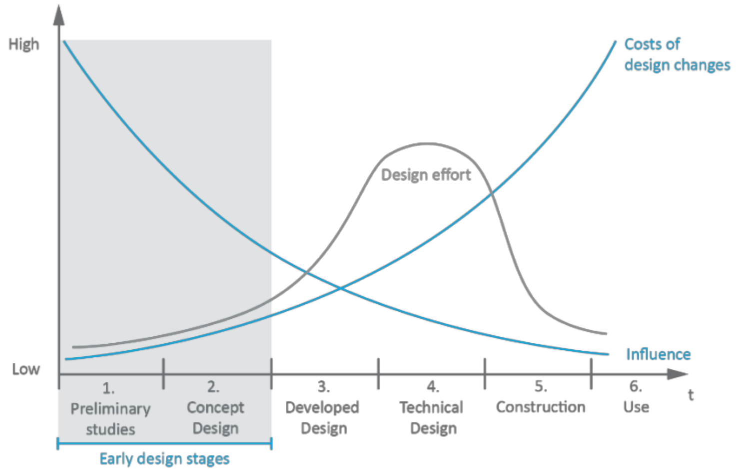

Figure 1. Influence of the early design stages (based on [5]).

Parametric design has been known for a long time [8], but gained popularity in architecture and design in the last ten to fifteen years. The main advantage of the parametric approach is the possibility to easily generate numerous different design variants. Lawson observed that many designers express a need to generate and assess alternative design ideas [9]. With the help of a parametric model, architects can fulfil this need. Once a parametric model has been developed, the generation of further design alternatives is nearly effortless. As such, the parametric approach is ideal for optimization, because design optimization is an iterative process of generating, evaluating, and comparing design variants. Parametric design allows for very quick generation of design solutions, but for time-efficient optimization, methods and tools for quick analysis are needed as well.

There is a wide range of parametric tools for building performance assessment, including energy performance, daylight availability or computational fluid dynamics. While a number of LCA tools have been developed in the last years [10], [11], only a few follow a parametric approach, e.g. Tortuga [12] or CAALA [13]. Regarding the Swiss contexts, there is a lack of adequate tools for design optimization in early design stages. Current tools are either over-simplified or too complex. Simplified tools aim to quickly estimate the embodied impact in early design stages (for example SIA 2040 Excel tool [14]), but they cannot be used to improve the building design, because of limited material options. Expert software (for example SimaPro) allow modelling the building and all materials in high detail, but inputting all necessary information is very time-consuming. Software primarily developed for engineers (for example Lesosai) is well suited for certification, but the effort to compare various design options including different geometries is high. The aim of applying LCA in early design stages should be to improve the building's environmental performance. This is not possible with the current set of tools using Swiss LCA data.

The goal of this paper is to describe the development of a parametric LCA tool for application in early design stages in the Swiss context. The envisioned users of the tool are primarily architecture and engineering students, but also practitioners. Furthermore, the tool is developed as an open source project to allow adaption to other national contexts and attract further developers in the future.

The paper first explains the method behind the tool and the implementation in form of a plug-in for Grasshopper 3D, a parametric design software based on Rhinoceros 3D. Then the intended application in a teaching project is explained and an example of using the tool in the design process is provided.

2. Concept of parametric LCA

The basic concept of the parametric LCA (PLCA) approach is combining the principles of parametric design with a simplified LCA method [15]. Here, the concept is used as described by Hollberg [16] and adapted to the Swiss context. In the following, the workflow of using the approach in the design process and the calculation procedures are described separately.

2.1 Workflow in the design process

Designer can typically influence the environmental performance of a building by three categories of parameters: 1) geometry, 2) materials, and 3) heating, ventilation, air conditioning (HVAC) systems. Each category consists of a number of parameters, such as orientation, dimensions, window area, etc. for the geometry. All parameters are input in a parametric LCA model.

The geometry is defined using a 3D model of surfaces, similar to a thermal model. The model includes, ceilings, balconies, etc. that might not be needed for calculating the energy demand but are necessary for calculating the embodied impact. The building is structured into eleven building elements (see Table 1). Each element consists of a number of components according to the Swiss structure for cost estimation e-BKP-H SN 506 511. The components are also the basis for defining the reference service life (RSL) according to SIA 2032.

The building materials are input by defining the materials for each element. This can be done in two level of details. 1) Selecting from typical pre-defined components, e.g. a timber-frame structure with mineral wool insulation (see Figure 2), or 2) by defining layers and selecting each material separately (see Figure 3). The second approach provides more flexibility and allows for a detailed assessment while the first approach reduces the effort to input the materials significantly and is therefore ideal for early design stages.

The technical equipment is always input on component level and based on the energy reference area (ERA) of the building, which equals the heated gross floor area.

Table 1. Structure of building elements and components

Building element	BKP-H Component
1. Base slab	C1 Base slab, foundation G2 Floor covering
2. Exterior wall under ground	C2.1A Exterior wall under ground E1 Exterior wall finishing under ground
3. Exterior wall above ground	C2.1B Exterior wall above ground E2 Exterior wall finishing above ground G3 Interior wall finishing
4. Window	E3 Window
5. Interior wall	C2.2 Interior wall G3 Interior wall finishing
6. Partition wall	G1 Partition wall G3 Interior wall finishing
7. Column	C3 Column
8. Ceiling	C4.1 Ceiling G2 Floor covering G4 Interior ceiling/roof finishing
9. Balcony	C4.3 Balcony
10. Roof	C4.4 Roof F1 Roof covering G4 Interior ceiling/roof finishing
11. Technical equipment	D1 Electric equipment D5.2 Heat generation D5.3 / D5.4 Heat distribution and delivery D7 Ventilation equipment D8 Water (sanitary) equipment

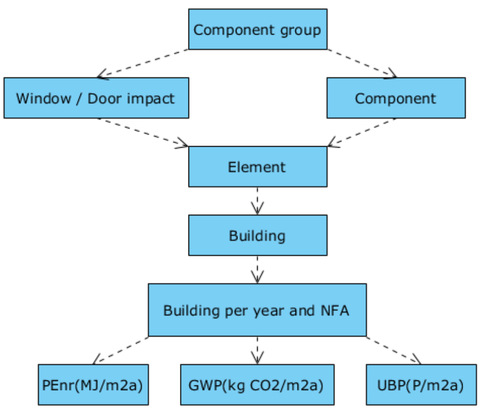

Figure 2. Component level

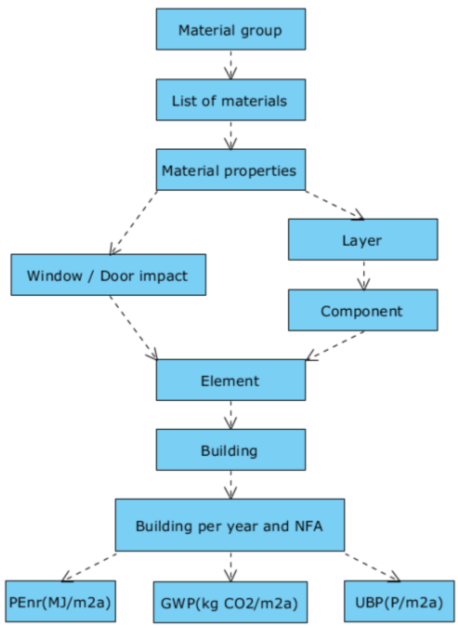

Figure 3. Material level

2.2 Calculation

The approach presented here combines the primary energy demand and environmental impact of the building in the term *impact*. It distinguishes between the *operational impact* (I_O) resulting from the operational energy use of the building (life cycle module B6 according to EN 15978 [17]) and the *embodied impact* (I_E) resulting from production and the end of life of the building (modules A1-A3, C3, and C4). The replacement of building components (module B4) is also considered as I_E. The *life cycle impact* (I_{LC}) is the sum of I_E and I_O (see Equation 1).

$$I_{LC} = I_O + I_E \quad (1)$$

2.2.1 Embodied impact

The embodied impact (I_E) is calculated by multiplying the mass of each material (M_j) by the specific *embodied impact factor* of the material ($IF_{E,j}$) (see Equation 2). To determine the mass, first of all, the areas of the different building element surfaces have to be calculated. The surface areas are then multiplied by the thickness and density of the specific material. The density is imported from the KBOB database *Ökobilanzdaten im Baubereich* [18] together with the specific IF_E. Furthermore, the number of replacements (R_j) is considered. In this way, the I_E of every component is calculated and summed up to obtain the I_E of the entire building.

$$I_E = \sum_j (M_j \times IF_{E,j} \times (1 + R_j)) \quad (2)$$

For some materials, such as windows, the KBOB database provides the IE per surface area of the element. In this case, the element area A_j can directly be multiplied with the IE.

$$I_E = \sum_j (A_j \times IF_{E,j} \times (1 + R_j)) \quad (3)$$

To calculate the number of replacements (Rj), the reference study period (RSP) is divided by the reference service life (RSL) of the building component. The RSP for residential buildings is 60 years in Switzerland. The RSL is defined in SIA 2032 [19]. R is calculated according to equation 4. For example, if a painting possesses a RSL of 20 years, it has to be renewed twice within an RSP of 60 years, so R equals 2.

$$R_j = \lceil RSP/RSL_j \rceil - 1 \quad (4)$$

2.2.2 Operational impact

The operational impact I_O consists of the sum of all different kinds of *operational energy demand* during the use phase (ED_i) multiplied by the *operational impact factor* of the energy carrier ($IF_{O,i}$) (see Equation 5). ED refers to the *final energy demand* and is calculated with reference to one year of operation. Therefore, the sum is multiplied by the number of years of the reference study period (RSP). The operational impact factor (IF_O) depends on the energy carrier employed and is taken from the KBOB database.

$$I_O = \sum_i (ED_i \times IF_{O,i}) \times RSP \quad (5)$$

The ED is calculated according to Swiss standards. The calculation approach is described in SIA 380/1 [20]. Various building categories (e.g. multi and single family houses, schools, office buildings etc.) can be calculated based on pre-defined parameters as the room temperature, floor area per person, occupancy schedule, etc. SIA provides data for 40 different climate stations in Switzerland including annual and monthly average temperatures, altitude above sea level and solar irradiation of South, East, West, North and Horizontal orientations. Here, we only include the calculation of residential buildings to simplify the process. The ED consists of space heating, hot water demand and electricity demand for appliances and lighting. The standard uses a quasi-steady state monthly energy balance to calculate the space heating demand. The monthly values are summed up to the annual value and added to the warm water demand to provide ED for heating. We use the simplified approach of SIA with fixed global values for the hot water and electricity demand.

The results of SIA 380/1 are the useful energy demand of a building. To account for different kinds of losses within a building and for the performance of the selected heating source (e.g. heat pump or gas-condensing boiler), the performance factor (PF) is used. The PF is introduced to describe different types of building services with one systematic approach. To calculate the final energy demand, the useful energy demand is divided by the PF.

The ED can also be calculated using other tools for building performance simulation, e.g. Honeybee/Energyplus or HIVE, and manually input in Bombyx. This allows for also evaluating more complex building with complex HVAC systems.

The impact factors (IFO,i, IFE,j) depend on the indicators chosen for the LCA. If more than one indicator is used, the impact factors are written as vectors of the indicators applied. In consequence, the resulting impact (IO, IE) is a vector as well. The advantage of using vectors for the impact factors is that the indicators chosen for evaluation can be easily modified depending on the available data. Equation 7 shows IFO,i and IFE,j for the indicators used by the Swiss KBOB database for building materials. UBP stand for *Umweltbelastungspunkte* or *eco points*, a single score indicator based on the Swiss *Method of Ecological Scarcity* [21]. Eco factors are used to relate between the actual emission situation in Switzerland and political targets [22]. The primary energy demand is provided as renewable part (Per) and non-renewable part (PEnr). Furthermore, Global Warming Potential 100 (GWP) expressed in CO2-equivalent as indicator for climate change is used as defined by IPCC [23].

$$IF_{O,i} = \begin{pmatrix} UBP \\ PEnr \\ PEr \\ GWP \end{pmatrix}, IF_{E,j} = \begin{pmatrix} UBP \\ PEnr \\ PEr \\ GWP \end{pmatrix} \tag{6}$$

3. Software implementation

Bombyx is designed and implemented as a plug-in for Grasshopper (GH), an add-on Rhinoceros 3D. The plug-in is free and available at Food4Rhino1. The core of the application is developed in C#. Grasshopper is based on visual programming and allows users to create scripts and components in C#, VB.NET and Python to further customise the functionality of Bombyx. The project is open source, so users can download the whole source code from GitHub2. They can also contribute with ideas and their own implementations.

The material and component data used in Bombyx is stored in a database. Further adjustments, as well as adding new materials and components can be done via specially prepared web page. Here, guest users can view all materials and components used by Bombyx and trusted users get the option to edit materials and components or add new ones. The SQL scripts to generate data tables are also provided on GitHub, but users need to setup and manage their own SQL server, where their database will reside. This could be useful to use Bombyx in other countries with other national databases in the future, for example.

[1] The latest version of Bombyx and example files can be downloaded from: https://www.food4rhino.com/app/bombyx

[2] GitHub source: https://github.com/Bombyx-ETH/Bombyx

The geometry can be directly defined within GH or drawn in Rhinoceros and automatically loaded into GH. For the second approach, a pre-defined layer structure using the eleven elements shown in Table 1 is provided (see Figure 4).

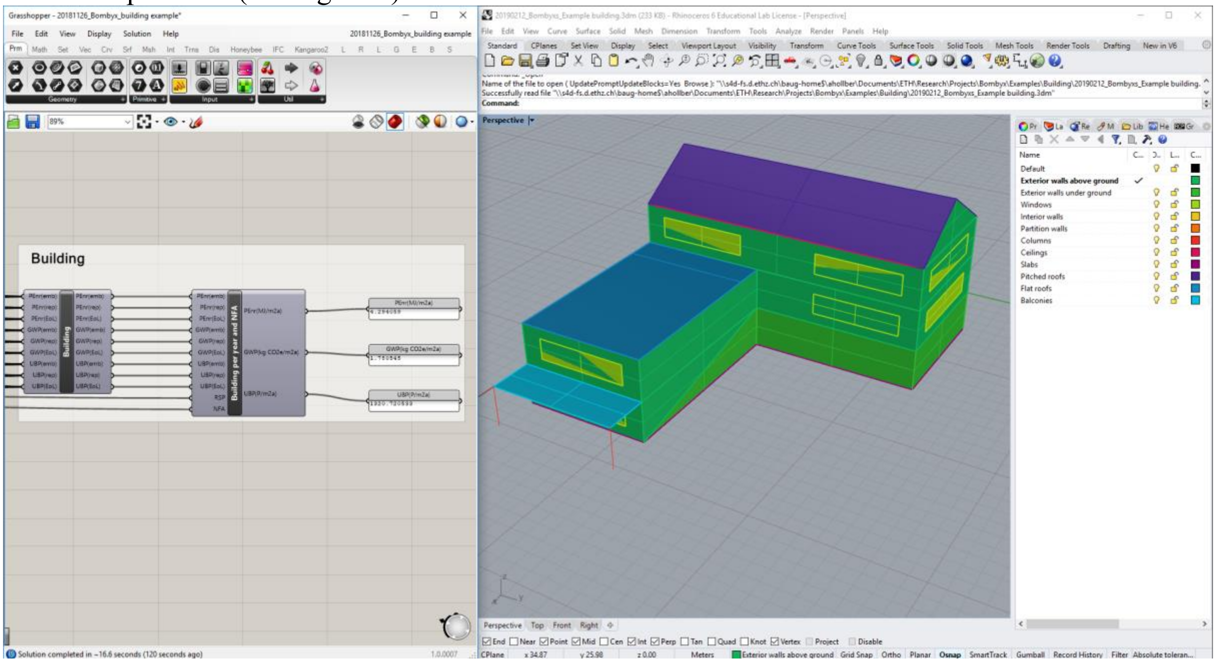

Figure 4. Bombyx plug-in in GH (left) and geometry with pre-defined layers (right).

Currently, Bombyx provides the LCA results as number in the GH viewport. They can be output on different levels of detail, for example the whole building per year, or individual components and materials separated into the life cycle stages production or end of life. A visual feedback is very import for designers [24] and will be implemented in the following versions of Bombyx (see section Future Developments).

4. Application for teaching

Bombyx will be used in the course Building Materials and Sustainability in the fall semester 2019 at ETH Zürich. It will be part of the Master course Integrated building systems and linked a design studio. A common question and concern of teachers of design studio when using performance assessment in the design process is whether this comes at the expense of the architectural design quality [25]. Clearly, the course aims at improving both environmental performance and architectural quality. We will therefore track both aspects using a graph to plot the architectural quality and the environmental quality (see Figure 5). Rating the architectural quality is not easy and can be partially subjective. Therefore, the final grades the students received in the design studio will be used as indicator for architectural quality. The environmental quality will be assessed with a simple Bombyx calculation. The comparison of students having followed the course with those who have not will be a direct evaluation of the quality of the course. If the environmental assessment has been effectively integrated during the design process, we expect that projects from our students will have a better environmental performance and a similar architecture quality, but this needs to be tested.

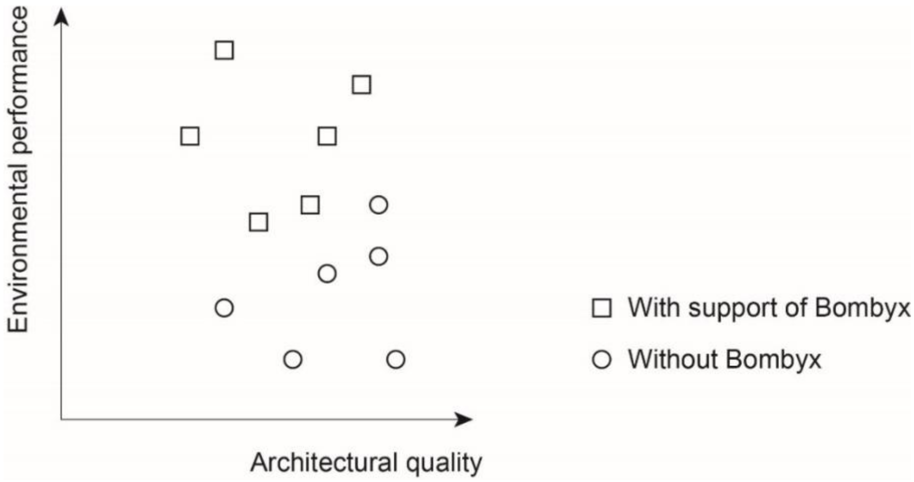

Figure 5. Expected result of the comparison between the final results of design studios of groups that used Bombyx with students that did not attend the course and apply the tool.

5. Future developments

The students' feedback will also be used to improve the Bombyx tool in the future. As mentioned above, a major task for the next version will be the integration of visualisations. We will follow two strategies. To provide insights into the relation between operational and embodied impact and the share of impact each components is responsible of, we will implement sunburst diagrams as shown by Kiss and Szalay [26] (see Figure 6). In addition, we will use the 3D model to map the results onto the model as previously shown by Röck et. al. [27] (see Figure 7). This approach allows for several types of result visualisations. The impact of each component can be directly shown on the specific component using a colour scale from green to red for example. Furthermore, to potential for improvement can be indicated by visualising the distance to a target or best-practice solution.

A future development could also integrate assumptions for buildings that have not yet been specified in early design stages. Benchmarks that can serve as reference values for Switzerland are provided by Hollberg, Lützkendorf, and Habert [28], for example. In addition, minimum and maximum values can be given out to provide a range of possible final results and show the uncertainty due to these assumptions.

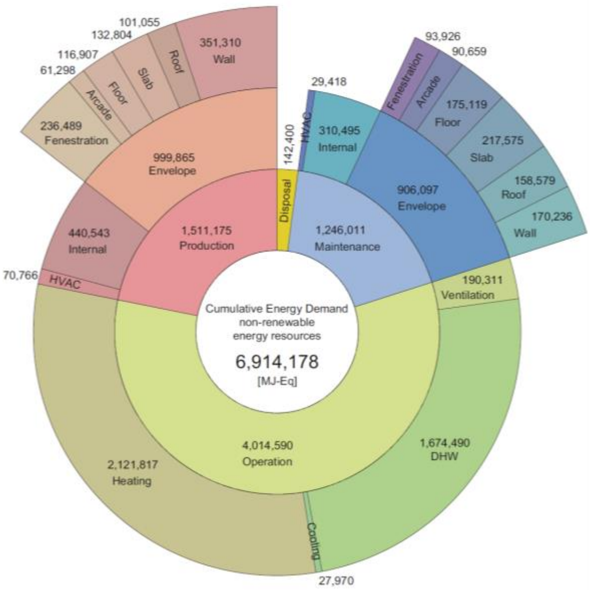

Figure 6. Sunburst diagram [26].

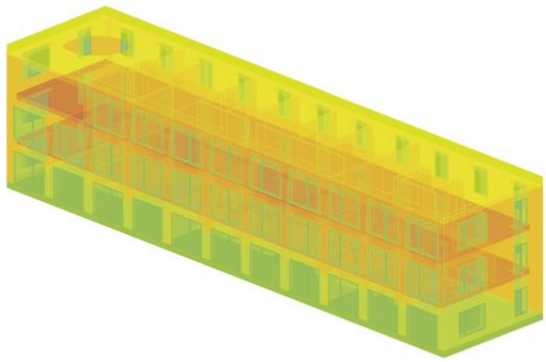

Figure 7. Mapping the results onto the 3D model to show improvement potential [27].

In the future, we will also link Bombyx to other tools for performance assessment, such as daylight analysis or structural analysis. The modular and quick calculation approach are ideal for employing optimizers, for example genetic algorithms. Furthermore, the parametric approach allows for employing machine-learning algorithms. A starting point could be to train these algorithms with saved data from student exercises to predict optimal materials and components for the geometry in either design or optimization stage. This step would significantly increase the quality and speed of the design, but would still need human verification.

Acknowledgements and remarks
We would like to thank the Innovedum fund of ETH Zürich for supporting for this project. We encourage every interested researcher, student and practitioner to collaborate on this open-source project.

Abstract. Solving complex issues of energy-efficiency – at the building as well as urban level – requires a holistic, integrated approach. The energetic behavior of a system should not only be considered in individual processes or phases, such as operation. A holistic optimization should rather consider the explicit energy flows as well as the material fluxes including the associated gray energies over the entire system life cycle. The realization of such a holistic integral planning process implies an integrated planning-accompanying evaluation and optimization of the planned object. The early use of LCA tools and sustainable building assessment systems (SBA) provides an important basis for assessing planning decisions at a conceptual level for their impact on the entire lifecycle of a building and for ensuring good sustainability performance.

In practice, however, it is currently evident that the non-standardized and inadequate connection of simulation and balancing tools (e.g. LCA) to BIM authoring tools and the resulting high time expenditure for data acquisition and LCA application counteracts with a targeted stronger penetration of the market.

For realizing a consistent integral planning process – especially in early planning phases – an IFC-based interface is being developed for the connection of LCA tools to BIM models (data input) and the preparation and configuration of the LCA result data for the designated use in different SBA. In this contribution, from the interface specifications for different levels of granularity and concretization in the different planning phases that are developed by means of norm-based processes of model standardization in an underlying research project, parts regarding the early project stages will be presented.

1. Introduction

In the field of sustainable building measurable ideas have grown up in recent years that enable a viewpoint shift by taking into account holistic lifecycle-oriented assessments of the environmental impacts of a building. Up to now the provided sustainable building assessment (SBA) systems are only used after the building is realized. Thus, great potential for optimized sustainable building design lies in the possibility to shift SBA alongside with accompanying tools as f.i. lifecycle assessment (LCA) upstream in the planning process. By showing to the decision maker and designer the consequences of their design decisions the environmental performance of the later building can be significantly enhanced.

Within the framework of a research project the question is pursued of how this can be achieved with regard to design methodology. Here, as a starting point a holistic phase model was developed for an integrated planning approach that is required for solving complex questions regarding energy efficiency and sustainability of buildings [3]. Rather than examining the energetic performance of the system in single phases only (e.g. use and operating phase), for an overall optimization all flows of explicit energy and matter together with the respective grey energy throughout the lifecycle have to be taken into consideration. In turn, a holistically integrated planning process implies a consistent accompanying evaluation and optimization of the planned object. Early application of lifecycle and sustainability assessment tools in the process constitutes an important basis in order to support decision making already during the first development of concepts for the building.

In the core of the approach stands the provision of a process-accompanying data basis for building information as needed for respective LCA. To facilitate a dynamic concretization of the building information consistently through the design process, a systematic has been developed for a gradual transformation and enrichment of an initially fuzzy and rough area-based building description towards a more and more detailed element-oriented specification (cf. fig. 1). Thus, the approach depicts multigrain information structuring for the level of development according to the project phases.

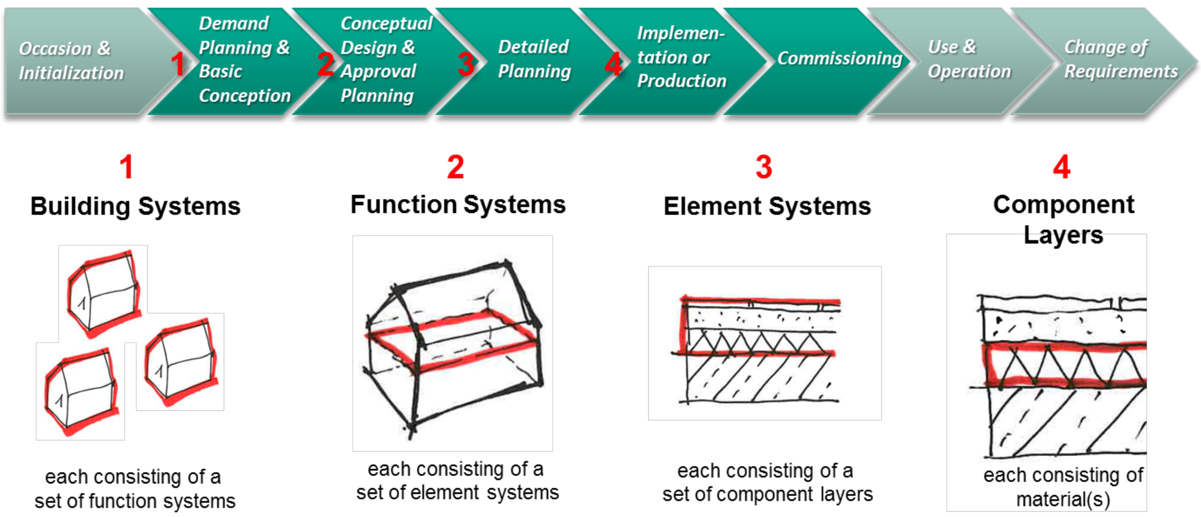

Figure 1. Multigrain information structuring approach for depicting the level of development.

At the beginning of a project, the strategic project development, a more abstract LCA-based description of targets, demands and their impacts is depicted. Successively, this building information can be enhanced to area- and shape-based descriptions, and then on to a detailed element-oriented model with references to materials and specific quantities. This granular concept will be implemented in the data model and the business logic of the IT-based tool chain from BIM to LCA and further to the SBA (c.f. [2] as well as [3]).

In this contribution we highlight norm-based methods applied in the research project in order to build a (technical) foundation regarding the data level from which shifting lifecycle and sustainability assessment tools into early planning stages can be accomplished (c.f. [1]). In order to provide model-based facility for early planning stages the information needs of two scenario-based use cases were thereby considered. As norm-based basis for specifying an appropriate data interface [4] these use cases will be presented following the short introduction to the background they are formally described in.

1.1. Foundations for norm-based generation of specific model view for sustainable building data

Within the digitalization in the field of planning and construction of the build environment a shift towards model-based methods on side of data can be observed. Thereby the established open virtual building model standard Industry Foundation Classes (IFC) plays an important role in cooperative planning as a neutral base for BIM-based software overarching data exchange. In order to specify certain agreements toward which information has to be exchanged among partners, e.g. in the framework of Employer's Information Requirements (EIR), the model standard offers the accompanying Model View Definition (MVD) Standard. Since it is important to also clearly describe the context, namely the sender resp. receiver of the information, the exchange process and (further) considered framing conditions, (technical) MVDs are specified with regard to comprehensively compiled norm-based Information Delivery Manuals (IDM).

Beside an introductory part, IDMs basically consist of two parts of definition. Process-related depictions of the exchange scenario are compiled on the basis of the Business Process Management Notation (BPMN). In this first part concerning the process diagrams the indication of where the information is to be exchanged (data transfer point) between which stakeholder is important. To each of the thereby indicated transfer points corresponding tables containing the respective one by one information demands have to be prepared in the second part of the IDM.

2. First Use Case: Assessment in Phase 1

The use case regards to sustainable building aspects as well as outlining respective coarse targets in an initial design brief prior to starting a respective project. In a first subchapter the side of process is introduced that is situated in the first phase of an underlying phase model [3] Here, actors and their specific parts in the (data) exchange are elaborated. In the following subchapter the corresponding data structures and contents regarding the data transfer points that are stated in the process are described.

2.1. Initialization phase: sustainability target corridor as part of project inspiration

A so called (initial) “design brief” document facilitates the initial information regarding sustainability in this use case. Within the document different aspects of the project to-be-initialized are compiled in a balanced way. As explicit ground work, it summarizes all initial ideas that were made in the first phase and supports the main decisions at the end of the phase – whether or not to pursue a project (and successively realize the building). If moved on from here, the initial design brief besides a documented decision support can set a first guideline on project generation and on what to (in a coarse manner) consider for this.

Fig. 2 shows a generic process of compiling the contents for the initial design brief exemplarily on behalf of the consideration of sustainability aspects. As with every thematic field that is entered into the design brief, the starting point is within the role of the initiator. This role will then finally – if all themes have been iteratively weighed carefully against each other – consume the resulting design brief alternatives as a basis of the decision making. Thus, finally one alternative with which to move on with a respective project is chosen (cf. “swim lane” at the top of fig. 2). At the beginning of each thematic field more or less information exists on side of the initiator. For the field of sustainable buildings a first set of requirements could be the basis of a first discussion with a sustainability advisor consulted by the initiator, such as coarse information on function/usage and ideas on building dimensions. Besides reiterating these initial set of requirements in terms of whether they are sufficient (or can be reduced already), the outcome of the consultation could be a task for the advisor to fix alternative inputs to the design brief. These could be based on broadly discussed alternate sustainability objectives for the project that are illustrated by the consultant on behalf of sample buildings to the initiator. Samples are thereby chosen from a benchmark database by taking into account the initially outlining requirements together with first coarse targets, e.g. a high energy standard. With these more or less structured inputs the consultant can now prepare a first set of exemplary sustainable objectives pointing to respective benchmarks or existing sample buildings that frame alternative archways of how to include sustainable aspects in the framework of the aspired project. The iterative process for generating these alternative target sustainability corridors as input to an structured BIM-based design brief is shown as interaction of the middle (executive role) and the bottom (operative role) swim lanes in figure 2. In the lane between them the data transfer points are defined where the model-based information firstly handed over to an actor in the LCA domain containing characteristics to the aspired project as well as specifier to different sustainability objectives. Secondly, after these incoming model-based information has been used to enhance the model with respective LCA-specific data in the bottom lane, it is handed back featuring the alternatives. The received models from the expert side can now be checked whether they are complete (and if not reiterated to the expert for completion) and finally, decorated with additional information characterizing them as parts of a design brief regarding sustainability, handed over to the initially requesting role of the initiator. With a decision for one of the handed in alternatives and merging its contents in the general BIM-based design brief the initiator finishes this process.

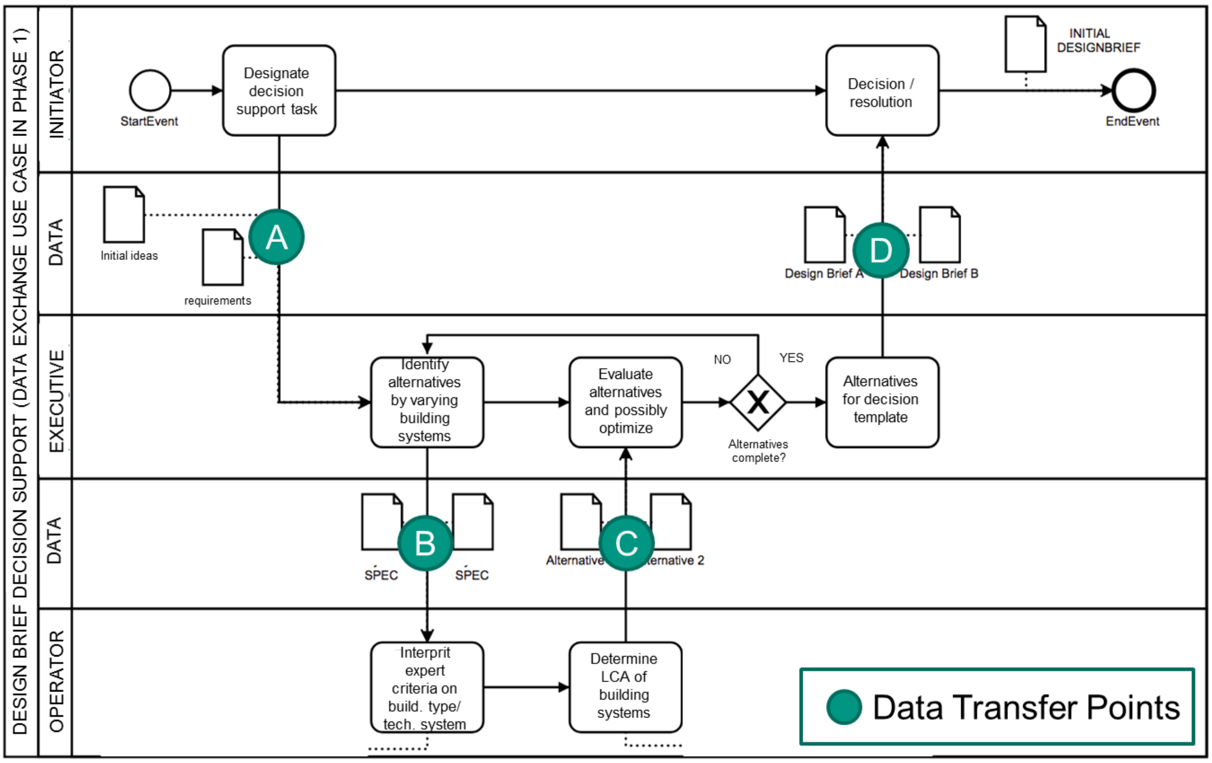

Figure 2. BPMN process map depicting a use case in the first phase.

2.2. Proposed data set of a BIM-based design brief

Different data might stand at the beginning of the above described process. The spectrum can range from a napkin with pinned down initial thoughts for a project up to (ideally) a well formed data base containing BIM-based design briefs of already realized buildings from which a template can be chosen. However, with the first (structured) data exchange between the executive role and the operative role (cf. fourth swim lane) a BIM-based model as structural base of the exchanged information is obligatory in the scenario set up. For the information systematic regarding concretization and matureness of the planned object (already published in the research project framework cf. fig. 1 and [2]), an instance of the class *IfcProject* with connected instance(s) of the class *IfcBuilding* builds the proposed base for depicting the most coarse representation stage of a „building system".

Data transfer point A – At this very early stage – prior to the manifestation of a project – especially the knowledge on sustainability on side of the initiator marks the deepness and granularity of respective involved information. For example, if the potential builder is completely new to the matter of sustainable building on the one hand side some exemplary buildings as whole (building system) where f.i. the focus is set to achieving a similar environmental performance of the hull can be feasible. Whereas on the other hand side an experienced builder might go much more into detail f.i. using benchmarked values of built samples to define concrete to be achieved boundaries while setting the outlines of his sustainability targets. Here, an example for such a systematic approach can be seen in the holistic system of Leitfaden Nachhaltiges Bauen/BNB. Although it is not obligatory yet, the early assessment of how to achieve to the most extend a sustainable building its guidelines advices the public builders to take into account can be seen as first step to respective required early goal setting.

Since the data involved in this stage is mostly generic, its central depiction concept is a linked data approach. Instead of adding information directly to these early BIM model instances, they are held as web based catalogs where the data can be referenced multiple times by respective references. In order to prepare the model instance with coarse characteristics (cf. above process description) as well as further specification of an initial target direction, e.g. by pointing out an energetic standard to be achieved, firstly the created building object is extended with a set of properties called „Sustainability benchmarks“. In this, properties can be added with a respective URL based catalogs referencing. By doing this for the added building object, all input information needed for the side of the LCA expert is already prepared. In order to precisely specify further objectives on the prepared building instance another property set “Sustainability target” can be added to the project object. Here, the specific objectives are then specified, f.i. „at least hull performance of sample building 1 and performance of technical system of building sample 2“ or „performance shall lay with in the average of building type 1 and type 2“.

Data transfer point B – By following the catalog references given in the handed-in model the expert gathers the arguments for filtering his data base. The results are then added to the corresponding building objects by extending them with a property that holds the respective value. Thereby, if the environmental performance data as CO_2 equivalent value that is filtered by the arguments given in the adjunct property set shall regard to the average of all buildings that meet the criteria instead of only one single sample building this has been indicated in the building object by setting its attribute „CompositionType“ to “COMPLEX” (as opposed to “ELEMENT” that regards to a single building).

Data transfer point C – The model-based data returned by the expert now holds the requested LCA-information, which can be checked whether it completely covers the requested sample/benchmark data. Now, by further specifying sustainability aspects through f.i. a range that is depicted by referencing the environmental impact of the hull of two returned example buildings, the advisor in the executive role can prepare the alternatives that he had earlier discussed with clients. By adding this information to different model files, explicit variants of target corridors can be specified as a decision basis.

Data transfer point D – Thus, the underlying alternative LCA-parts of a designated design brief model is finally handed back to the initiator. Here, the decision is supported by consuming the model-based information, by e.g. generating tables from its contents to visually compare the received alternatives that can also finally be used to explain in a transparent way the chosen variant. Through its standard-based depiction the chosen alternative design brief builds the (referenceable) root instance for a BIM-based data handling in the to be initialized project.

3. Second Use Case: Assessment in Phase 2

Thematically the use case regards to an implementation road map for the sustainability targets on behalf of respective project objectives. Thereby, compiling sets of strategic functional systems stands at the core of the road maps. In the first subchapter the side of process is described. The use case is situated at the end of the second phase „initialization and basic concept“ (cf. fig.1, Rexroth 2018). Here, it marks the final stage of the phase in which a respective project has been initialized by assessing and compiling the core requirements as a basis of decision whether all parts of the project are checked in terms of investment security. For this on side of data a derived set of evaluated objectives regarding sustainable building that is carefully considered in a basic concept can build a frame for the design task to be delegated to a respective planning team.

3.1. Requirements planning and basic design: support for investment security

The process shown for the previous phase involved an actor in the role of an initiator (usually a builder, or a resp. department of an institutional investment organization) that decided to move on and initialize a project on behalf of first ideas that were compiled in the frame of a model-based design brief (cf. chapt. 2). As input to the following phase, the design brief can help to set up the framework for initialization of the project e.g. by the designation of a suitable planning team to develop the design. Especially as a guideline to discussions on sustainability aspects in the requirements planning, it can thereby help to explicitly form concrete objectives derived within the initially set target corridor.

Instead of directly placing the followingly described use case at beginning of the second phase and use the design brief as direct input it was intentionally shifted to the end of the phase. By doing this the manifold and therefore difficult to generalize possible ways of how these concrete objectives are formed in different situations can be better taken into account. The end of the second phase is thereby determined by the process of the builder who wants to assure prior to kick starting the project that all contents have been carefully considered in a comprehensive investment security effort. Thus, before delegating the design to designated planners, this common decision situation is given where it should be decided upon whether all requirements of the potential builder are (explicitly) determined and respective investments are safeguarded.

Regarding the sustainability objectives within these requirements the process depicted in figure 3 shows a possible involvement of an respective sustainability advisor. After the conclusion of all requirements from the initiator the advisor is designated with the task to develop alternative setups of concrete sustainability objectives. Each of them should thereby be bound in a basic implementation concept that sets a (feasible) road map on how to achieve the expressed goals during the construction of the building. Here, it is crucial to set the right anchors for achieving the aspired sustainable building quality in order to e.g. get a specific SBA label as needed for a designated added value when placing the building in the market. Therefore, in this context the initiator delegates the task of offering alternatives on how to explicitly set project objectives regarding the building sustainability within the tender terms for respective design work to an advisor. Placed in this decision situation of the initiator, who is advised with alternative strategies that help him safeguarding his investments (cf. top process swim lane in process map), the subprocess of data exchange is furthermore embedded between the sustainability advisor and an expert LCA discipline (cf. swim lanes in the middle as well as the bottom).

Although it is not obligatory that the advisor as an input to his task of preparing the alternatives is handed over already structured (model-based) data, in an ideal case the initial design brief is at least given to build up upon in order to continually update the data in context of the project in a holistic manner. By having this single source of truth in a singleton document also all data at the basis of decisions along the lifecycle of the building can be process-accompanying captured. However, for the requirement-driven planning concerning the sustainability objectives the advisor prepares an according requirements model as a basis of the information on the environmental impact to be added. Since at this stage only coarse information is given, the modeling effort focusses on strategic building components. These are the parts of the building depicted by so called “functional systems” in the framework of the systematic on step-wise concretization of the planned object as developed in the underlying research project (cf. fig.1). In a first step based on expert knowledge regarding which of these building components are “the most relevant ones” on behalf of the advisor’s experience alternative roadmaps are considered. For these building components as in early cost planning, e.g. based on methods like the German Baukostenindex (BKI), with respective functional systems provided as items in a catalog voids of information can be filled as different kinds of construction are given based on typological data. This, together with the data that can be derived from coarse information, builds the modeling base of the requirements model. Here, for the rough information e.g. on office usage and on the coverture of the building by taking into account statistic data already default measures e.g. mean floor areas can be approximated (Rexroth Bausim 2018). In order to assess the modeled sets of (strategic) functional systems, the prepared requirement model is then in a second step enhanced with respectively characterizing information. As an example different building elements are added to the modeled alternatives each one holding a set of characteristics, e.g. medium standard equipped wood frame light weight construction, which addresses a particular item in the catalog. This model is then handed over to the expert in the role of the operator (cf. fig.3 bottom swim lane in process map) for further detailing.

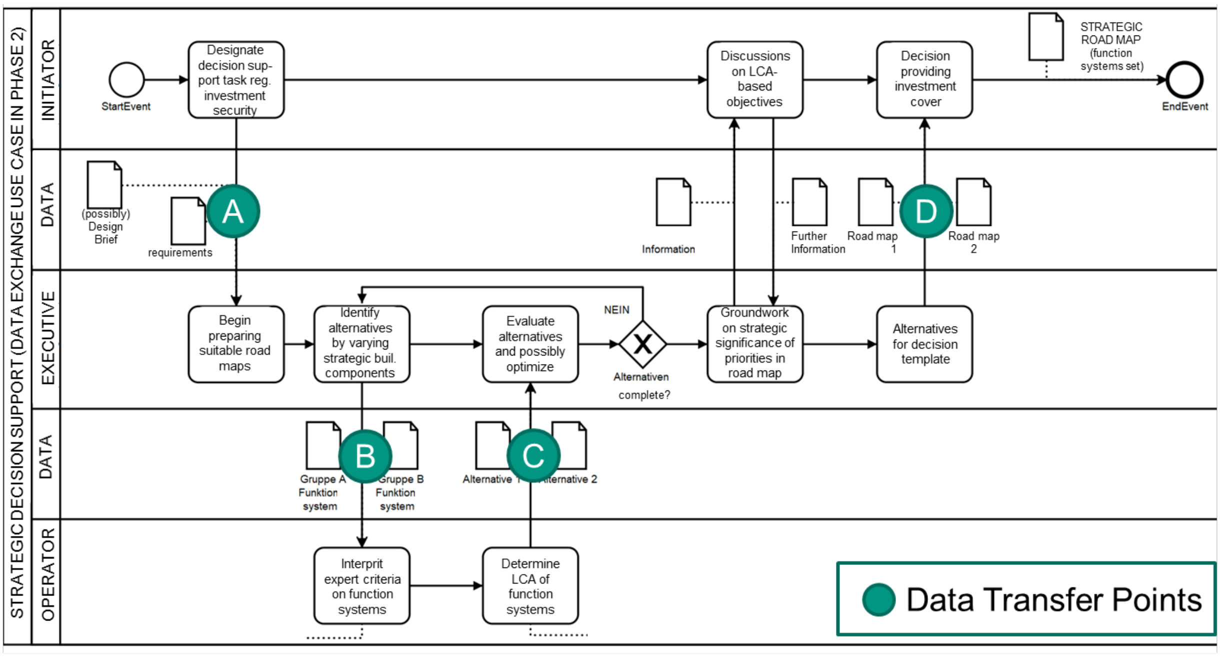

Figure 3. BPMN process map depicting a use case and data transfer points in the second phase

Once obtained the characterized model-based functional systems as well as their (approximated) measurements as an input, the environmental impacts can be added. Therefore, firstly the characteristics of each functional system of the handed in models are used to extract the according items from the catalog database. Then the required value, e.g. the environmental impact as CO_2 equivalent is calculated by taking into account other metadata like the usage that has been populated in the model. As a result, the models depicting the building requirements that have been further enhanced with the LCA-based impact information are returned to the advisor as different weighted alternatives. Here, they are checked whether they are complete and, if not, iteratively exchanged with the expert (cf. process map in fig. 3). Once the advisor approves the completeness of the prepared alternatives he can use them in further discussions with the builder about the objectives regarding sustainability to be pursued. Ultimately the alternatives are handed back to the builder that uses them as basis for his decision which strategic path to follow in the project. The chosen alternative depicting the LCA-based weighted requirements that from the view of the experienced advisor have been considered in terms of investment security can then be used downstream as basis of tender terms for respective design work.

3.2. Proposed data set for capturing the requirements planning regarding the sustainability objectives

The data exchanged in the above described process is based on IFC 4. For this a MVD is further enhanced that already contains the specification needed for the information demands regarding the first use case (cf. chapter 2.). For preparing a requirements model an instance of the class *IfcBuilding* is used. Thus, by adding a building element as complementary model for the later to be added planned object (that will reside in a separate building instance), an appropriate concept builds the base of the depiction concept for requirements information proposed in this contribution.

Data transfer point A –If an design brief was issued in the first phase (cf. chapter 2.), there has been already instantiated an enveloping project object (instance of the *IfcProject* class). This, in terms of the proposed MVD is maintained as single instance throughout the building lifecycle and can thereby help to ensure uniqueness of all the data involved. So besides the building instance(s), that represent sample (benchmark) buildings and might have already been added as design brief to the model in the first phase, another building instance is added and characterized as requirements model. In order to accomplish a consistent data exchange throughout the following described data transfer points (as indicated in the above process), different copies of this one building are the base for differently alternatives populated within it. As the first step all meta-data regarding e.g. usage or coverture that is needed in the framework of an LCA are added to this common building object.

Data transfer point B – For the different alternatives the respective copies of the base model are added with instances of derivations of the *IfcBuildingElementType* class that represents the corresponding type for a functional system. As an example, an *IfcWallType* instance is added in order to depict all building elements of the buildings' hull. This added object is then decorated with attributes and properties that characterize it in the way it corresponds to one item in the catalog of functional systems on the side of the LCA-expert.

Data transfer point C – For each object representing a respective functional system the according characteristics are extracted from the input model and used to match the environmental impact value in the catalog. This catalog value is then aggregated to the concrete value of all respective building elements, e.g. the outer walls or the roof etc., by taking into account the meta data that is stored in the building element. Finally all building element objects are enhanced with the requested information, as e.g. their environmental impacts, in the copies of the building model that represent the alternatives. Furthermore the environmental impact of the whole building can also be added before returning the resulting models to the advisor.

Data transfer point D – By adding further arbitrary information to the LCA-weighted alternatives the advisor can document certain aspects regarding the requirements as further discussed with the initiator. These could include f.i. scheduling, implementation steps or further details, e.g. regarding materials needed to be taken into account. The final prepared IFC-based information models are then returned to the initiator. As well documented basis of his decision the chosen alternative holds all relevant data concerning the involved requirements that are depicted with strategic building elements that enable for achieving the targeted sustainable building quality. Thereby the concrete objectives for that quality are also stored as the environmental impact value of each building element.

4. Summary and outlook

In this contribution we proposed a BIM-based data handling of sustainability information in the initial stages of a construction project. In the framework of two use cases a IFC-based depiction concept was thereby presented that enables for starting with BIM already with the first ideas to a project. Here, major decision that have the greatest impacts on the sustainability of the later building are made. Thus, as also emphasized by the paradigm of integral planning the transparent depiction of all data involved in decision making at these earliest stages comes along with benefits of being able to optimize the environmental performance of the building before (design) decisions are made that hinder this in a (cost) effective way. The presented use cases with their interrelated data exchange scenario are thereby contents of an general IDM for the context of BIM and SBA. A therefore proposed MVD is being further developed in the underlying research project. Thereby following the systematic in figure 1, it will be extended with contents of the data exchange use case: design tools to LCA tools and further to SBA systems.

5. Acknowledgments

The underlying research project of this contribution was sponsored by the Federal Ministry of Economy and Energy (BMWI) of Germany.

Abstract. IBPSA Project 1 develops and demonstrates an open-source BIM/GIS and Modelica Framework for building and community energy system design and operation. The project builds further on the completed project IEA EBC Annex 60 ”New generation computational tools for building and community energy systems based on the Modelica and Functional Mockup Interface standards.” This paper describes the motivation and approach of the project, and it provides an update about recent activities. These activities include development of a core Modelica library for building and community energy systems; development of BOPTEST, a virtual test bed to test advanced controllers such as MPC; development of GIS/BIM data model translators for Modelica; development of new workflows for improved productivity and quality assurance of urban-scale energy simulation; and development of DESTEST, a validation test for district energy models.

1. Introduction

In the building energy modeling community, there is a need to standardize the approach for how component and system models are represented, both as data-model and as mathematical models that formalize the physics, dynamics and control algorithms. This is required to agree upon the physics that should be included in such components for specific use cases, and to share resources for development, validation and distribution of such component and system models; at scales ranging from individual components, through buildings to communities of buildings. There is also a need for a consolidation of models for HVAC and controls that can be used for testing [1]. Similar objectives have been shared by IEA EBC Annex 60, a project in which 41 institutes from 16 countries participated between 2012 and 2017 [2]. Annex 60 developed and demonstrated new computational technologies based on the open standards Modelica [3], used as a modeling language, Functional Mockup Interface (FMI) [4], used to exchange legacy models or simulators, and Industry Foundation Classes (IFC) [5], used to represent Building Information Models (BIM). A recent study has shown that the FMI standard is considered as the most promising standard for co-simulation [6]; furthermore, recent studies have shown that equation-based languages such as Modelica have many advantages for simulating and optimizing buildings and district energy systems over state of the art modeling languages based on causal modeling approaches [7], [8].

A subset of the Annex 60 work is now continued under the umbrella of the International Building Performance Simulation Association (IBPSA). This continuation is conducted within the IBPSA Project 1 "BIM/GIS and Modelica framework for building and community energy system design and operation." It is conducted from summer 2017 to summer 2022.

The objective of this paper is to report on the current status and future developments of this project. The paper is structured as follows: In Section 2 we summarize the challenges and in Section 3 we summarize the goals and structure of the Project 1. The challenges and goals are based on the IEA EBC Annex 60 final report, as they remain unchanged since its publication and provide the motivation for IBPSA Project 1. In Section 4 we discuss ongoing developments within the project, and in Section 5 we present concluding remarks.

2. Challenges

To meet increasingly stringent energy performance targets and challenges posed by distributed renewable energy generation in the building and district energy community, recent attention has been given to system-level integration of thermal, electrical, control and communcation systems as well as to operational optimization of buildings. The intent is to design and operate a building or a neighborhood optimally as a performance-based, robust system that can shed and shift demand, storage and production across energy carriers to provide flexible loads. This requires taking into account system-level interactions between thermal (including the building fabric) and electrical storage, electrical appliances, HVAC and renewable energy systems and the electrical and thermal grids. Such a system-level analysis requires multi-physics and multi-scale simulation and optimization using coupled thermal, electrical, behavioural and control models. Optimal operation also requires closing the gap between designed and actual performance through commissioning, energy monitoring and fault detection and diagnostics. All of these activities can benefit from using models that represent the design intent. These models can then be used to verify responses of installed equipment and control sequences, and to compute optimal control sequences in a Model Predictive Controller (MPC), the latter of which possibly requiring simplified models.

Furthermore, in the AEC domain the processes of designing, constructing and commissioning buildings and energy systems are rapidly changing toward digitalization. BIM and City Information Modeling (CIM) [9] is an enabler as collaborative method and tool to consistently gather, manage and exchange building- and infrastructure-related data on a digital basis over the entire life cycle of a facility. BIM/CIM are not a specific software, it is rather a method as part of, but not limited to, the integral design. A truly added value is expected for the near future when design and commissioning in the sense of computer aided facility management comes together. The above mentioned issues of commissioning, energy monitoring and fault detection and diagnostics can therefore highly benefit from a thorough digital planning when location and function of technical systems are together referenced in a digital model, when the as-built state is harmonized with and well documented in a model and when home and building automation becomes integrally linked with BIM. This shift in focus will require an increased use of models throughout the building delivery stages and continuing into the operational phase. It also gives rise to new requirements for building and urban simulation tools, including the following:

- Mechanical engineers should be able to design, assess the performance and verify the correctness of local and, in particular, supervisory control sequences in simulation. They should then use such a verified, non-ambiguous specification to communicate their design intent to the control provider

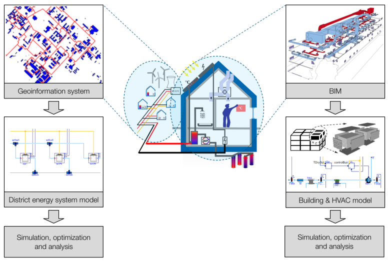

Figure 1. Overview of the scope of IBPSA Project 1.

[10]. Moreover, the specification should be used during commissioning to verify that the control contractor implemented the design intent.

- Controls engineers should be able to extract subsystem models from models used during the building design in order to use them within building control systems for commissioning, model-based controls, fault detection and diagnostics.
- Urban planners and researchers should be able to combine models of buildings, thermal and electrical grids and controls in order to improve the design and operation of such systems to ensure low greenhouse gas emissions or costs, and high quality power delivery [7].
- Mechanical engineers should be able to convert design models to a form that allows the efficient and robust solution of optimal control problems as part of MPC [11]. Such models may then be combined with state estimation techniques that adapt the model to the actual building [12].

The first item requires modeling and simulation of actual control sequences, including proper handling of hybrid systems, i.e., systems in which the state evolves in time based on continuous time semantics that arises from physics, and discrete time and discrete event semantics that arises from digital control [13]. This poses computing challenges for the deterministic synchronization of these domains [14]. The second item requires extraction of a subsystem model and exporting this model in a self-contained form that can readily be executed as part of a building automation system as shown in [15]. The third item requires models of different physical domains and models of control systems to be combined for a dynamic, multi-physics simulation that involves electrical systems, thermal systems, controls and possibly communication systems, which may evolve at vastly different time scales. The fourth item greatly benefits if model equations are accessible to perform model order reduction and to solve optimal control problems.

3. Goals and organization of the Project 1

Currently fragmented duplicative activities in modeling, simulation and optimization of building and community energy systems are coordinated through the use of the open, non-proprietary standards IFC/CityGML for BIM/CIM representation, and Modelica for model implementation. Figure 1 shows the scope of IBPSA Project 1. There are two thrusts, one for district modeling and one for building modeling. Each thrust is separated into data modeling, modeling of the physics and controls, and simulation, optimization and analysis. Data modeling include standards and transformation algorithms to link object-oriented simulation modeling with building and Geographic Information System (GIS) by adopting standards such as IFC and CityGML. Mathematical modeling include the development and validation of dynamic models that represent the physics and control logic of components and systems. Optimization includes research and benchmarking in model predictive control, and simulation includes validation of component and city quarter models. For the implementation of models for simulation and optimization, the Modelica language is used.

The anticipated outcomes are documented, validated and verified Modelica libraries, and BIM/CIM to/from Modelica translators that allow buildings and community energy systems and grids to be designed and operated as integrated, robust, performance based systems with low energy use and low peak power demand. To ensure open collaboration among the participants, all code will be released as open-source using a BSD 3-Clause License. IBPSA will be the copyright owner. The liberal nature of the license allows others to implement the code in their software and distribute it to others at no cost. Hence, IBPSA ownership of the copyright will allow others to reuse and distribute the software. All workshops, software and documentation will be open accessible to anyone. The primary target audience is the building energy research community, students in building energy related sciences, and providers of computing tools for buildings.

The project is organized into three tasks, which are further refined into work packages as follows: Task 1 further develops the open-source infrastructure of models and test suite to coordinate Modelica-based model developments for building and district energy system design and operation. Furthermore, it coordinates research in MPC and it develops a test suite for comparing the performance of advanced control sequences called BOPTEST. Task 2 is developing tool-chains that link object-oriented CAD systems, GIS, building and urban design tools at various levels of detail with one another and with Modelica models. Task 3 is focusing on validation, application, demonstration and dissemination. It includes the development of a validation test for district energy system simulation called DESTEST.

4. Ongoing developments

This section describes the goal, approach and results of the various work packages.

4.1. Task 1

Task 1 develops Modelica and FMI-based software that support the design and operation of buildings and community energy systems. It develops Modelica libraries, coordinates research in MPC, and develops a test for the performance comparison of advanced control approaches.

4.1.1. WP 1.1 Modelica library for design and operation The goal of this work package is to provide a robust, validated and well documented library of Modelica models that serve as the core of Modelica libraries for building and district energy simulation. The approach is to jointly develop the so-called *Modelica IBPSA Library*, hosted at `https://github.com/ibpsa/modelica-ibpsa` and formerly called the *Modelica Annex 60 Library*. The Modelica IBPSA Library is an open-source library that has more than 500 models, blocks and functions [16]. This library serves now as the core of the four Modelica libraries AixLib from RWTH Aachen University in Germany [17], Buildings from LBNL at Berkeley [13], BuildingSystems from UdK Berlin in Germany [18], and IDEAS from KU Leuven in Belgium [19]. These libraries integrate the IBPSA library as their core, add additional models and documentation, and distribute it to their end users. Through this method, the IBPSA library also becomes part of the redesign of EnergyPlus called ”Spawn of EnergyPlus” (`https://lbl-srg.github.io/soep/`). Recent activities and results include the addition of models for heat pumps, borefields and glycol solutions, as well as models that allow generating from a Modelica model a building emulator, packaged as a Functional Mockup Unit, for use in the BOPTEST (Building Optimization Performance Test) that is developed in Work Package 1.2 described below. Moreover, models have been further improved and are now fully compatible with the open-source, freely available JModelica simulation environment.

4.1.2. WP 1.2 Model Predictive Control The goal of this work package is to develop a framework that facilitates the formulation of MPC and that allows testing, assessing, comparing and benchmarking MPC formulations. The approach is (1) to jointly develop an open-source library of models that can be used to efficiently solve optimal control problems for building and district energy systems, and that can be combined with parameter and state estimation algorithms; (2) to develop a framework, called BOPTEST (Building Optimization Performance Test, hosted at `https://github.com/ibpsa/project1-boptest`), to virtually test and assess the performance of controllers, among them MPC. The BOPTEST concept consist of reference building emulation test cases, key performance indicators (KPIs) for quantification and assessment, and a software platform to select and manage test cases, exchange control and measurement data, calculate KPIs and generate reports. The aim of a test case is to provide a clear and unambiguously defined scenario where any controller can be tested to enable a fair comparison between different control strategies. Therefore, a test case is defined as a combination of a building emulator model and a data-set gathering boundary conditions like weather, energy prices, emission factors, occupancy schedules and comfort requirements for a one-year duration, where building location, construction type and HVAC system are consistently aligned. The ten test cases selected represent combinations of buildings and energy systems typically encountered in Europe and the US. Each test case describes the signals that are accessible at different control levels, e.g. room temperature set points at high level, damper positions, fan and pump speeds, flow rates at low level. Baseline controllers are included and operate whenever the control signal is not overwritten by the external (tested) controller. The software platform architecture for deployment and interaction with controllers has been set up. It consists of an emulator pool, a database, a simulation manager and a HTTP Rest API, which is an interface that is independent of the modelling and controller programming languages. The framework is being implemented in Docker containers, and an example test case has illustrated the capabilities of the framework [20].

4.2. Task 2

Task 2 concerns the transformation process from digital district and building information models to simulation.

4.2.1. WP 2.1 City District Information Modeling This work package addresses urban scale energy performance simulation of domestic and non-domestic buildings. Highlighting the exchange requirements and country-specific data mapping approaches, the work package also deals with archetypal definitions of buildings with respect to the generalization of country-specific age-bands, geometrical forms and building functions. Semantic data enrichment, parsimonious geometric information processing and the participation in development of the CityGML schema and EnergyADE for specific simulation tools is also emphasized. Considering different modelling techniques, generic import-export functionalities and enrichment algorithms, the team aims to demonstrate the application of the developed workflows for a range of tools, including Modelica and EnergyPlus, and for a range of geographical contexts and application use cases. The GML ToolBox [21], which extends the pre-processing of geometric prerequisites, modelling of thermal zones and openings and checks CityGML base standards and ADE conformance conditions for dynamic heating and cooling demand simulations in EnergyPlus, is one such example. Another example is an extension to the TEASER [22] tool that is currently being developed to process the five CityGML Levels of Detail and Energy ADE information as an input for annual thermal simulation using Modelica. A further example is the development of a new workflow for the preparation of large (thousands to tens of thousands of buildings) urban scenes for simulation using the CitySim+ urban enery simulation engine [23]. Open source translators and workflows for district energy simulations can be recognized as some of the outputs for this work package.

4.2.2. WP 2.2 BIM The work package starts from the core observations that CAD-integrated calculation and dimensioning requires detailed models and that such models are typically not available in the early design stages. Furthermore, common HVAC classification schemes are lacking, HVAC wiring diagrams, which are relevant for linking with control descriptions, cannot be exchanged with common software, standards are not available for digital function specification exchange and existing BIM software is typically not capable of extracting space boundary descriptions in a way to be used for energy performance simulation using zonal modeling or for CFD approaches for detailed indoor air flow analysis. The work package therefore addresses such data classification and specification, geometry and HVAC model processing. In the first phase, groundwork was set up for the collaborative development and testing of different classes of geometric algorithms for transforming building information models to building performance simulation. Various libraries were considered for reading IFC data and for processing geometric information such as IfcOpenShell, IfcPlusPlus, xBIM (IFC) as well as the geometry kernels OpenCascade, ParaSolid and ACIS.

Based on this experience, developments will be continued using the IfcOpenShell and OpenCascade libraries. Advanced space boundary algorithms for model topology analysis and model generation are currently tested [24],[25] and new algorithms are developed. Code and models are organized in the IBPSA Project 1 GIT repository. Test cases are collected with contribution from the international consortium in order to set up a robust test bed for the space boundary algorithms. A background software service analyses on an hourly basis the content of the entire repository for IFC files and automatically organizes these test cases in terms of contained entities and structures in a database with interlinked and browsable content. As of today, 54 IFC2x3 and 28 IFC4 test files containing 245 IFC entities are registered.

4.3. Task 3

The aim of Task 3 is to develop a test suite for district energy systems, referred to as the DESTEST, and to demonstrate through applications the capabilities that are enabled through Modelica. These applications will also provide feedback to the technology development in Tasks 1 and 2.

4.3.1. WP 3.1 DESTEST The aim of DESTEST is to provide a means to validate models of urban energy systems by defining specific district energy cases for testing in different simulation environments. By carefully selecting and specifying these cases, and by using different libraries for modeling these energy systems, a thorough verification, comparison and benchmarking will become possible. The description of the DESTEST cases and the simulation results of extensively verified models for urban energy systems will be available as a reference for comparing other simulation programs and model libraries. The first common exercise, a simple case in which the energy demand and the distribution subsystem of a district heating system are modelled, demonstrates how such a DESTEST could be used. The energy demand was modelled with five simulation environments, illustrating the difficulty of modelling the exact same building in different environments. Similarly, the network modelling was also used to compare the output of five network simulation models. Supplementary to this comparison, a simulation study focusing on the performance of solvers was done using one particular model.

In future work other building typologies and characteristics, climate and occupancy patterns as well as districts with different scales will be implemented. With respect to networks, cooling networks and electrical grids will also be analysed. Finally, demand and distribution subsystems will be combined to assess the performance of control actions and to check interoperability of tools that model separate subsystems.

4.3.2. WP 3.2 Application The aim of this work package is to demonstrate capabilities enabled by the use of Modelica for building and district energy systems. This task will be accomplished by gathering a number of case studies and describe them through a unified template that facilitates a systematic comparison and illustrates key findings from different applications. The template includes information such as description of the physical problem, objective of the simulation study, building/district system diagram and advantages and limitations of the use of Modelica. The expected outcome of this work package is a collection of application case studies that aim at sharing best practices and document them for dissemination to the simulation community. The systematic collection of application case studies will further lead to the identification of research needs for Tasks 1 and 2.

5. Conclusions

IBPSA Project 1 covers a wide range from data modeling to simulation of buildings and district energy systems, including detailed feedback control algorithms, performance comparison of control approaches and validation of district energy simulations. The work is based around open standards for data modeling (IFC and CityGML), for modeling of physical and control systems (Modelica) and for exchange of simulators (FMI). The tight collaboration and joint development of technologies among groups from different countries and continents, each funded by their own respective projects, would not have been possible had our work not been based on open standards, as these standards provide a common basis around which research, development and deployment activities can be organized. As such, our intent is that this project provides a strong basis for continued collaborative development of tools that lead to high performance building and district energy solutions.

Sustainability Assessment in Architectural Competitions in Switzerland

Mobiglia M, Cellina F, Castri R

Campus Trevano, 6952 Canobbio, Switzerland

massimo.mobiglia@supsi.ch

Abstract. Architectural and urban planning decisions, that have a strong impact on all areas of sustainability, are often set during preliminary phases of project development. This work focuses on the architectural competition, that is traditionally an instrument for enhancing quality in architecture and urban planning in the preliminary phase. However, in Switzerland, only occasionally assessment criteria adopted in such competitions include principles of sustainable development (SD), as there are no specific references to SD in the specific national SIA 142 "Regulation of architecture competitions".

In the Swiss Canton of Ticino, in some architectural competitions the evaluation criteria of sustainable development have been already clearly enumerated in the tender documents. Those criteria were selected according to existing tools (Sustainable neighbourhood by SMEO, SNBS, SIA 112/1) widely used in Switzerland. In addition to the usual graphic documents each project team had to structure a sustainability report. The presented projects have been then assessed by an interdisciplinary team, after that the resultsin several representations (global index, dimension index, category index, bar graph diagram and spider web diagram) and compared them to show the strengths and weaknesses from an integrated point of view.

A change in the competition culture is needed because the sensitivity for the topic depends strongly on subjectives purposes, namely primarily on the composition of the jury.

1. Introduction

"The uncontrolled proliferation of settlements is only an indication that settlements and infrastructure development is not yet resource efficient. And this impacts not only land use, but also energy and material use, as well as social aspects. However, the high rates of land use also reflect the fact that the various practices of settlement formation and infrastructure development have not yet been brought together and integrated into an overall context. Too often, the various aspects are optimized on their own. For example, the current efforts to renovate buildings usually have no real connection to the wider building environment, and the modernization of city centers often neglects the related social aspects. Even the self-sufficient one-family house in the countryside without connection to public transport indicate that the different disciplines work independently of each other.

What is needed is a fundamental change towards an integrative approach and processing of our settlements and infrastructures in all their dimensions. [...] a change in society, only through a reduction of the growth, an economic development that leads to quality instead of quantity [...].

It is necessary to check whether it is really necessary to build a project before designing it."

Dr. Prof Eugen Brühwiler, President of the NFP 54 Steering Group

Sustainable is a development that meets the needs of the current generation without putting at risk the ability of future generations to meet their own needs and choose their lifestyle. [1][2]

Still, today the various actors (public and private clients, associations, designers, builders, etc.) involved in the design and / or transformation processes of the micro-urban environment deal with decisions that are often at the limit of the underlying concept of sustainability. Based on appropriate knowledge of the disciplines and methods that enable the prediction and assessment of the impact on SD, this approach requires a more multidisciplinary approach.

This paper focuses on the assessment of sustainability in the architectural competition phase, which sets architectural and urban planning decisions that will have a strong impact in all areas of SD. Furthermore, it generates results, that can be used more widely, for example as a general framework. The presentation of the results of four case studies aims to propose new approaches towards integrating SD criteria in architectural competitions, by setting new tasks in the process management.

2. Architectural competition procedure

In Switzerland the competition procedure is described by the specific SIA 142 "Regulation of architecture and engineering competitions" [3]. Although the procedure is dedicated to find the best quality projects, there are no specific references to SD in its recommendations. This is delegated to the involved actors, above all to the jury, the client or the experts. The regulation, for example, defines the composition of the jury, only by differentiating jury members between professional and non-professional subjects and fixing that the majority has to be represented by professionals.

In this procedure, the few instruments available to stakeholders to guarantee the inclusion of SD criteria are the selection of the jury, who is in charge of choosing the winner project, the project assessment by a team of experts in SD, the requirements defined in the competition program or the sensibility of the competition coordinator.

To encourage the introduction of sustainability criteria in the construction sector, the trend of recent years has been to move from simple environmental requirements to a complete analysis, pursued by representative interdisciplinary teams.

3. Assessment tools

In addition to the competition procedure, the SIA proposes a documentation with a methodology to assess sustainability, namely the SNARC (System to assess environmental sustainability in architectural projects) [4]. Moreover, contracting authorities may use the Albatros tool, a methodology that incorporates the criteria of SD in the strategic planning of public buildings [5]. In recent years, the SméO / Sustainable Neighbourhood by SméO, a project promoted by the two Swiss Federal Offices of Energy and Territorial Development [6], has partly replaced SNARC and Albatros.

To evaluate a topic as complex as sustainability, a multi-criteria analysis has to be used, as they allow the solution of complex problems by assessing each variable and assigning each one its relative importance.

However, the tools to evaluate a complex concept such as sustainability, which aggregate the results into a single index, are very problematic. The Dashboard of sustainability, model created within the UN Commission on Sustainable Development (UNCSD) and later enhanced by a small group of researchers led by the International Institute for Sustainable Development (Canada) and presented in 2002 at the World Summit in Johannesburg, aims to integrate everything into a single index of economic, social and environmental aspects. The objective pursued is therefore to provide an instrument that can be used to briefly illustrate the level of sustainability of a given territorial reality based on a set of selected indicators.

For this reason, the interpretation and understanding of the obtained results is very difficult. Consequently, the "dashboard" has also been defined as a "black box": an instrument that shows an output after entering data, but without knowing what exactly is happening in there.

Aggregating different criteria into a single sustainability index, even if it is obtained as a result of a multi-criteria evaluation process, is very close to the concept of weak sustainability due to the compensatory effect that appears between socio-economic and environmental aspects.

The approach that currently obtains the greatest favours and attentions is the one of an instrument close to strong sustainability, which, according to many, should be considered true sustainability. This aggregative logic leads to the integration of social, economic and environmental aspects, while maintaining their own autonomy, so that no aspect is penalised. This approach of multi-criteria analysis is at the basis of evaluation tools as decisional support. [7]

4. Competition tender

The involved stakeholder has the chance to influence, positively or negatively, the process of sustainability in the architectural competition. Among them the clients/promoters have the main and most important role. In fact, it is up to them to define the composition of the jury and the experts. As assistance they have a coordinator which has the role to follow the SIA 142 Regulation. Afterwards, promoter and jury define the criteria of judgment in the competition announcement and define the experts. This means that in the initial phase of the architectural competition, key decisions are taken by the promoter. Those decisions significantly influence the sustainability of the project.

The preparatory phase of the competition is the right moment to integrate the principles of SD in the tender, that will be held throughout the process. Namely it is necessary to clearly set the evaluation criteria. The selection of indicators is mainly based on the SméO instrument.

5. Case studies

In 2018, the Institute for Applied Sustainability to the Built Environment (ISAAC) of the University of Applied Sciences of southern Switzerland (SUPSI) had the opportunity to assess the sustainability of four different architectural competitions in Canton Ticino:

- New Campus SUPSI in Mendrisio [8], 22 projects in the 2nd competition phase
- New Campus USI-SUPSI in Viganello, 12 projects in the 2nd competition phase
- New Retirement home in Coldrerio, 5 projects in the 2nd competition phase
- New Kindergarden in Gerra Cugnasco, 6 projects in the 2nd competition phase

In the specific case of the Campus in Mendrisio, thanks to the involvement of a team of sustainability experts before publishing the tenders, it was possible to introduce some SD principles already in the preface: "The new campus will serve as a showcase and model of sustainability for its users and territory, in order to guarantee the principles of sustainable development a diffusion in today's society".

The experience of this first competition served as solid base for the other ones.

In each competition, the evaluation of the projects reaching the second selection phase was carried out by an interdisciplinary team. Each project team produced a specific sustainability report that explicitly described the decisions taken. These should also be visible in the provided plans.

The multi-criteria analyses carried out are based on an aggregation principle. A colour is assigned to each answer (from green - good to red - bad).

6. Results

6.1. Sustainability assessment

At the end of each evaluation process, it is necessary to explore how to deliver results in ways that are easy to understand to all the possible actors, even non-experts.

The evaluation results of the various architectural competitions have been presented in several variants.

The first option is to present the results of aggregate logic with the global index, but this does not express the full complexity of a score. In Figure 1 in the next page an example from the architectural competition of the Campus SUPSI in Mendrisio is shown with single or global index, for all the projects accepted in the second phase of the competition: weaknesses and strengths of each project are not visible here, but only the general ranking.

Dividing the global index into the domains of sustainability, and dividing each domain into categories can facilitate the comparison. The Figure 3 and Figure 4 in the following page have the advantage that a compensation logic between the different domains is not possible. In this way, the weaknesses and strengths of each project are better visible. Hence the expert can express clear and understandable recommendations.

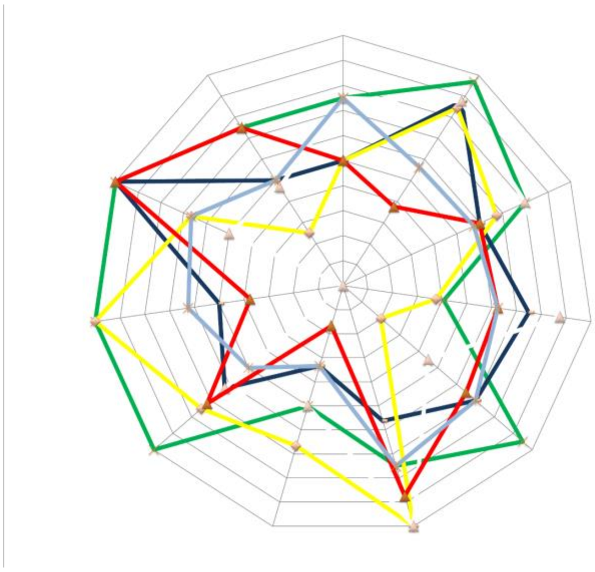

Figure 1: Competition Campus SUPSI in Mendrisio: spider web

Figure 2: Competition Campus SUPSI in Mendrisio: global index

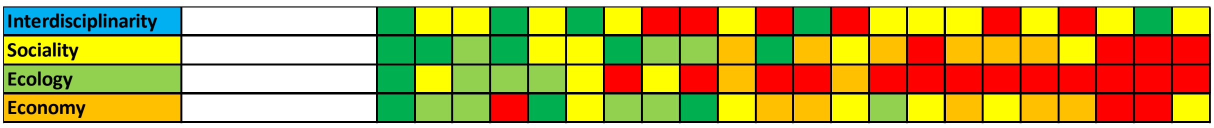

Figure 3: Competition Campus SUPSI in Mendrisio: dimension index

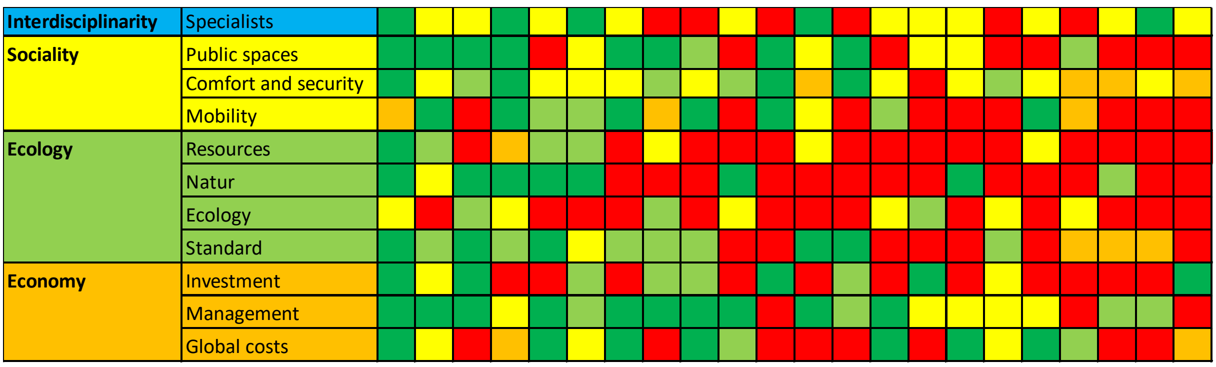

Figure 4: Competition Campus SUPSI in Mendrisio: category index

Another possibility of representation is the bar chart. The Figure 5 shows again the comparison between the 22 projects of the SUPSI campus in Mendrisio.

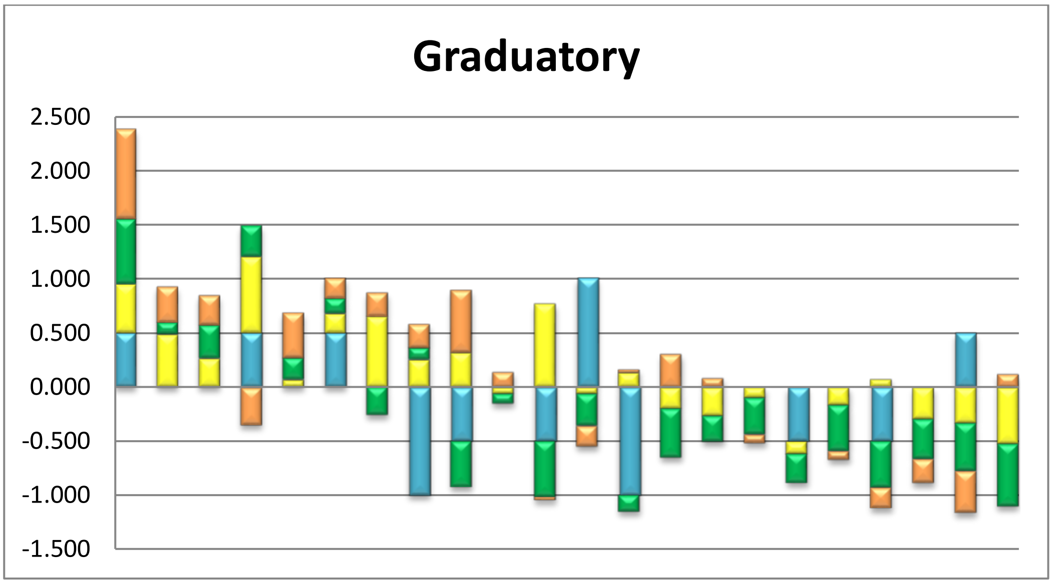

Figure 5: Competition Campus SUPSI in Mendrisio: bar chart

At first glance, Figure 5 easily allows everybody to see the peculiarities of every project: on one hand, the height above 0 of the cumulative bars identify the strength of each project, on the other hand, the bars below 0 identify the weaknesses.

A further representation is the spider web diagram. This type of illustration is easy to understand, as long as it displays a rather limited number of projects.

The following figures show two different ways to use spider web diagrams:

- Figure 6: the six projects of the SUPSI campus in Mendrisio, which have received the best sustainability indices. Reading is difficult in this representation.
- Figure 7: three projects of the architectural competition of the new campus USI-SUPSI in Viganello. Here the comparison of the projects is easier.

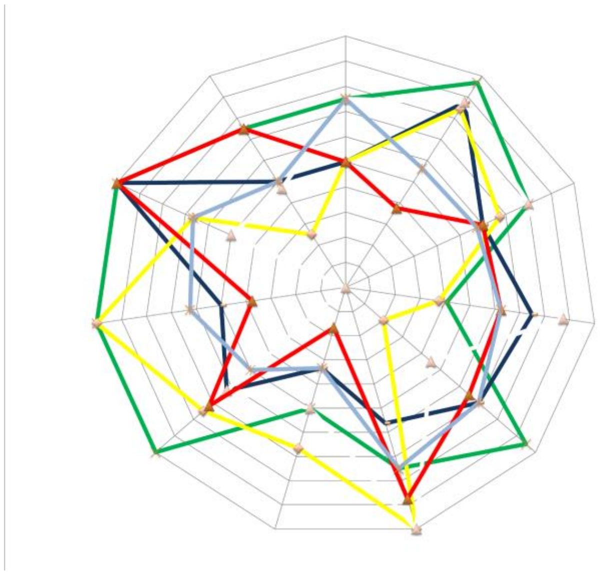

Figure 6: Competition Campus SUPSI in Mendrisio: spider web with the best 6 projects

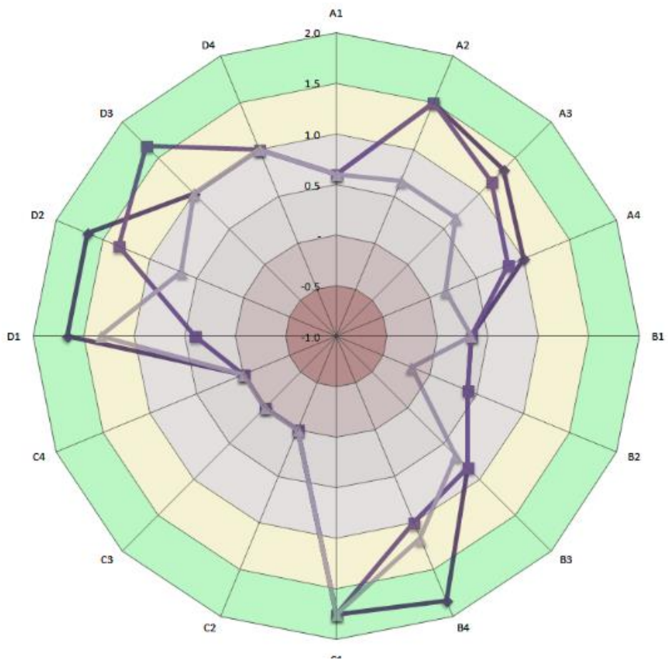

Figure 7: Competition Campus SUPSI in Viganello: spider web with the 3 best projects

6.2. Winners of the competitions

Only in the competition related to the SUPSI Campus of Mendrisio the decision of the jury coincides with the ranking of the sustainability assessment. In this case, more jury members were really interested in the SD assessment and did clearly understand the potential.

In the Coldrerio case study, the winner was placed second in the sustainability assessment, among the 5 competitors passing the second selection phase.

In Cugnasco Gerra, the winner reached the fifth place in the sustainability assessment, among the 6 selected competitors of the second phase.

In Viganello, the winner attained the eleventh place in the sustainability assessment, among the 12 selected competitors of the second phase.

This shows that the criteria of the jury differ from the ones of the sustainability team. In our experience the composition of the jury plays an essential role.

7. Conclusions

7.1. Choice of the best representation of the results

Thanks to the experience accumulated in the four architectural competitions, it was possible to identify the representation of the results that better visualize the facets of the assessment of SD:

1. The representation that allows in a quick way to highlight the strengths and weaknesses of a project is the bar chart. We therefore believe that this is the right way to represent the results of a sustainability assessment with more projects;
2. The spider web diagram is useful to present a single project rather than comparing many projects. But it has the advantage to better follow the development of a single project in its realisation;
3. The global index is of great interest to the client because it explicitly expresses a ranking, but it does not allow for any comparison.

7.2. New approaches towards more sustainability in architectural competitions

The architectural competition is traditionally an instrument for quality research in architecture and urban planning. Often, however, the assessment criteria do not include the principles of SD or, if they do so, they are very weak.

In order to emphasize the qualitative requirements of projects, including architectural aspects or urban planning, it is necessary to change the culture, as the sensitivity to the topic depends heavily on the composition of the jury.

Therefore, we propose a new approach toward more sustainability in architectural competitions. The new tasks in the process management are:

- Adaptation of legislation
  an adaptation of the SIA Recommendation 142 would be desirable by introducing explicit paragraphs on SD. First of all, in the initial preface, then in the definition of the type of architectural competition, but especially in the definition of the different actors involved in the competition procedure and in the definition of the documentation.
- Coordinators' training - drafting of the tender
  in order to implement the proposed change in the SIA Recommendation it is necessary that the involved personnel are prepared. From this point of view, the person who has the most influence is the coordinator of the competition, namely the person to whom the public bodies normally refer to, to prepare the competition procedure. If the coordinator has a solid foundation in SD, he can make sure that the tenders include the underlying concepts of sustainability as one of the main criteria of choice.
  The training of coordinators could be implemented by the order of architects.
- Composition of the jury
  To include sustainability in those processes, it would be desirable a composition of the jury 1/3 professional (Architect, urbanist), 1/3 SD-professionals, 1/3 non-professional.
- Role of the experts of SD
  Actually, the experts of SD only have advisory function without voting rights. In this way the proposal is to include them in the jury (1/3 of the jurors).

7.3. Next steps

In the near future, the method will be applied to other architectural competitions in the Canton of Ticino, Switzerland, and namely for a new retirement home in Vacallo and for the refurbishment and extension of the retirement home in Morbio Inferiore.

It would be desirable to propose the following proposal to the SIA.

Multi-objective optimization of building's life cycle performance in early design stages

Yu H, Yang W, Li Q

School of Architecture, Tianjin University, 300072, Tianjin, China

hanzeyu@tju.edu.cn

Abstract. The early design stages of buildings have the highest potential for optimizing energy efficiency. From the aspect of architectural design, the architects can hardly make the best decisions of the complexed variables of geometries and materials. The choice and weighting of different optimization objectives also have no reference while considering the impacts from the whole view of the life cycle. In this paper, a simulation-based parametric approach through the use of multi-objective optimization method is framed. The extraction of geometry variables from the original design and the principles of explaining optimization results obtained from different objective combinations are discussed.

This process is carried out in Rhino and Grasshopper. To fully consider the aesthetic and building performance step by step in early design stages, the geometry and material parameters are tested simultaneously. The life cycle inventory data of materials and energy resources are imported by programming, and local data is partly used. Life cycle environmental impacts (PED and GWP), life cycle cost, and operating energy consumption are used as optimization objectives. A case study is verified on a project of a small campus museum building in northern China. The results indicate that the combination of geometry and material values in the optimal solution set is various and needs to be artificially selected according to actual needs. The optimization objectives should be considered comprehensively; an incomplete set may result in poorly behavior of the unselected objectives.

1. Introduction

The construction, operation, and demolition of buildings are the essential reasons for the consumption of resources and energies worldwide, which also lead to vast amounts of pollutions. In 2016, China's total building energy consumption was 899 million tons of standard coal, accounting for about 20.6% of the country's total energy consumption[1]. The resource conversion rate of construction waste is lower than the average level of developed countries. Less than 5% of the construction waste is recycled[2]. It is necessary to consider the environmental impacts of buildings from the early design stages. The International Standards Organization identifies the Life Cycle Assessment (LCA) and Life Cycle Cost (LCC) methods as an essential method for building sustainability assessment (ISO TS 21929-1). The optimization which aimed at life cycle environmental impacts and costs plays a vital role in improving the overall performance of the building[3].

In the process of building design, due to the variety of parameters, the influence of these parameters (such as orientation, layout, geometry, structure, equipment, etc.) on the performance of the building is not intuitive[4]. The concept generation will become too complicated for designers while considering environmental impact, economic performance and aesthetics requirement at the same time. Questionnaire research also points out that time-consuming and none available workflow are the two main factors that the design companies do not run simulation and optimization in the concept generation[5].

Most of the decisions related to building performance occurred in the early stages of design[6]. At these stages, the variable range of the building geometry parameters is broad, and the material selection often comes from conventional construction practice. The parametric modelling platform can take care of these two demands. It can effectively complete the modelling of simple mass and combine the geometry with life cycle inventory (LCI) data to achieve multi-objective optimization of building's life cycle performance.

2. Framework

This paper proposes a framework for performing multi-objective optimization of building design using parametric modelling platform. Figure 1 shows an overview of the frame.

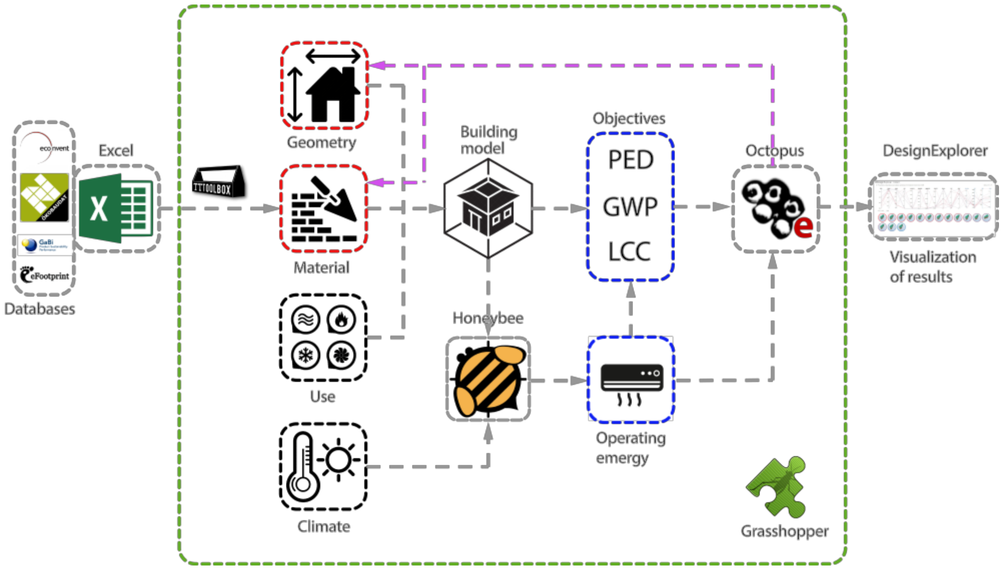

Figure 1. Framework for performing multi-objective optimization.

The framework is based on Rhino's plugin Grasshopper[7] and its components. Firstly, the physical and LCI information of materials are collected from the database and imported into GH as an Excel file. Then the data is compared with a geometric model to generate the building model containing the complete information. Secondly, the Honeybee[8] component is used after completing the geographical location, equipment, running time and other information of the model to calculate the energy consumption of the building. Then the environmental impact and LCC of the project is estimated by comparing the material quantity and energy consumption with the LCI information. Finally, the objectives are optimized by the genetic algorithm through the Octopus[9] component to obtain the optimal parameter combination. The combinations of parameters and results can be exported to Design Explorer[10] for visual visualization of further guidance on architectural design.

3. Case study

This study selects a public building with a strong diversity of geometric variables. The small museum is located in Tianjin (39°N), a northern city in China. The air conditioning in summer is run by electricity and the central heating in winter is powered by burning natural gas. It is used to display the dinosaur skeleton donated by alumni of a university, four floors above ground and a total area of 5,200 square meters. The building is located on an east-west narrow site on campus. The main exhibition hall is designed on the north side. The curtain wall of the exhibition hall has a wrinkled shape to simulate the geological effect of the rock formation（Figure 2）. Designed for a service life of 50 years, the price index and discount rate of the material are 2.0%/2.3%, of the energy are 3.0%/2.3%[11]. Table 1 shows the variables.

Table 1. Input variables and their ranges for optimization.

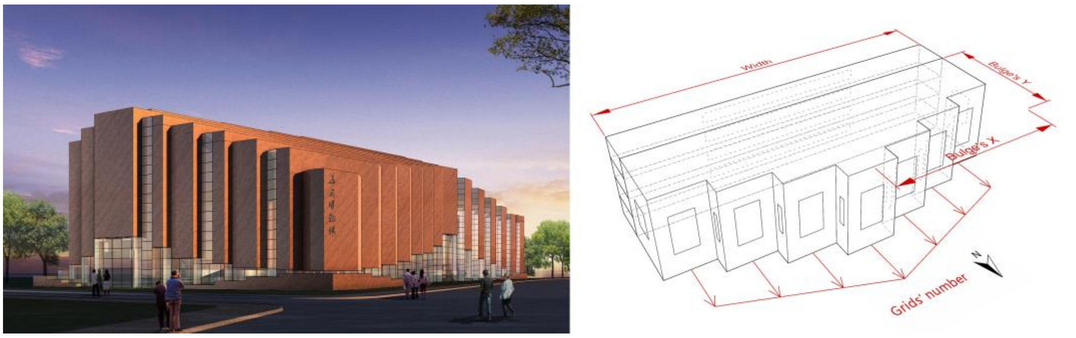

Figure 2. The rendering(left) and energy analyse model(right).

Categories	Description of variables	Unit	Distribution	Sampling ranges
Building geometry	Width	m	Uniform	(70.0,80.0)
	Bulge's X	%	Uniform	(0,100)
	Bulge's Y	m	Uniform	(40.0,60.0)
	Grid's number	-	Discrete	(3,5,7,9,11,13,15)
Window to wall ratio	North WWR	%	Uniform	(20,40)
(WWR)	West WWR	%	Uniform	(10,30)
	South WWR	%	Uniform	(20,30)
	East WWR	%	Uniform	(10,30)
Building element	Window	-	Discrete	(1-5)
	Exterior wall	-	Discrete	(1-21)
	Roof	-	Discrete	(1-19)

Table 2 shows the physical properties of the building elements.

Table 2. Building elements in this case study.

Index number (Window)	Glass type	Frame type	U-value [W/m^2·K]	SHGC	Visible transmittance
1	Double Low-E	Aluminum alloy	2.16	0.4767	0.76
2	Triple Low-E	Aluminum alloy	1.78	0.4759	0.72
3	Triple Low-E (Argon filled)	Aluminum alloy	1.51	0.4721	0.68
4	Double Low-E	Wood-aluminum	1.30	0.4767	0.76
5	Triple Low-E	Wood-aluminum	0.80	0.4759	0.72
Index number (Exterior wall)	**Layers (from outside to inside)**	**Thickness [m]**	**Thermal conductivity [W/m·K]**	**Density [kg/m^3]**	**Specific heat capacity [J/kg·K]**
	Curtain (Stone panel)	0.005	3.5	3300	920
	Curtain (Aluminum frame)	0.02	203	2700	900
	Cement mortar	0.01	0.93	1800	1050
1-11	Rock wool panel	0.05-0.15 [a]	0.048	140	1220
12-21	XPS panel	0.04-0.13 [a]	0.0384	30	1380

Index number	Layers (from outside to inside)	Thickness [m]	Thermal conductivity [W/m·K]	Density [kg/m³]	Specific heat capacity [J/kg·K]
	Autoclaved aerated con crete block	0.2	0.175	500	1050
	Cement mortar	0.01	0.93	1800	1050
Index number (Roof)	**Layers (from outside to inside)**	**Thickness [m]**	**Thermal conductivity [W/m·K]**	**Density [kg/m³]**	**Specific heat capacity [J/kg·K]**
	Polymer waterproofing membrane	0.002	0.15	580	1680
	Thermal insulation mortar	0.065	0.08	400	1050
	Perlite insulating concrete	0.002	0.435	800	1320
1-11	Rock wool panel	0.1-0.2 [a]	0.048	140	1220
12-19	XPS panel	0.08-0.15 [a]	0.0384	30	1380
	Reinforced concrete	0.1	1.74	2500	920

[a] Due to the consideration of the actual product specifications, the thickness of the insulation material is not set as uniform but discrete with a span of 0.01 m. Study has also pointed out that too many uniform variables will produce a near-infinite combination, reducing the efficiency of the optimization process[12].

Table 3 shows the environmental data of the building materials.

Table 3. Environmental data of materials used.

Categories	Components	Unit	PED [MJ]	GWP [kg CO2 eq]	Database	Initial cost [Yuan]	Initial cost's unit	RSL [a]

3.1. Variables' preparation
Based on the original design, geometry parameters that can make a significant change in the shape are selected. All the extreme combinations of geometric variables have been tested to prevent modelling errors during the optimization process and to meets the requirements from the site and function.
A pre-optimization artificial selection of the material variables has been made to make sure the material be chosen is not performing poorly at either thermal property or embodied energy than the others, as shown in Table 4. If insulation material A is poorly at all three factors (λ·PED, λ·GWP, λ·LCC) than material B, it means A has a more significant environmental impact and cost than B while providing the same thermal resistance. Only material that has its own strength in at least one factor can be chosen.

Table 4. Insulation variables pre-optimization compare.

Compared variables	Thermal conductivity λ [W/m·K]	λ·PED	λ·GWP	λ·LCC
Rock wool panel	0.0480	100.50	7.60	22.78
XPS panel	0.0384	115.97	3.70	28.69

3.2. Genetic algorithm parameters and computational efficiency
The optimization process uses the HypE[14] algorithm within Octopus. The following parameters are used: population size = 50, crossover rate = 0.8, mutation rate = 0.5, and elitism = 0.5. Five optimization scenarios are performed with the objectives of Operating energy(OE, kWh/m^2/a), Life cycle cost(LCC, Yuan/m^2), Primary energy demand(PED, GJ/m^2), Global warming potential(GWP, t CO_2 eq/m^2) and any of the three among the four. The convergences of the objective functions in all these five scenarios complete within 50 generations. It takes a desktop computer with a 3.6 GHz Intel® I9-9900K CPU 20-22 hours for one single scenario.

3.3. Results
In the five optimization scenarios, the objective functions converge to the Pareto optimal solution set in four out of the results. Only in the case of OE, PED, and GWP, the only optimal solution is approached in the 30th generation, as shown in Figure 3.

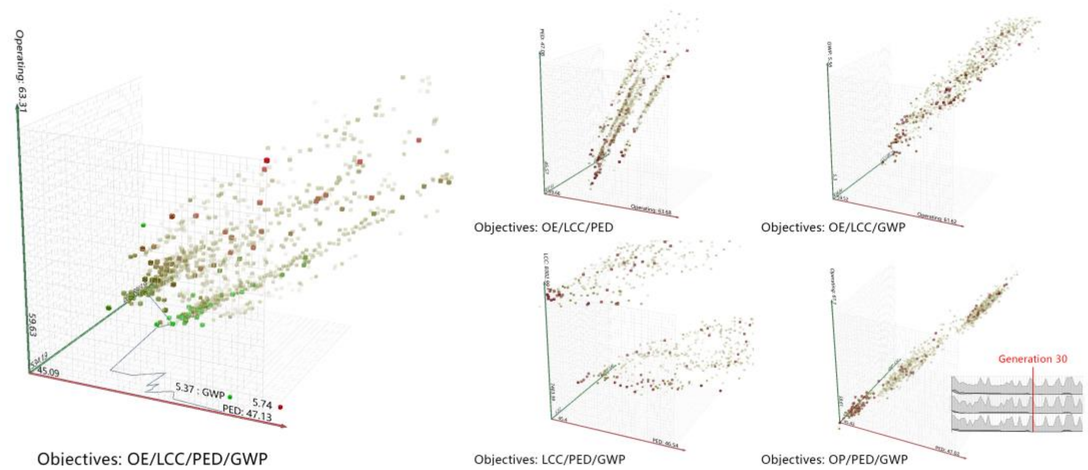

Figure 3. The scatter charts of all scenarios.

Due to the different dimensions and units of optimization objectives, the 50th generation Pareto optimal solution sets is standardized by SPSS[15] to make a comparison. It can be seen from Figure 4 that the objectives' value of OE, PED, and GWP is inversely related to LCC and there is not a clear trade-off relationship between the operating energy and embodied energy (PED, GWP) as some previous studies[16, 17].

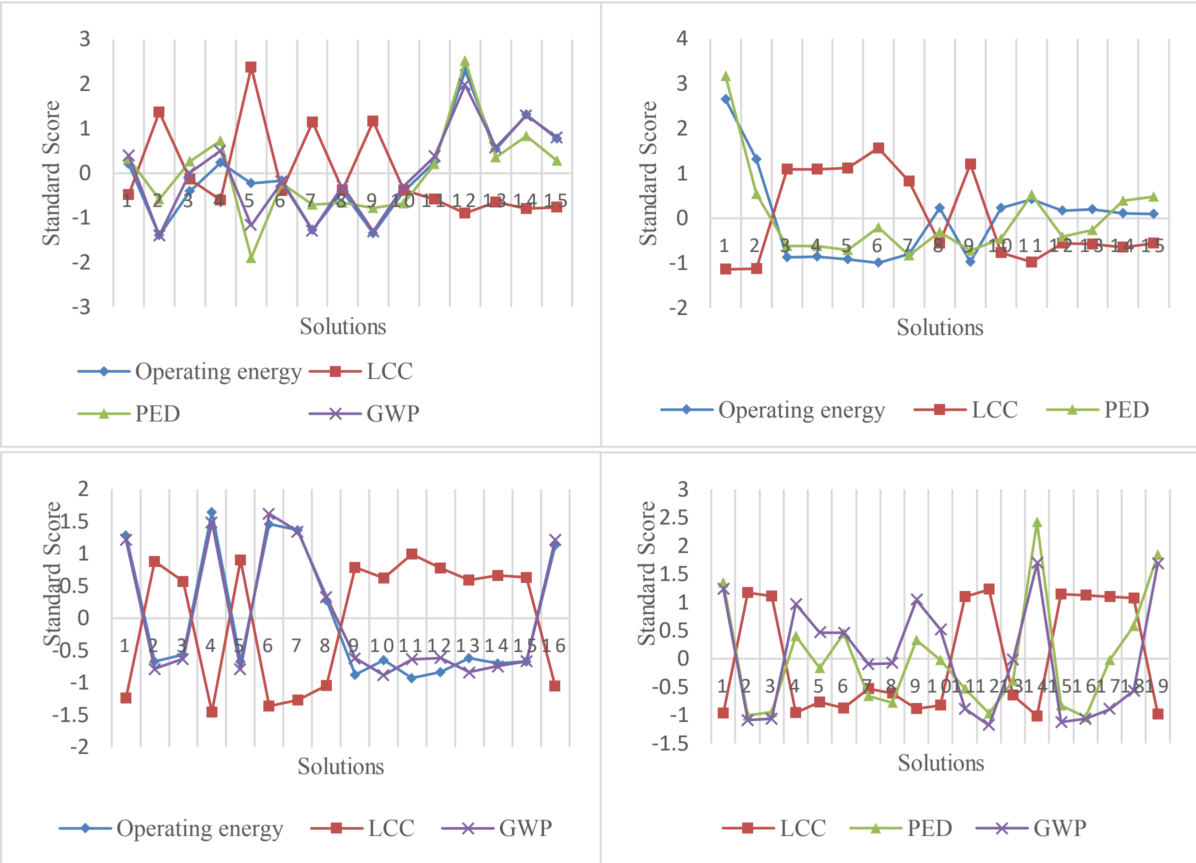

Figure 4. The standardized Pareto optimal solution sets.

By using Design Explorer[10] to visualize the optimal solution set and the related 3D models, it can be seen from Figure 5 that the solution space of geometric and material parameters are scattered. Architects need to make a subjective choice.

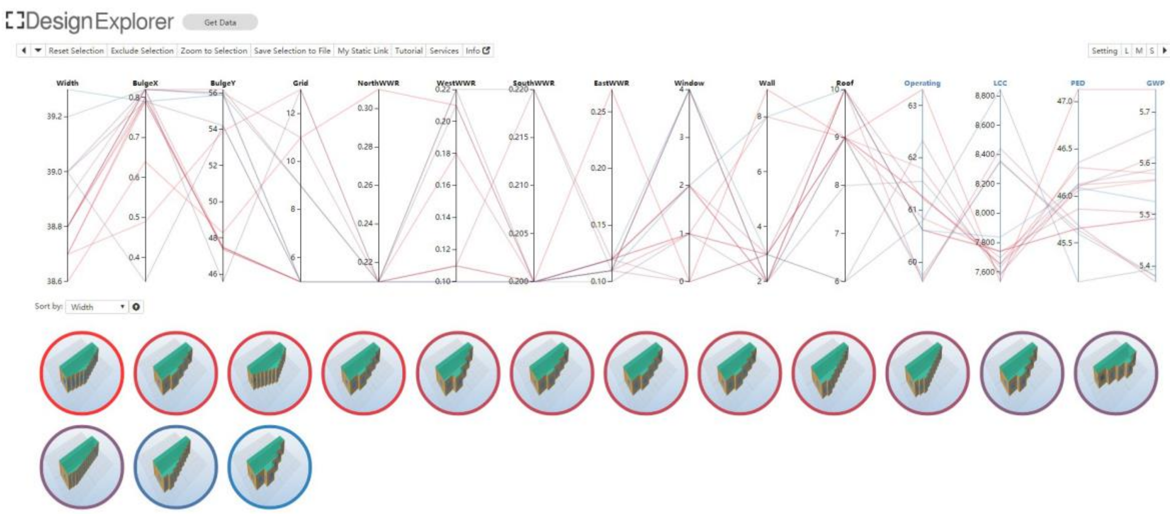

Figure 5. Pareto optimal solution set of OE/LCC/PED/GWP scenario.

4. Discussion

For each scenario, the optimal solution set obtained by this experimental framework is only more than ten, which can be used for manual comparison. The selection process by the architect can be based on specific values. For example, each objective is normalized in the set and summed to obtain a total score (the lower the better) for comparison, or only the LCC (or initial cost) which below the average cost is selected (Figure 6). Also, it can be considered from the architectural form: whether the optimal solution geometry meets the size of the exhibits or the site and surroundings.

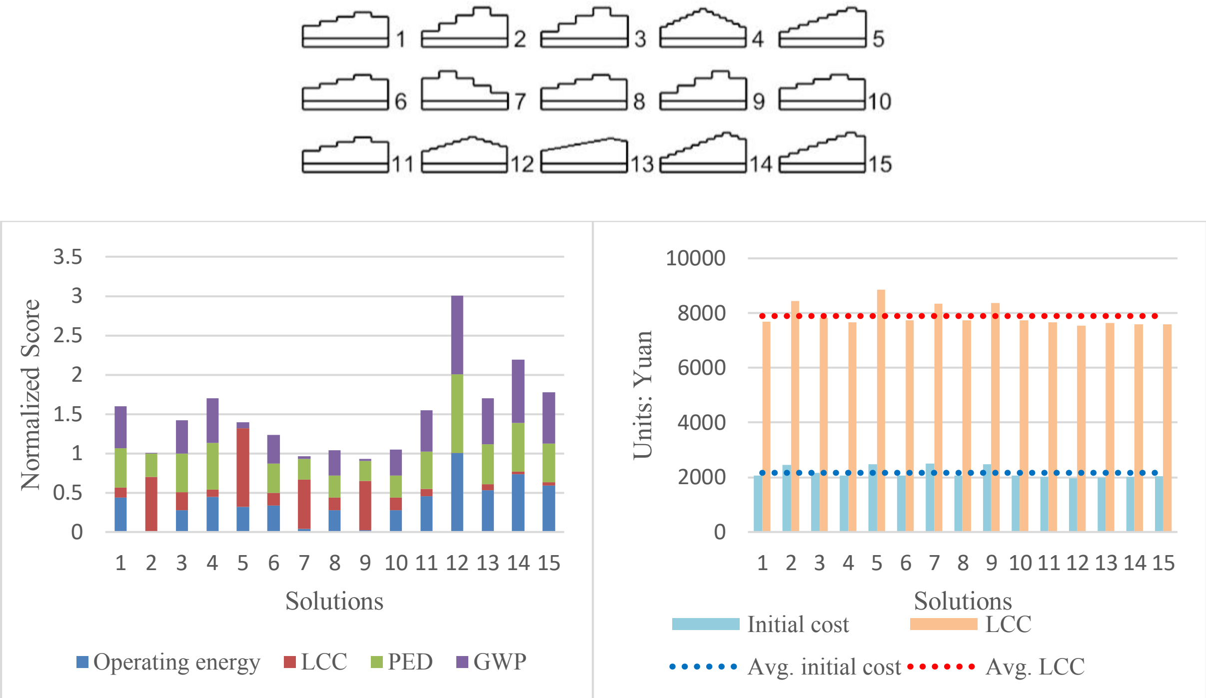

Figure 6. The OE/LCC/PED/GWP scenario's optimal solution set. Solution No.9 has the lowest sum normalized score (left) and solution No. 1/3/4/6/8/10/11/12/13/14/15's initial cost and LCC are both under the average (right).

The interpretation of the same optimization objective in different optimization scenarios is also different. When there is no explicit requirement, including as many optimization objectives as possible can ensure the generation of the optimal solution set after the multi-objective optimization process. Otherwise it can lead to poor performance of the unconsidered objective. In this study, the LCC value of the optimal solution from the OE/PED/GEP scenario is 8652.74 Yuan/m^2. The average LCC of the optimal solution set from the OE/LCC/PED/GEP scenario is 7893.48 Yuan/m^2, and the minimum value is 7534.19 Yuan/m^2. When comparing the values of the parameters between the optimal solution sets in different scenarios, it is found that there is no set of solutions with all eleven variables close to each other. This also proves that there is no clear linear relationship between the optimization objectives.

5. Conclusions and future work

This study attempts to optimize the parameters of building performance, environmental impact and LCC from the process of the initial stages of the architectural design. It is more detailed than the previous research in the geometry of the shape, but it also leads to a problem that the model is only for this project and cannot be reused. The relationship between the objective functions and the consistent and inconsistent among the optimizations with different objectives also requires more case studies to prove its universality.

Future work should be broken down into the early stages of design and deepened into the late stages, combined with BIM models and databases for detailed calculations. Another issue is that the original plan is to use local LCA data, but the Chinese database currently only has a small number of basic building materials, the EPD data from the manufacturers is also lacking, which is necessary for improvement in the future.

Abstract. There is an increasing demand for Life Cycle Assessment (LCA) as a method for environmental impact and resource assessments of buildings. At early design stages, where major design decisions are made, the potential for improving the environmental performance using LCA is greatest. However, detailed building information is usually not available at this time. This paper presents the recent extension of LCAbyg, the official Danish building LCA-tool, integrating an LCA approach for situations, where building design and material choices are not yet fully determined. The tool assists the user in establishing a complete building inventory by providing a default component library including building services and a guide for estimating quantities. Default components in the library are based on the integrated product database Ökobaudat. A convenient generation and comparison of variants improves usability, while a new LCA design guide shall increase the uptake of LCA in larger parts of the building industry. The methodological choices of the approach are laid out and discussed. The presented approach is not limited for use in early stages, but may improve feasibility in building LCA in general as default and estimated values may be refined towards more detail in later stages of the project.

1. Introduction

Life cycle assessment (LCA) has become a widely accepted approach for assessing the environmental performance of buildings. Comprehensive LCA, however, require expert competencies, a considerable data processing and advanced calculation tools and databases. In order to increase feasibility and making it a routine building parameter, LCA is often conducted based on simplifications, such as in green building certification schemes, which have been a driver for the uptake of LCA in the built environment [1][2][3][4].

In Denmark, LCA requirements for integration into the Building Code are currently under development. As a precondition, the requirements shall be voluntary to follow and feasible for broader parts of the building sector. This paper proposes a simplified approach to LCA, allowing a feasible and low-cost adoption at the current state of the industry. Based on LCAbyg, a free building LCA tool recognized by DGNB in Denmark [5], the approach is implemented in the new version LCAbyg 4.0 beta [6].

Existing LCA simplification often includes reducing the number of parameters in the building life cycle or the functional unit, which may be called a horizontal approach. Simplification by reducing data quality and allowing generic data address information depth and may belong to a vertical approach.

Integrating LCA feedback in early design stages, where major decisions can be made, is essential for meeting a given benchmark at a later stage of the project [7]. Here, feasibility is dependent on the level of integration into existing workflows, since clients cannot be expected to accept the cost for advancing detailed design e.g. regarding building services or structural analysis solely for achieving a complete LCA inventory. However, there are different strategies for filling data gaps.

Some research contributions attempt at identifying critical parameters with greatest relevance or sensitivity to variation regarding the overall result in order to omit other parameters for workload [2][8][9][7]. Selective approaches are dependent on knowledge on the relevance and sensitivity of included building parts for all the cases to which an LCA is applied, however studies are limited to a narrow range of building types and properties [9][8]. The same problem of generalization applies to the level of detail in a given building element, where often neglected products show varying relative influence depending on the construction principle, building type or other variables[10]. Common to a selective approach is an uncertainty related to the omitted parameters.

Another approach is pursuing a complete and detailed inventory from the start. As a full building model is usually not available, this approach is dependent on a reliable methods for bridging missing input data related to building design, material choice and environmental impact.

A possible, emerging solution is linking LCA with existing BIM/CAD models [11][12]. Here, feasibility is dependent on the question, if digital models with suited data structure are already used in early design stages and if eventually more parameters such as energy and indoor environment are assigned to a shared model.

Yet, complete and detailed inventories may be achieved by manual input as well. Similar to the BIM approach, this solution shares the dependency on data bridging methods. Manual inputs are independent from the adoption of certain design tools and potential data compatibility issues in early design. Crucial for feasibility is the availability of default values and an easy transfer of quantities, which are based on already available information in concept design.

The manual input approach is chosen, because it is expected to meet the requirements of an LCA tool adoptable for most of the building practitioners and different projects type and scale. The new functions are implemented in the existing LCAbyg tool enabling building generalists to integrate LCA into early stages of design, eventually pursuing a DGNB screening, however, and providing a seamless adaptability for further refinement e.g. later full DGNB reportings. LCAbyg already uses a simplified system boundary including the product stage, replacements, operational energy and End-of-Life stages [13], see the feature list in the appendix.

2. Method

The three main features presented are a component library, guided quantification and comparison of variants (figure 1). A case study-based test of deviation compared to LCA with specific inventory is presented in a separate paper [14]. The project was carried out in collaboration with architects, civil engineers, surveyors and other representatives from the Danish building sector in series of open workshops in 2017/18.

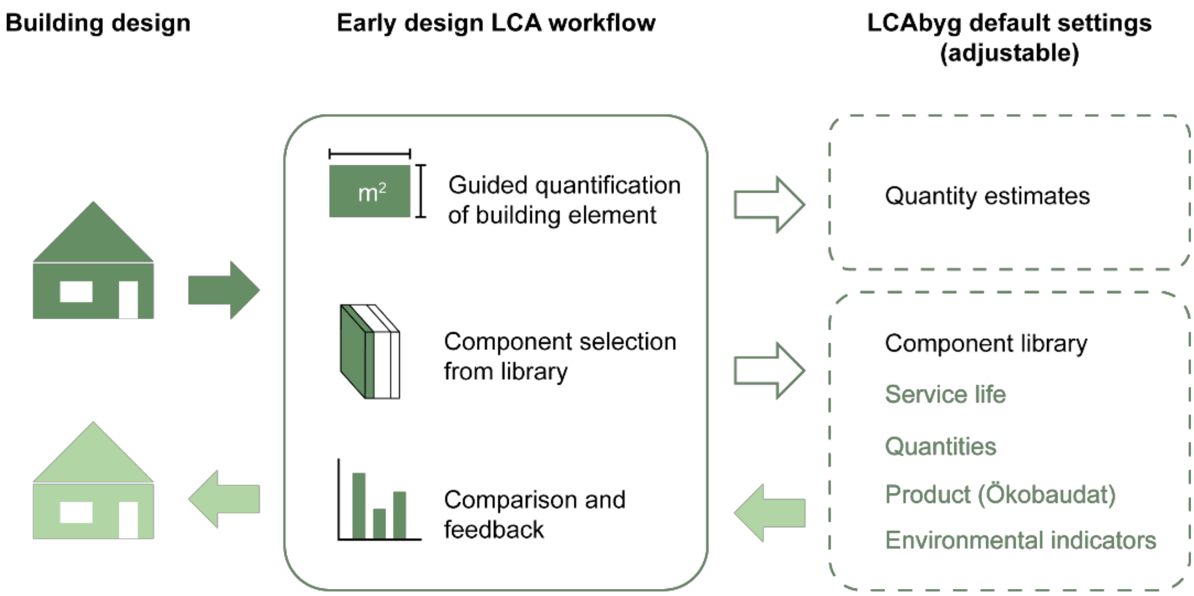

Figure 1. Early design LCA approach: Key elements include guided quantification, component library and comparison & feedback

3. Proposed early design approach

3.1. Default component library

A default library is proposed for bridging incomplete information on the detailing of the building model – or just for quicker and more convenient data input in general. Components are based on the data structure level between building elements and building products (table 1).

Table 1. Building model structure

Level	Function	Example
Element category	Main building parts	*External wall*
Element subcategory	Quantity estimation rules for specific kinds of building elements	*External basement wall*
Element	A member of the actual building design	*Specific wall in project*
Component	Functional layer of an element	*Brick wall with EPS insulation*
Product (Ökobaudat)	Includes quantities and service life	*Brick*
Stage	Environmental life cycle data	*Brick production (A1-3)*

Components consist of aggregated products and are functionally independent layers (figure 2). Making use of the already integrated database Ökobaudat, products are further aggregated to components (table 1). The layering method has been innovated by the previous LCA-profiles approach[15], however with different rules for layer division. The present approach is based on a load-bearing and insulating core layer (figure 2). Including both functions in one layer allows for specifying their mutual quantities, as in framed constructions and for better compatibility among all layers in general. This approach, though, requires a larger number of core samples in each element category in order to provide a palette of different dimensions and insulation types.

The two remaining layers cover the core from each side. These layers do not need to be scaled within each solution as much as the core allowing for a greater variety of solutions for covering layers. Scaling may include fire protection or acoustic insulation functions.

A given exterior wall might for instance include plaster rendering as interior layer (1), a brick wall with EPS-insulation as the core layer (2) and a facing brick façade layer (3).

Non-planar building elements use the layer structure conceptually for functionally independent system parts such as production (layer 1), distribution (2) and terminal units (3) in building services (table 2).

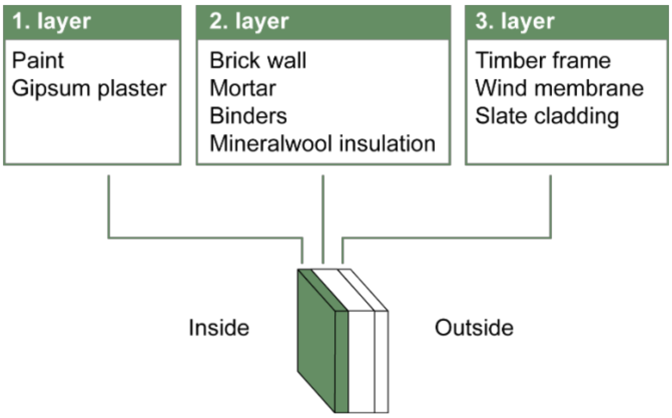

Figure 2. Layering of building elements. Example of an exterior wall divided into three functional layers. The individual layers can be replaced by compatible items from the component library.

The library offers sufficient components for modelling inventories of all supported building types. A complete level of detail including membranes and fastening is pursued, however joints between elements, corners or overlaps are not considered in most of components.

Both detailing and assignment of environmental product data follow conservative assumptions, such as low-energy insulation, ample dimensioning and tight grids. The approach tries to avoid rewarding the use of default values by accepting slightly higher mass and environmental impact compared with LCA based on complete specific inventory data.

Table 2. The function of levels and number of variants

Element category	#	Layer 1	#	Layer 2	#	Layer 3	# 1-3
Foundations	13	Foundations		-		-	13
Ground floor slabs	15	Flooring	3	Load-bearing system	2	Insulation and underlay	15
External walls	17	Inside finishing	31	Load-bearing and insulating system	19	Façade system	67
Internal walls	15	Finishing	25	Load-bearing and insulating system	16	Finishing	56
Floor decks	15	Flooring	11	Load-bearing and insulating system	12	Ceiling	38

Element category	#	Layer 1	#	Layer 2	#	Layer 3	# 1-3
Stairs and ramps[2]	0	Structure	0	Flooring	0	Balustrades and handrails	0
Columns and beams	84	Columns and beams		-		-	84
Balconies	5	Platform	8	-	3	-	16
Roofs	7	Roof cladding	20	Load-bearing and insulating system	12	Ceiling	39
Windows, doors, glazing systems	18	Profiles[1]	2	Panes	0	Solar shading[2]	20
Building services[3]	18	Production unit	6	Distribution	3	Terminal unit	27

3.2. Guided quantification

LCAbyg provides help for estimating quantities within a couple of element subcategories requiring no more than the information given in concept design (table 4). Some guidelines are mere intermediate calculations integrated in the tool, while others are based on actual default values based on estimates. The latter includes building services, balconies and foundations.

Guided quantification is presented as a proposal in a permanent wizard section of the programme window. As a principle, the user has to actively select the transfer from the wizard to the model every time, an adjustment is performed in order to prevent unintended change of quantities. User help text explains the assumptions and procedures related to every estimate. The calculation of relevant quantity suggestions requires the placement of building elements under correct subcategories and a minimum building information (table 3).

Table 3. Required basic building information input

Building type
Gross area
Gross area, heated
Gross area over terrain
Floor-to-floor height
Number of basement floors

Table 4. Required input for element quantification

Element category	Element subcategory	Required quantity input[4]
Foundations	Strip footings, deep	Length
	Pad foundations, shallow	Number
	Pad foundations	Number
	Pile foundations	-

[1] Including full product datasets, which are not divided into components, e.g. doors
[2] Not implemented yet
[3] Includes the categories drainage, electrical systems, water systems, ventilation/cooling and heating
[4] Minimum input refers to assigning area-based quantities to the components. Not included is the specification og layer thickness and basis building data (table 3)

Element category	Element subcategory	Required quantity input[4]
Ground floor deck	Ground floor deck	-
External walls	Basement external walls	Length
	External walls	Length
Partition walls	Non-load-bearing basement walls	Length
	Load-bearing basement walls	Length
	Non-load-bearing walls	Length
	Load-bearing walls	Length
Floor deck	Ground floor deck	-
	Floor deck	-
Stairs and ramps	Stairs and ramps	Number
Columns and beams	Columns	Number
	Beams	Length
	Fire protection	-
Balconies	Platform	Length, width
	Balustrades and handrails	Length, width
	Mounting	Number of balconies
Roofs	Roofs	Inclination
Windows, doors, glazing systems	Windows	Window number and area or Window-facade ratio and facade area
	Doors	Number, area
	Glazing systems	Area
Drainage	Plumbing	-
	Down comer	-
Drinking water	Production unit	Number of shafts
	Plumbing	Number of shafts
Space heating	Production unit	-
	Plumbing	Number of shafts
	Radiators	-
	Underfloor heating	-
Ventilation and cooling	Production unit	-
	Ductwork	Number of shafts

3.3. Comparison & feedback

The tool offers data comparison in different ways. First, Items on any level may be compared by checking a box. Up to five items can be displayed in a graph showing results within three indicators. Alternatively, comparison may be performed already in the dialogue window for selecting new items from the library. Finally, the currently opened project can be compared with a number of other projects, results are aggregated on building level.

Separate projects files can be opened in multiple windows, eventually for generating variants or for review reasons. Input changes are immediately shown in the results, although these changes are not traced or marked for immediate review.

4. Conclusions and discussion

An early design approach has been developed and implemented based on existing simplifications and integrated product database in LCAbyg. New functions include a default component library and a guide for estimating material quantities in order to fill incomplete data with default values. Focus has been on guiding practitioners to achieve a complete and detailed inventory and allowing for variant-based design.

Since the system boundary given in LCAbyg 3.2 is already simplified and all stages for embodied impacts are being calculated by default, a further simplification by reducing stages would not increase feasibility.

The functional unit is based on a whole building approach and a detailed and complete inventory already in early design. The effort and robustness of achieving a full detail and complete model has been evaluated more manageable than managing uncertainty in a reduced inventory approach. Here, simplification refers to making full detail inventories as simple to generate and manage as possible.

Functional layers make the detailing of building elements manageable, since the user selects solution packages without having to specify every single product, its dimension and quantity.

Further, the user is guided through specifying a number of element quantities including those, which often remain undefined in concept design such as foundations and building services. Inventory input is based on information on quantities, which usually will be available during concept design such as wall length, storey height and number of cores. Insulation thickness is given by default, however dimensions of load-bearing walls, columns or beams have to be selected from a handful of choices, since this information is evaluated difficult to generalize.

The full and complete inventory approach is expected to reduce the risk of incomplete Bill of Masses, however, the risk is being transferred to the reliability of default quantities and components. This uncertainty is sought to be addressed by making conservative assumptions and choices in specifying dimensions, included products, membranes, densities, lambda-values or selection of environmental dataset. Ideally, this in-built uncertainty margin shall lead to slightly higher mass and impact results in the early stages. However, guided input and default values are optional to use and may be edited or replaced as the project evolves and specific data becomes available.

Since the project result may serve as a prototype for potential LCA regulation in the building code, the solution had to be accessible to a large variety of actors and projects under the given digitalization level in the Danish building sector. A stand-alone LCA tool is proposed in order to achieve robustness in light of a diversity of workflows.

5. Perspective

Component library and quantity estimates will need further testing and feedback from practical use in order to better meet real life building inventories. Future improvements in usability may be achieved by integrating a visual representation of components or results, a sensitivity analysis module and the integration with building design tools.

Acknowledgements

The authors wish to thank the numerous building practitioners, which have participated in workshops on the development of the tool and component library and for testing the approach on their projects. Thanks also to Karoline Geneser and Steen Haugaard from Moe consulting engineers for estimating quantities of building services as well as Thomas Cornelius from the Danish Building Research Institute for estimating dimensions of load bearing elements. The project was supported by ELFORSK, the Danish Energy's research and development programme.

Appendix: LCAbyg 3.2 and new features in LCAbyg 4.0 beta[5]

Topic	Feature	Definition	New
Input	Building model structure	Default building model structure (table 1)	x
	Data exchange	Import/export on all levels of detail, manual EPD input, project export to Microsoft Excel format	
	Default database (product)	Building product library, adopted from Ökobaudat 2016	
	Default database (component)	Component library covering solutions for all supported building types, 3-layer structure, conservative assumptions	x
	Reference study period	Guidance in national report [16]	
	Service life	Guidance in national report [16]	
	Environmental indicators	GWP, ODP, POCP, AP, EP, ADPe, ADPf, PEtot, Sek	
	System boundary	A1-3, B4, B6, C3-4	
Output	Quantification	Bill of Quantities including assigned service life	
	Score	Aggregated score on all levels between building and product life cycle module (all supported environmental indicators)	
	Functional unit	Buildings in total, gross area or gross area / year	
Usability	User support	Built-in user guide (revised version), no user forum	
	Learning resources	Publication[6] introducing early design LCA	x
	Flexibility & adaptability	Default building model structure and component library are optional	
	Incomplete inventory support	Guided quantity estimation, building model structure as a checklist for completeness	x
	Building types	Residential (detached / terraced, multi-storey), school / day-care, office	
	Data review/change	Component dimensioning indirectly available by a variation in the library. Responsive quantity estimation based on a few available variables (table 3)	x
	Loss of data	No auto save or undo/redo functions	
	Variant-based design	Create, replace and duplicate functions on all instances. Variants are stored in the project file. Persistent user data can alternatively be stored by using export/import (external user database)	x
	Comparison & feedback loops	Variant comparison on the level of elements, components, products and stages both in the model or dialogue for selecting new items. Project comparison on building level. Multi-window work possible	x
	Visual editor	No visual representation of the building	
	Proposal generator	No automatic solution generation	
	Integration with other tools	No direct link. Developer solution for indirect BIM-integration	
	Results informing design decisions	Exportable results in table and graph format, mass and indicators aggregated on all instances and indicators. They include operational/embodied impacts comparison, accumulated life cycle impact, hot-spot analysis, and DGNB reference values. Export to Microsoft Excel format for further data analysis.	
	Normalization	CML 2001	
	Documentation	Report generator including a selection of results.	
	Uncertainty	No integrated sensitivity analysis	
	Calculation time	Real-time calculation and results

Abstract. Life Cycle Assessment (LCA) is used and accepted as a method to assess environmental impacts and resource use of buildings. In practice, LCA is typically used in stages where the design of the building is already finalized. However, LCA-calculations from early design stages can be used actively in design and optimization of the building. One of the obstacles to early stage LCA is that extensive data input on precise material types and amounts is needed, which is limited in early design stages. The simplifications needed for a designer in an early design LCA is addressed in a research project, where an extensive library of predefined building components and installations were developed and integrated into the existing Danish LCAbyg tool. The library assists the user in establishing a full building inventory by simple inputs of geometry of the building and a selection from the library of building element layers. However, the simplified approach to LCA of a building at early design stages inevitably affects results compared with results of a calculation made at later design stages where more, specific data is available. This paper presents an evaluation of building cases, modelled with the same background database and life cycle stages, using the simplified early design LCA approach and a detailed LCA approach. The evaluation includes testing of how well the predefined components in the early design approach fit with the case buildings and comparisons of the total material input and precision of the final LCA results.

1. Introduction

1.1. Early design LCA for buildings

Life Cycle Assessment (LCA) is an established and widely used method for assessing and documenting the environmental impact and resource use for products and services.

Conducting a full scope and detailed building model LCA requires both qualifications and large amounts of documentation. Full scope LCA's on buildings are thus rarely made [1,2]. The LCA scope is typically adjusted to a more simplified LCA approach that includes less processes, for instance by reducing the number of life cycle stages, which is also the recommended approach in the sustainability initiatives from the European Commission's Joint Research Centre Level(s) and EeBGuide [3][4]]. But even with these simplifications, the work going into a building LCA is still very large: For instance, it requires inputs of quantity and product type for all the materials used.

In the early design phases of the building project it is an even larger challenge to quantify and specify building products because final dimensions are not known and several design options may need to be compared. However, the early design phases are the phases when informed decisions can be made. The LCA-task should therefore be easy and fast in early design phases.

Approaches for early design tools for LCA include simplifying the method even further with a selective approach; by only including elements that have the greatest relevance to the results [5]. Another approach is to use predefined elements from a library which is also a recommended approach for early design environmental assessment tools [6]. This is the approach used in the new LCAbyg tool

1.2. LCAbyg tool – Early design functions in version 4.0 Beta

In the new version of LCAbyg (version 4.0 beta), a library-based simplification approach has been used [7]. LCAbyg is a free tool from Denmark for performing LCA on buildings [8,9]. The predefined component library in version 4.0 beta contains building products that are bundled together in typical or conservative dimensions. For estimating quantities, the tool introduces a "guided inventory input". The tool is designed to be used in all stages of the building project, and it is therefore possible to adjust dimension in the component library, as more knowledge becomes available in the project.

LCAbyg 4.0 Beta differs from the existing LCAbyg version 3.2 only by introducing the above mentioned functions. The calculations are based on the same selected life cycle stages and LCIA data.

1.3. Evaluating early design approach

When using an early design approach with a library of building components, the results will naturally vary from the detailed LCA approach. Testing the performance of the early design tool compared to a more detailed LCA is therefore relevant for estimating if the tool gives a true representation of the building's environmental performance. This can be evaluated by testing the early design approach against a more detailed approach.

A similar evaluation has previously been done in the library based (and simplified geometry) early design tool, LCAP [10], where the performance of the early design tool is tested against a more detailed LCA approach [11]. The result is 4-19% lower in global warming potential (GWP) for the buildings where the early design tool was used. The reduced impact is mainly due to the exclusion of some building elements in the early design tool, including building services and internal doors.

In LCAbyg 4.0 Beta, the early design approach has a comprehensive component library, that also includes several building services and the completeness of the inventory is high. The component library uses conservative estimates in terms of material use and LCIA data. Contrary to the LCAP-tool, the impact from the materials in the early design approach should therefore give higher impacts than a detailed approach because the catalogue is conservative and completeness is higher than a typical LCA on building.

This paper evaluates building cases where a detailed LCA has been performed with an early design component library-based LCA approach using two generations of the tool, LCAbyg (version 3.2 and 4.0 beta). The evaluation will consider the inventory of cases with a detailed LCA approach compared with component library in early stage approach, and the mass and impact in GWP of the two approaches. Lastly the precision of the early design approach will be estimated.

2. Method

2.1. Study samples

The case samples presented in table 1 consists of three residential buildings that have been certified with the Danish version of DGNB certification system for sustainable buildings [12]. The buildings are completed between 2016 and 2018. The cases are selected because they represent different material compositions: One with wooden-frames, one in Cross Laminated Timber (CLT), and the final with concrete walls and wooden roof.

Table 1. Case buildings

	Building type	Description
Case A	Residential, Terraced house	*Foundation and ground floor slab*: concrete, EPS insulation *Walls and slabs/roof:* prefab wood elements, mineral wool insulation *Surfaces:* paint on internal surfaces, externally plaster on ventilated facade and roofing felt on roof.
Case B	Residential, Multi-family building	*Foundation and ground floor slab*: concrete, EPS insulation *Walls and slabs/roof:* CLT wall elements with columns and beams in steel and wood, slabs in concrete/CLT-hybrid, truss roof, mineral wool and cellulose insulation *Surfaces* in wood and roofing felt on roof.
Case C	Residential, Terraced house	*Foundation and ground floor slab*: concrete, EPS insulation *Walls and slabs/roof:* concrete walls with roof in wood and CLT. Mineral wool insulation. Structure with steel and wood beams and columns. *Surfaces:* paint on internal surfaces, externally brick and roofing felt on roof.

2.2. Scenarios

The early design approach for LCA is evaluated through three modeling scenarios listed in table 2. BL scenario has been calculated using LCAbyg 3.2, while LCAbyg 4.0 is used for scenarios ED1 and 2 in order to make use of the new component library.

Table 2. Scenarios

Abbr.	Scenario	Inventory
BL	Baseline (detailed approach)	**Specific inventory** taken from DGNB-certified cases. Example (wall): Actual wall area with material type and dimension according to inventory from DGNB.
ED1	Early design 1	**Component library.** A combination of predefined components from library and specific element areas from DGNB-certified cases. Example (wall): Actual wall area, but material type and dimension according to the closest match available in the component library.
ED2	Early design 2	**Adjusted component library.** Same as ED1, but with adjustments of materials type and dimensions. Example (wall): Actual wall area with material type and dimension according to inventory from DGNB, however, without removing extra library elements such as paint, connecters etc. (which may not be included in BL).

BL is the life cycle inventory taken from cases, which have been DGNB certified. The inventory elements from the three cases can be seen in table 3.

ED1 uses the component library to match material type and dimensions of the building elements in the cases as good as possible.

ED2 follows ED1, however, dimensions and material type for major elements in the building structure and insulation have been adjusted where needed according to the original case inventory. Table 3 shows all adjustments and their nature, may it be changes in material property or quantity.

Scenarios ED1 and ED2 include all the element layers listed in table 3 (if applicable), thus making the building inventory more complete than the detailed approach (BL). For estimating quantities in the element layers that are not included in the DGNB cases (and therefore no data is available); the "guided inventory input" from LCAbyg 4.0 Beta is used. The guided inventory input uses basic building information including gross and heated floor area, floor height, no. of floors etc. for estimating quantities. In this study only the technical installations have been estimated, if they are not already given in the DGNB cases.

Table 3. Inventory scheme. Level of completeness and adjustments are given for all cases and scenarios. Columns BL show the as-is state of completeness in the DGNB cases. Columns ED2 show the adjustments made. Scenario ED1 uses library material choice and detailing for all element layers and is not shown.

Building element	Element layers	Case A		Case B		Case C	
		BL	ED2	BL	ED2	BL	ED2
Foundations	Foundations	x		x		(x)	
Ground floor slab	Flooring	x		x		x	
	Load-bearing system	x	m	x	q	x	q
	Insulation and underlay	(x)	q	(x)		x	q
External walls	Inside finishing	(x)		n/a		x	
	Load-bearing and insulating system	x	q, m	x	q, m	x	q
	Façade system	x		x	m	x	
Internal walls	Finishing	x		x		x	
	Load-bearing	x	q, m	x	q, m	x	q
	Finishing	x		n/a		x	
Floor deck	Flooring	x		x		x	
	Load-bearing and insulating system	x	q	x	q	x	q, m
	Ceiling	(x)		x		x	
Columns and beams	Columns and beams	n/a		x		n/a	
	Finishing	n/a		-		n/a	
Balconies	Platform	x	q	n/a		n/a	
	Mounting	-		n/a		n/a	
	Balustrates and handrails	x		n/a		n/a	
Roof	Roof cladding	x		x		x	
	Load-bearing and insulating system	x	q, m	x	q, m	x	q, m
	Ceiling	x		x		x	
Windows, doors, glazing systems	Profiles	x		x		x	q
	Panes	x		x		x	
	Doors	x		-		x	
Drainage	Soil pipe	-		-		-	
	Down comer	x		-		-	
Drinking water	Hot water tank	-		-		x	
	Piping	x		-		-	
Space heating	Supply	x		-		-	
	Piping	n/a		-		-	
	Radiator / floor heating	x		x		-	
Ventilation and cooling	Supply	-		x		-	
	Ductwork	x		-		-	
Electrical units	PV-panels	x		n/a		x	

BL: [x] complete or including main elements. [(x)] poor completeness within the element layer. [-] not included. [n/a]: not relevant to case.
ED2: [q] quantity adjustments. [m] material adjustments.

2.3. *Life cycle assessment*

The LCA is conducted in compliance with the standards ISO 14040-44 and [13,14] EN 15978 standard [15] for LCA on buildings. The functional equivalent is set to 1 m^2 residential gross floor area. The LCA includes the following life cycle stages: A1-A3 production of building products, B4 replacement of building products in use stage, C3-C4 waste treatment and disposal of building products at End of Life (EoL). Operational energy consumption (stage B6) is not included in the LCA, due to the study's focus on impacts related to embodied materials. The LCA uses a reference study period of 100 years following the Danish guidelines on building's service life [16]. This report also provide service lives for building products, which are used for estimating the number of replacements of building products in the use stage (B4).

The modelling is carried out in two generations of the Danish LCAbyg tool. Both tools use the same LCIA database, which consists of mainly extracts of Ökobau generic database from version 2016. In the Ökobau database the life cycle impact assessment is done with characterisation method

CML-IA baseline version 4.1. The study only reports on the impact category Global Warming Potential (GWP), for simplicity reasons.

3. Results

3.1. Impacts from early design scenarios

Impacts for GWP can be seen in figure 1 for the three scenarios. Using the early design tool (scenario ED1) gives a higher impact of 18-42% for the whole building compared to the detailed LCA approach. This is due to the additional building elements, the conservative materials estimation and the completeness of inventory from the early design approach.

The library material estimates are adjusted to the specific case in scenario ED2; here the impacts in GWP for the building cases are still higher than BL, but for cases B and C the GWP has decreased from 42% down to 31% and from 27% to 21% above BL. However, case A has an increase in GWP from 18% to 33% higher than BL. One of the reasons case A increases is that the insulation quantity is underestimated in ED1. This is because case A is a low energy building and the house is more insulated than a house that only complies with operational energy demands from the Danish Building Code. Another reason is that the type of insulation material used some places in case A, has a substantially higher impact than the insulation in the case building, such as rigid mineral wool.

Insulation material also gives inaccurate results in case B, where the external walls in ED1, gives an impact three times that of BL and ED2, as shown in Figure 1. This is mainly due to use of cellulose insulation in the case building, which is not an option in the component library, see table 4. Furthermore the CLT dimensions is highly overestimated in the library layer because this is designed as a load carrying element, while the case element is not. A better option would have been to choose the frame construction in library, which has the opportunity to choose cellulose insulation. While most building elements have a higher impact in the early design scenarios, this is not the case for the foundation. For all cases; the impacts from foundation are smaller in early design scenarios, due to a smaller amount of materials used for the scenarios. Overall, however, figure 1 shows that on a building element level, the impacts from the early design approach in ED1 gives a good representation of the adjusted scenario impacts in ED2.

3.2. Impact related to inventory completeness

The impact from added inventory elements shown above the dotted line in figure 1 (these are the elements layers from table 3 that were not included in BL) contribute with between 3% and 20% of the building's total GWP, depending on case building and scenario. Case B has the smallest inclusion of building elements in BL, and consequently this is where we see the largest contribution when elements are added. The added impacts from building services and doors contribute notably in case B. Case A shows the lowest impact from only adding a number of elements in building services.

If we exclude the added elements from the early design inventory, thereby only including element layers that exist in BL, we get a clearer picture of the library's difference from BL when it comes to completeness and conservative estimates. These differences can be seen in the case results for scenario ED1, and shows that GWP is 14%, 21% and 19% above BL. When adjustments have been made in scenario ED2, the results provides an understanding of just the difference in completeness between early design approach and BL; the GWP is 29% higher for case A and only 9% and 12% higher for cases B and C than baseline.

The difference in completeness for Case A is substantially higher due to impacts from finishes on internal walls and from floors and ceiling on floor deck, roof and ground floor slab as illustrated in figure 1. The higher completeness comes from including the structure in floors and ceiling, and amounts of paint to cover all internal as well as inside parts of external walls, which was not adequate in the BL scenarios for case A.

For case B and C; the higher GWP also stems from finishes on walls and floor and ceilings, and for case B; the windows were missing materials for frame.

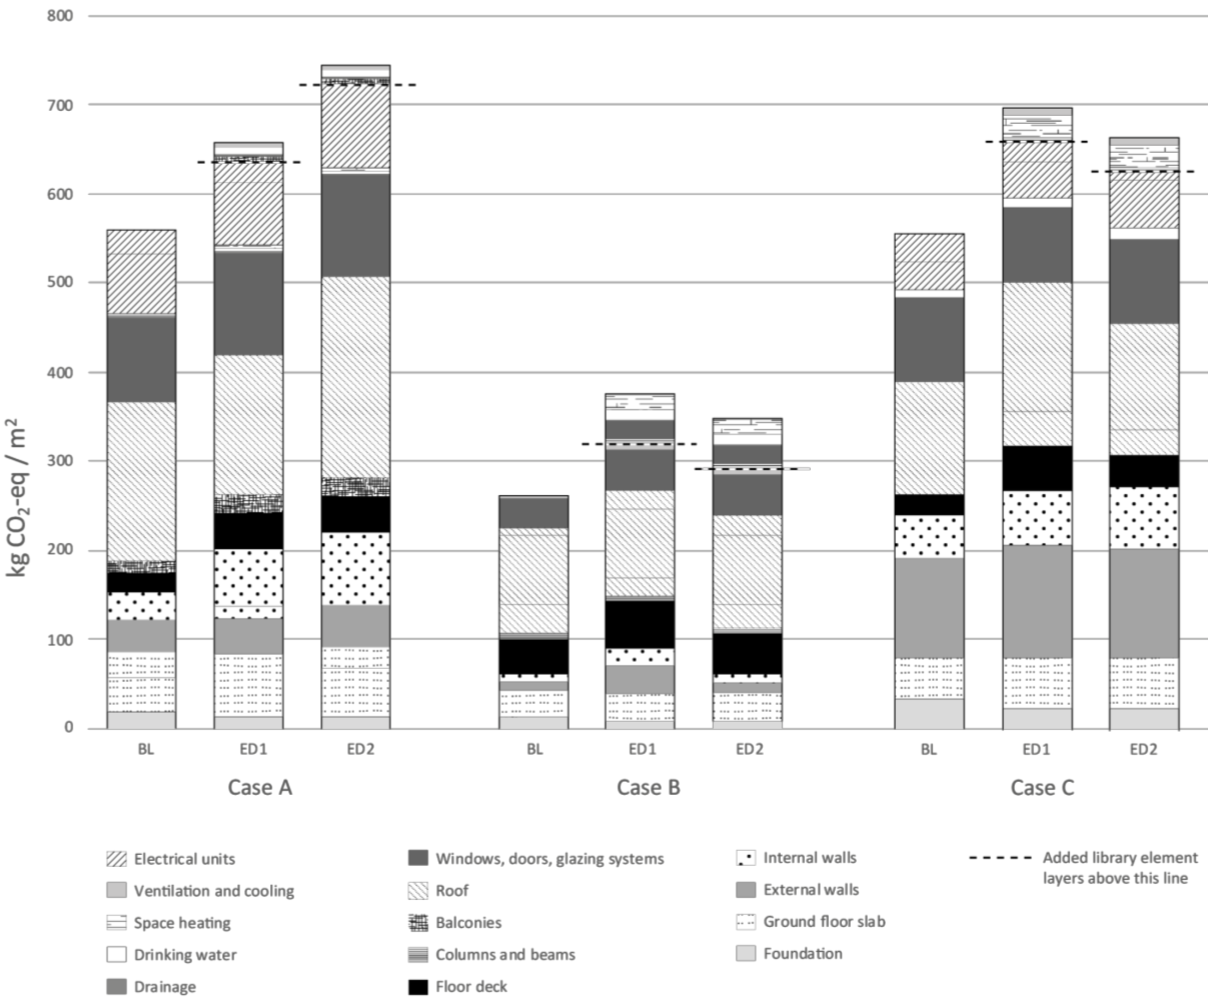

Figure 1. GWP impacts for building elements in the three case buildings for the different scenarios: Detailed approach (BL), early design (ED1), early design with adjustements of material and dimension (ED2). Included life cycle stages are A1-A3, B4 and C3-C4.

Table 4. Materials use of 1 m^2 external wall in case building B. The element has a notable difference in GWP for the three scenarios, mainly due to a different insulation type in the component library used in ED1.

BL		**ED1**		**ED2**	
260 mm	Cellulose fibre	300 mm	Mineral wool	*260* mm	Cellulose fibre
40 mm	CLT	100 mm	CLT	*40* mm	CLT
-	-	0.38 kg	Wood protection	-	-
30 mm	Pine wood	30 mm	Pine wood	30 mm	Pine wood
-	-	150 g	Screws, nails, fittings in galvanized steel	150 g	Screws, nails, fittings in galvanized steel
150 g	Aluminum profile	2 mm	Wood lists	2 mm	Wood lists
1 pcs	Plaster board, wind barrier	1 pcs	Plaster board, wind barrier	1 pcs	Plaster board, wind barrier

3.3. Correlation of mass and impact for early design scenarios

In early design scenarios both material mass and GWP is increased compared to BL scenario, the relation to BL on mass and GWP can be seen in Figure 2. For cases B and C, the GWP has increased substantially more than the mass, implying that the extra material included in the component library has a large impact on GWP compared to the existing mass. A specific example of this is the internal walls in case B: In scenario B2 the increase in mass is 7 %, while the increase in GWP is 54%. This is due to adding material elements such as paint and membrane conjoining wet rooms, which are materials with high impact in GWP per mass.

Case A shows the opposite trend with a higher added mass, and lower GWP. This is mainly due to the gravel below the ground floor slab, which was not included in BL. Gravel has relatively low GWP per mass, which explains the results. If gravel is removed from the assessment; case A will have a mass compared to BL of 116%, which is similar to the trend for case B and C (103% and 113%). The reduced GWP from removing gravel is only from 133% to 132%, thereby showing a similar trend in case A; of higher increase in GWP than in mass when using ED-scenarios.

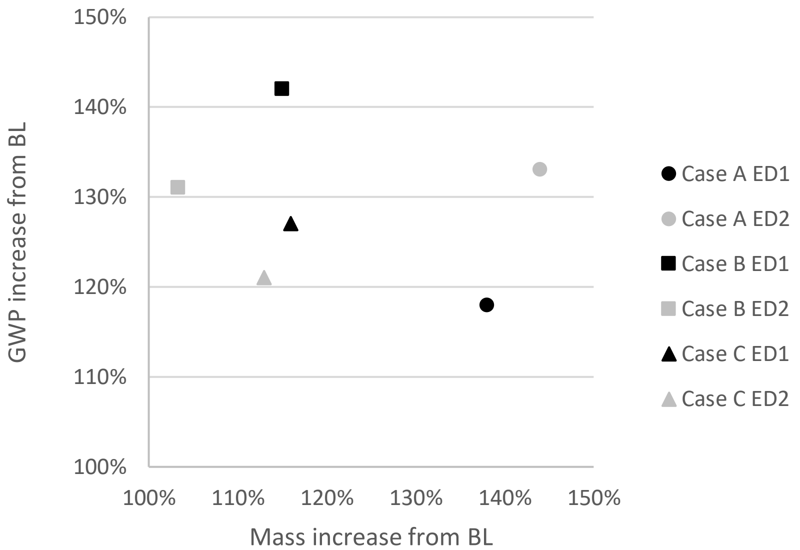

Figure 2. Mass and GWP of building cases for the two scenarios (ED1 and ED2) seen in relation to BL scenario (100 %).

4. Discussion

4.1. Component library

Differences in inventory completeness across the scenarios have shown to have a large impact on the results. The BL inventory both lack entire building elements and components or building products in the original cases. These additional materials included in the early design scenarios even shows to have a large impact on GWP when seen in relation to the building mass, making them an important part of the LCA.

The component library is conservative in estimating materials, especially insulating materials. The insulating materials is dimensioned to comply with building regulations in terms of thermal conductivity, where only the insulating material is used to dimension the thermal conductivity (without taking the remaining layers in the building element into account) [7]. However, special circumstances such as low energy buildings will likely surpass the dimension of insulating material in the component library, as was the case for case A. For low energy buildings and buildings that have special demands, the LCA practitioner must take it into account by adjusting dimensions of the insulating material first and foremost (this will likely be a natural process, because the practitioner, typically an architect or engineer, is aware of all elements that are not standard throughout designing). This will apply for all cases with special designs that are likely to make material use greater than the norm.

The same approach should apply to the material type used to insulation materials. Some of the notable differences in impacts in the component library estimates stem from the type of insulation material. The LCIA data used for rigid mineral wool has a much higher impact in GWP than normal mineral wool, and cellulose insulation, on the other hand, performs much better. When there is no cellulose to choose in the library, the results of the assessment will give a higher impact and thus a conservative estimation, which is as expected. However, when the rigid mineral wool cannot be chosen in the library, this can have a large impact on the results, giving the assumption that the building performs better than it actually does. In the component library of LCAbyg 4.0 Beta it is possible to choose elements with rigid insulation, just not for the particular structure used in Case A. A solution could be to include more types of insulation materials in the catalogue, however, a value of the catalogue is also that it is not too large.

4.2. Precision of results

The early design tool is evaluated by comparing with a detailed LCA, however, in material completeness, the early design tool can be considered even more 'detailed', than the detailed approach. Evaluating precision by comparing to the detailed approach would therefore be misleading.

The estimates on material and dimensions made in the component library, however, can be evaluated for GWP by looking at the two early design scenarios and the deviation in results from using the library (ED1) compared to the scenario where the library has been adjusted (ED2). For cases A, B and C the library shows a deviation in results of -12%, 11% and 6%, (not including the added library elements, which will only make the difference smaller). The precision of the component library can therefore be considered to be within a deviation of 12% of result, which is considered good for early design. Case A is negative due to the wrong type and quantity of insulation from the library. However, Case B and C are conservative in the estimated impact, which is typically considered a quality in early design, especially if the goal is to gain a certain amount of points for i.e. green certifications.

Only GWP was investigated in this study, however, other impact categories will be necessary for a broader approach to environmental performance.

5. Conclusion

As expected; the ED-tool gives a higher GWP impact overall than the detailed LCA. This is because the early design approach is more conservative in estimating materials and has a higher completeness in material use: both by including more of the typical building elements such as building systems and by providing a more complete bill of materials for the defined element layers, for instance by including finishes of elements such as paint as well as membranes, fastenings and structures for build-up floor, ceilings etc. These added elements in the early design approach contributed to a high increase in GWP compared to their mass contribution, which hints to the importance of including these elements for a better understanding of impacts from buildings.

The component library used in the early design approach overall gives a good representation of the building, however, in some cases it is important to the result, to specify material type and dimensions, especially for insulating materials. However, without specification, the precision of estimates made on material type and dimension in the component library is within a deviation of 12% of the result, which is considered good for early design.

Acknowledgements

The authors would like to thank Danish Green Building Council (DK-GBC) for providing data for case buildings.

Evaluation of BIM based LCA in early design phase (low LOD) of buildings

Nilsen M, Bohne R A

Norwegian University of Science and Technology

matsnil@stud.ntnu.no

Abstract. Building Information Modelling (BIM) is a convenient tool that is capable of collecting information throughout the whole life cycle of a building in one platform. The evolution in the digital BIM model in early design stages is not standardized, but Level of Development (LOD) is a concept that systematically structures the design processes divided into five levels. LOD is assessed in this paper as an opportunity to enhance the calculation of the environmental impacts in different early design stages more efficiently, using the methodology Life Cycle Assessment (LCA). Enlightening the building elements that contribute to highest release of CO_2, permits early building material selection. This facilitates a pathway towards sustainable and environmentally friendly buildings. This study evaluates BIM based LCA in early design stages (low LOD) through literature reviews and a case study. This papers' case study executes LCAs at different LOD levels using the LCA software One Click LCA (OCL). Assessments in LOD 200, LOD 300, LOD 350 and an additional LOD 350 were utilized. The additional LOD 350 was deployed when LCA experts had implemented changes within OCL. Moreover, a concretized suggestion where today's unpredictable development of BIM becomes part of a LOD framework is proposed.

1 Introduction

There are several basic, well-established scientific links that constitute the background for this report. The UN Intergovernmental Panel on Climate Change (IPCC) states that the human fingerprint on greenhouse gases (GHGs) have risen to record levels not seen in three million years [1]. There are limitations to adaption and adaptive capacity for human and natural systems, but most adaptation needs will be lower for global warming of 1.5 °C compared to 2 °C according to the Paris Agreement [2].

The proposal of this report is to investigate which features that are required in an interaction between BIM and LCA in the early design stage (low LOD), to evaluate the environmental performance of a building. In addition, this paper research question is how an early design LCA framework corresponds to LOD.

The sustainability of buildings is depending on several aspects. This report is evaluating one of them, namely the environmental impact of buildings regarding CO_2 emission. This study focuses on the LOD in the design stage using BIM, and how a BIM based LCA can help improve the environmental impacts, limited to buildings. The study is illustrated by one case study, Valle Wood in Oslo (Norway), and one LCA tool, OCL. Cradle to gate processes for materials and services used in construction is considered as the system boundary for the study [3]. The embodied energy is the energy required to produce the building materials, and it is related to the production stage (A1-A3) of the life cycle stages. Furthermore, the in-use energy is energy consumption related to the use stage, and will not be considered in this report. Moreover, the incidence of embodied energy in building energy analyses account for the major part (50 %) of the whole primary energy demand, compared to the operational energy stages in the use stage [4–6]. The built environment have the highest potential to limit the global warming [7], and therefor an LCA framework regards to LOD is proposed.

2 Method

2.1 Conduction of LCAs

Qualitative and quantitative methods are the basis of this report's results. The qualitative methods investigate the findings regarding the interactions between BIM and LCA, as well as how BIM based LCAs can be advantageously rendered through comprehensive literature reviews. BIM models were deliberated this study through document reviews, received from NCC. The quantitative LCA calculations on the BIM models are based on using quantity take-off generated by BIM, as well as one LCA using input data retrieved from designers in Valle Wood, to obtain environmental impact in OCL.

All smc files were made available through NCC's own PortWise Access Manager 4.12. In the same portal, all relevant documents were available such as subcontractors' drawings and calculations. In addition, description of materials were listed. This study took advantage of three different smc files and distinguished the LOD levels based on [8, 9] requirements. The different BIM models (Figure 2, 3 and 4) express maturity in the design.

(i) **.smc-file published February 2017 - LOD 200**. The model is represented with approximate quantities, size and shape. There are limited objects that are similar to the planned type of materials in the project description (Figure 1). It looks like elements are generic placeholders. See Figure 2.

(ii) **.smc-file published July 2018 - LOD 300**. The model contains more specific and developed objects. Non-graphic information does also occur in this LOD level, but the size, shape and orientation of elements are located with respect to the project origin. See Figure 3.

(iii) **.smc-file published December 2018 - LOD 350**. The quantity, size, shape, location and orientation of the element as designed, can be measured directly from the BIM model. Despite that there are existing non-graphical information to the model, the model can now be used to decision making and as project guide into different locations. See Figure 4.

Table 1 describes theoretical aspects in an LCA along with OCL features, as well as assumptions made. OCL is an online LCA application that require reports, such as a BIM model inventory file from either MS Excel or gbXML. The elaboration of the LCAs that use MS Excel reports from Solibri Model Checker were based on quantity take-offs from BIM and attached automatically to EPDs in OCL. These LCAs represents three calculations, namely LOD 200, LOD 300 and LOD 350. The LCA obtained from NCC, called *final LCA*, used empirical input data because the Industry Foundation Class (IFC) convey objects to the information take-off reports that causes errors. The structural systems are better to analyze on empirical values in OCL, as they will save time compared to checking all objects from the IFC [10].

2.2 Proposed LCA framework

The proposed framework consist of three main steps [11].

(i) The definition of an evolution of LOD: The definition of element categories is the Norwegian Standard NS 3451 shown in Table 3. The definition of early design phases which appear as project delivery phases is shown in Figure 6 with respect to LOD evolution.

(ii) Consistent combination of LCA databases: EPDs are the determined LCA database. Where no EPDs are available, average values should be employed as Table 5 shows.

(iii) The link between LOD levels and LCA databases: At LOD 400, the exact quantities of each materials should be known as product specific data can be utilized.

3 Case

> "Valle Wood is going to be Norway's largest commercial building in cross laminated timber. The building will be certified in accordance with BREEAM, the world's most demanding environmental certification system, which takes a holistic view of the building's entire ecocycle" [16].

Valle Wood covers the first phase of the project. This phase is 6700 m^2, and the total site is going to be 60000 m^2 including all five phases [16].

Table 1: LCA methodology in One Click LCA

LCA methodology and assumptions made in One Click LCA	
Goal and scope definition	Evaluate the Global Warming Potential (GWP) caused by Valle Wood using OCL.
Functional Unit (FU)	FU of this LCA is Kg $CO_2 - eq$ emission per material. The reference unit is m^3. Other units like kg, kW, kWh, 1 m and m^2 could have been applied, but OCL do not possess a unit conversion factor.
Temporal- and geographical scope	OCL execute a static LCA model. It is possible to setup the service of the materials that would be preferable to include. This will have an impact on B4-B5 (Replacements) during the building life cycle and impacts associated with B6-B7 are introduced on an annual basis. At the moment OCL do not allow changes to the energy mix as this is not allowed in the standards OCL follow. Operating variables do not affect the inventory of the system. Nevertheless - this is out of the scope of the study, and mitigate the potential downsides in terms of only gather Life Cycle Inventory (LCI) data to unit processes, which is the smallest element considered in the LCI for which input and output are quantified [12]. The time period covered in this LCA is updates in the BIM model as per December 2018 [13]. Geographical scope is Oslo, Norway.
Technology coverage	The tool utilized is LCA for BREEAM NOR. The template used to export and structure information from Solibri is "One Click LCA (metric).ITO".
Change-oriented LCA	This is a change-oriented LCA that comparing three BIM models (three LOD levels), up against a modified and reliable LCA at a correct LOD 350.
Intended application	This is a LCA that can be applied to different situations; BIM-model improvement, strategic planning and public decision making.
System boundary	Consider embodied emission, cradle to gate, A1-A3 as this contribute the most to GWP.
LCI analysis and data collection	MS Excel file that imported materials from the BIM (.smc file) and grouped them based on 5 criteria: CLASS: values have to be one of the listed ones in exactly the same format (sorted in .ITO template used in information takeoff in Solibri). IFC-MATERIAL: Use the distinguishable material name to map the material to the label in the tool. Mapping is based on CLASS and IFC-MATERIAL combination. For material label, the database is EPD-Norway. When importing it for the first time, one can teach it to the tool and it will be automatically recognized in the future. QUANTITY: Number, comma as decimal separator. QTY-TYPE: Units. TRANSPORT-KM: Transport distance in km from manufacturer site to the building site (optional, can also be added later in the query).
Data quality	Cut-off criteria to this LCA is materials < 1% of the volume. Also, OCL's category 6, Building Technology, is out of the scope. The cut-off lead to the fallacy of disaggregation by splitting up processes which lower the data quality and putting flows explicitly to zero [14]. The cut-offs are related to undefined objects from the BIM model. Data information included are obtained from EPDs witch follows the same sets of standards.
Life Cycle Impact assessment (LCIA)	The impact category is global warming, characterized as per CML-IA 2012 methodology, required by EN 15978 and EN 15804 [15].
Interpretation	OCL is an transparent analysis as the tool is online and can be easily modified. As this features, this assessment is also a comparative analysis in the way the assessments comparing four alternatives to which performance at different LOD.

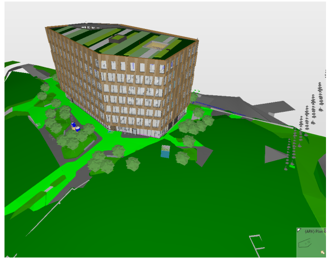

Figure 4: LOD 350

4 Results and Discussion

There are three main approaches ranging from the use of several software, the inclusion of LCA information in BIM, and quantity take-offs generated by BIM, to conduct BIM based LCAs. All approaches are seeking on reduce costs, lower the GHG emissions and increase the efficiency during early design stages of buildings [17]. Moreover, the interaction of BIM-LCA is utilized in several ways. Studies in [11, 18–27] have used several programs and LCIA databases to conduct LCAs at different stages. Some of the studies also take advantage of LOD implementation. In spite of several attempts, there is clearly a missing linkage of different databases, automatized design and impact calculation. However, the integration of LCA within the BIM is not available.

4.1 LCA of Valle Wood

The quantity takeoff information for building materials provided by Solibri Model Checker is obtained in units of volume. The mismatch between the properties in the smc files, quantity takeoff information, and OCL screening method, provides errors regarding the actual amount of materials and due to dissimilar products and EPDs. The MS Excel upload purely contains the information from the .smc file, but it is structured in a way so that the MS Excel can be read by OCL. When this occurs, a unit conversion factor is needed to evaluate the embodied environmental impacts. OCL does not possess this feature, which leads to heavier workload on the LCA performance in early design. An example can be incomplete design by architects that ignore specific requirements, regarding fire or lighting in the BIM.

4.2 LCAs Using Quantity Take-Off Generated by BIM With EPD-Norway as the LCA Database to Obtain Environmental Impact in OCL

LOD 200, LOD 300 and LOD 350 in Table 2 shows LCA results from OCL when the quantity take-off in Solibri Model Checker was used to generate the LCI report that was attached to EPDs in OCL.

The main contributors to GWP in all these designs are *horizontal structures* and *other structures*. Metals and concrete are the materials with the highest impact on the environment. Despite the fact that steel and concrete are the materials responsible for the high GHG emission, a reduction of 75% between LOD 200 and LOD 350 is present. The absence of data information through the transitional process into OCL, initiated unreliable results.

The LCA on LOD 200 indicates a low level of information in the BIM object, as the GHG emission is calculated to be more than 32000 tons of $CO_2 - eq$. Valle Wood, presented in Section 3, is going to be built in cross-laminated timber, which is not the case illustrated in February 2017 (LOD 200). Only 1% of the materials are timber. In low LOD levels, there is not a requirement to specify the type of materials, and because of the low level of information inside the BIM object, the design has not distinguished the environmental and material properties. Default settings were probably sat to materials during the early design process in BIM.

At LOD 300, the materials are not yet in accordance with the project description. Steel and concrete are still dominating the design, and no timber is contributing to the design, which contradicts to the information in the BIM model (Figure 3).

At LOD 350, [28] state that the BIM model should contain all relevant information to be environmentally assessed, but as one can see from Table 2, essential data elements are missing. This leads to errors that do not correspond to the reality of materials that should have been in the LCA. Despite the great improvement in GHG emission, the LCA is not reliable as the material distribution differs from the project description. In addition, the number of materials in OCL are incorrect compared to the BIM model in Solibri Model Checker.

4.3 Final LCA Conducted With Empirical Values

Instead of improving the quantity take-off generated by Solibri Model Checker and the transitional format (.ITO template), empirical values were added in OCL to calculate a correct value for the GHG emissions, with the right quantity for the right type of materials. This is shown in Table 2. Here, 42% of the material contribution is timber, which is in accordance with the project description.

The great reduction in GHG emission was calculated with the right type of materials, linked to the right EPD, which resulted in 2700 Tons of $CO_2 - eq$. The measurements and units were obtained from the BIM model without utilizing the quantity take-off generated by Solibri Model Checker at LOD 350 (Figure 4).

Table 2: Results from OCL related to different LODs

LOD	**Builing Element**	**%**	**Material Type**	**%**	**Material Subtypes**	**%**	**Tons of CO_2-eq**
LOD 200	Horizontal Structures (HS)	82	Steel and Metals (SM)	88	Aluminum	87	32523
	Other Structures (OS)	12	Concrete	8	Prefab. concrete walls	4	
	Vertical Structures (VS)	6	Glass	2	Concrete foundation	3	
			Timber	1	Cross Laminated Timber (CLT)	1	
			Gypsum	0	Glass	2	
LOD 300	OS	51	SM	74	Aluminum	67	9553
	HS	25	Concrete	21	Prefab. concrete	13	
	VS	24	Floor (undefined)	2	Concrete	5	
	Ground and Foundation (GF)	0	Glass	1	Steel	4	
			Insulation	1	Steel and Iron	3	
LOD 350	OS	56	SM	75	Aluminum	67	8066

	GF	11	Gypsum	14	Interior walls	12	
	Building technology	3	Insulation	11	Rockwool	11	
	OS	1	Floor (undefined)	8	Carpets	8	

4.4 Suggested Use of LOD in a BIM Environment With Respect to LCA Application

To support an efficient and user-friendly LCA application in early design, strategies for simplification in BIM based LCAs have been proposed by several parties. The common knowledge gap in the proposals is the need for an envelope that deprives BIM to carry out an LCA single-handily.

To minimize the carbon footprint, the writers of this report believes that early design delivery phases can help the efficiency and the automated work regarding LCAs. By using LOD as the direction-setting process in

LCA, the more environmental attention is given to the design and, the GHG emission will be considered as a determining factor through decisions. This approach and proposal desires to connect Architecture, Engineering and Construction (AEC) professionals and designers to deal with the issues through BIM based LCA in the early design stages (low LOD). The influence to alter the functionality of the building is high and the costs are low in early design stages [29, 30].

The capability of IFC's layered data structure, which has different objects with different level of details for the representation of information, should be specific regards to Model View Definitions (MVD) standard before heading to a higher LOD level. There is two distinct advantages of a standardized LOD related to the embodiment of an LCA. These are that the IFC can be imported into LCA analysis tools from any BIM authoring tools, without performing further data manipulation for mapping imported data to the used LCI database [21]. In addition, more realistic and concise results can be achieved by choosing a proper LCI database and a LCA calculation method, with respect to LOD of the elements contained in a BIM model [21].

A BIM model is a comprehensive collection of objects that are rich in information, and an LCA is a set of unit processes that are linked with each other using flows [31, 32]. It is by this required to link object in the BIM to LCI database using flows. Therefore, it can be hard for designers to handle several unit processes at a time. Henceforth, this proposal allow to break down this information into manageable and logical groups according to NS 3451 building table of building elements and OCL main distribution of building elements shown in Table 4. In addition, milestones to which LOD levels construction categories have to be developed in the BIM are expressed in the same table.

Table 3: NS 3451 - Table of building elements

NS 3451 - Table of Building Elements	
1 digit building element	**2 digits building element**
2 - Building	20 - Building in general 21 - Ground and foundation 22 - Structural system 23 - External walls 24 - Interior walls 25 - Slab 26 - Roof 27 - Building inventory 28 - Stairs and balcony 29 - Other building related parts
3 - Plumbing installations	30-39: out of scope of this study
4 - Electrical Power	40-49: out of scope of this study
5 - Telecom and automation	50-59: out of scope of this study
6 - Other installations	60-69: out of scope of this study
7 - Outdoor area	70-79: out of scope of this study

Table 4: Construction categories divided with respect to LOD and its milestones

Construction categories divided with respect to LOD		
OCL main distributions	**NS 3451**	**LOD**
1) Ground and foundation	20 21	100 150
2) Vertical structures and facade	22 23 24	175 175 175
3) Horizontal structures	25 26	175 200
4) Other structures and materials	27 27 29	300 300 350
6) Building technology	3 4 5 6	350 350 350 400
5) Outdoor area and elements on site	7	400

To systematize to which early design phase (or project delivery phase) that represents the different LOD levels is suggested in Figure 6.

A comprehensive LCA is to be done at LOD 350, building permit stage [11, 18, 21, 24, 25, 28, 33–35]. By this stage, the major elements are stated, and 80% of the 3, 4, 5, 6 and 7 categories (see Table 3) are agreed upon. The building can be stated complete in the BIM, apart from the uncertainty in the empirical, min/max or most likely values in the 80% of LOD 400 posts. Generic LCA databases can be used to obtain LCIA data when the BIM is incomplete and not considered as LOD 400. Another source to most likely values is considering conservative EPDs. An example of conservative EPD can be concrete instead of CLT.

At technical elaboration, the BIM represents LOD 400 (Figure 6), and the environmental impacts should be assessed on equal terms as the structural design issues. EPDs are the dominated LCIA database at LOD 400. Environmental impacts on different products are various, and therefore should EPDs represent the specific brand of the selected material. This will lower the uncertainty in the complete LCA. By using endpoint indicators instead of midpoint indicators in the low LOD LCAs, it would simplify the results and turn the interpretation phase into a more understandable phase for AEC professionals.

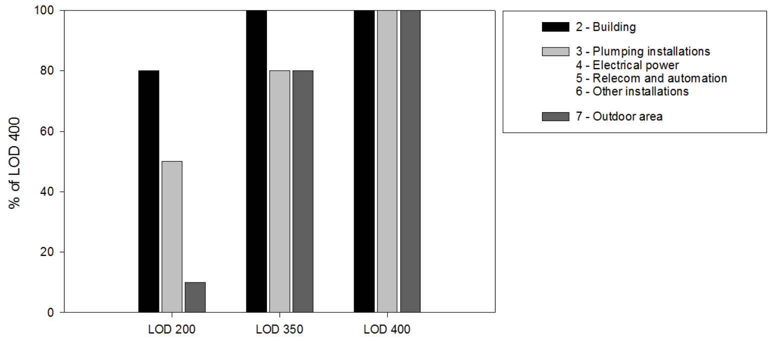

Figure 5: Degree of completeness in different stages of LOD

Table 5: Level of completeness and LCIA databases

LOD	NS 345 (1 digit)	% of LOD 400	LCIA database for building elements
LOD 200	2	80	Average values, mean values, min/max values, most likely value
	3, 4, 5, 6	50	
	7	10	
LOD 350	2	100	EPD-Norway
	3, 4, 5, 6	80	Average values, mean values, min/max values, most likely value
	7	80	
LOD 400	2	100	EPD-Norway
	3, 4, 5, 6	100	
	7	100	

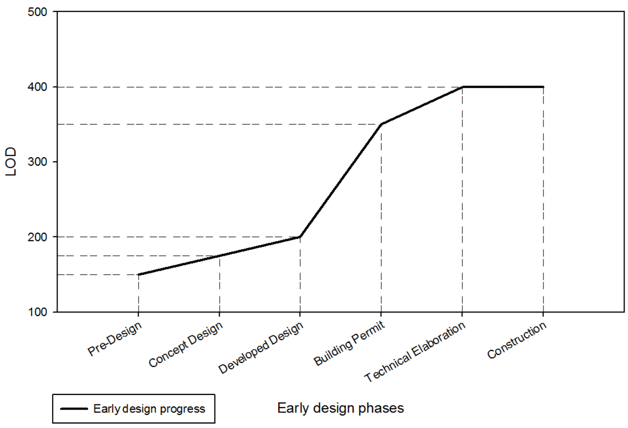

Figure 6: Design phase evolution according to LOD

Components regarding building manner should be given important effort in LOD 200, while plumping, electrical, telecom and automation and other installations are usually depending on the architectural design as Figure 5 and Table 5 shows. The building components are 80% completed at LOD 200. This is due to unpredictable issues regarding clash detection and if building elements within 3, 4, 5 or 6 categories are determinate. At LOD 350, building components is fixed as these components are the major contributors to GWP and determine the structural design of buildings. In addition, the building components determines the structural design of buildings. By clearly state these materials in LOD 350, than the majority of building materials can be assessed with high accuracy.

5 Conclusion

Main aims of a BIM based LCA is to establish a convenient decision-making method with an environmental perspective, and an ongoing environmental assessment during the early design stages. Investing more time in the design stages and utilize LOD and its requirements consistently, would enhance the level of information and detail in BIM objects. This amplifies the information within the IFC files and leads to fewer errors in BIM-LCA tools.

Therefore, we suggest the designers and design tools to be acquainted with the requirements to each LOD levels, and consequently use average, mean (±) values and best practice where the LOD level is low. The proposed LCA framework is corresponding to LOD levels, as the design delivery phases are determined by milestones of completeness in the BIM model. Designing the building project in BIM in accordance with this framework will improve the GWP, as interaction with BIM and LCA tools enables substitution of materials that contribute to the highest release of CO_2. Such automation in LCAs, and the ability for ongoing assessments will assist the decision-making processes to emphasize the environmental issues during design.

Acknowledgments

We want to thank NCC Building Nordics for handing over IFC files and access into the project "Valle Wood". Thanks for the great information and method regarding environmental assessments in the LCA application One Click LCA.

Lessons learned from assessing life cycle impacts for an environmental product declaration: Examples for run-of-river power plant

Meili C, Jungbluth N

ESU-services Ltd., Vorstadt 14, CH-8200 Schaffhausen, Switzerland

meili@esu-services.ch

Abstract. When conducting life cycle assessments (LCA) for environmental product declarations (EPD), researchers struggle with many methodological questions. For certain products there are several standards (e.g. ISO and EN) and Product Category Rules (PCR) available which all seem applicable. These standards, however, might lead to different results. Depending on the standard, system boundaries might be drawn differently than typically done in ones preferred background database. Another common issue is a lack of a clear definition of assessment methods (version, download of factors) to be applied. Or on a more practical level, you might not know how or where to obtain certain requested figures from your LCA data or even how to start with building an appropriate model in the LCA-software. The authors of this paper explain each of these issues with an example from their practical work, provide their instant solutions and make suggestions for general improvement of the situation. In general, they call for a more precise and practical guideline and easy-to-use LCIA methods for conducting EPDs.

1. Introduction

Environmental Product Declarations (EPD) present transparent, verified, and comparable information about the life-cycle environmental impact of products. The overall goal of an EPD is to provide relevant and verified information to meet various communication needs. An important aspect of EPD is to provide the basis of a fair comparison of products and services by its environmental performance. EPDs can reflect the continuous environmental improvement of products and services over time and are able to communicate and add up relevant environmental information along a product's supply chain. EPDs are based on principles inherent in the ISO standard for Type III environmental declarations (ISO 14025) giving them a wide-spread international acceptance.

Consultants at ESU-services dealt with these questions in projects and trainings. Here, we present some lessons learned when assessing life cycle impacts for an EPD on run-of-river power plants [1], revisioning a PCR for electricity [2], reviewing of an EPD on concrete products[1] and EPD of consulting services [3]. During such work the following challenges have been identified when trying to elaborate EPD:

[1] http://www.graspointner.at/fileadmin/Prospekte/FCT_one_screen.pdf

- The choice of the correct LCIA indicators is often difficult because PCR lack details such as version of method or default characterisation factors for the methods to be used. Also, there seem to be contradictory hints in standards of different countries.
- When distinguishing between upstream, core and downstream module, relevant aspects for optimisation were hidden in background-data. Getting transparency using unit processes from ecoinvent was more helpful for this goal.
- Some indicators do not follow customary practice and logic of LCA, e.g. stating which parts of resources is used for materials or reporting on waste instead of including emissions of waste treatment.
- There are no indications on how to set findings in perspective. With bare numbers on several single emissions, the values give no order of relevance and little encouragement for improvement.

2. Goals

The main goal of this paper is to provide suggestions for the optimization of guidelines and easy-to-use methods for conducting EPDs.

The following questions are tackled:

- Which standard (ISO, EN) and Product Category Rules (PCR) to apply?
    - How to draw system boundaries accordingly?
    - Which life cycle impact assessment methods match the standard?
    - How to obtain other requested information from LCI data?
- Restrictions concerning databases to be used.
- How to build an appropriate model in the LCA-software of choice?
- How to set findings in perspective and foster encouragement improvement?

3. Example: Run-of-river power plant

3.1 Goal and scope

3.1.1 Goal

The main goal of one underlying case study was to provide insights for the optimization of run-of-river power plants to the operators. It also enables the power plant operator to make a rough calculation for the environmental impacts due to electricity production in the client's existing and prospective power plants. In order to simplify the calculation of results the approach follows the Product Category Rules (PCR) guidelines for developing an environmental product declaration (EPD) for this type of power plants.

The model provides results for the two functional units: kilowatt-hour electricity, produced in a run-of-river power plant, “at power plant” and “at final customer”. For electricity at customer, also transformation to low voltage and transmission through different grid levels is included [1].

3.1.2 Scope and system description

Modelling is done according to latest available PCR [2], in accordance with ISO 14025:2006. Data collection is based on a model for run-of-river power plants without reservoirs in Switzerland [4-6].

For the impact assessment, besides required impact categories according to PCR for EPDs also an assessment with the Swiss-specific ecological scarcity method is implemented to simplify communication with Swiss stakeholders [7].

The model is implemented in excel and allows exchange of parameterized data in the EcoSpold v1-format. Thus, it is also possible to easily import the life cycle inventory analysis in SimaPro in order to do more detailed assessments.

The following modules of the life cycle are modelled (see Figure 1):

- Upstream processes: Provision of auxiliaries for ongoing operation, mainly lubricants and corrosion protection.
- Core process, operation: Water and land use for the operation of the turbine, as well as emissions from the use of lubricants (chemical oxygen demand, COD).
- Core process, infrastructure: Materials and energy requirements for the construction and dismantling of the power plant (dams, canals, power plant, etc.) and the installation of components in the power plant (turbines, generators, etc.), including necessary material and energy consumption, e.g. diesel and explosives.
- Downstream operation: Operation of the transmission and distribution network for the supply of electricity to end customers. Includes power losses during transformation and transmission, use of SF6 and associated losses.
- Downstream operation, infrastructure: Construction and disposal of the transmission and distribution network for supplying electricity to the end customer.

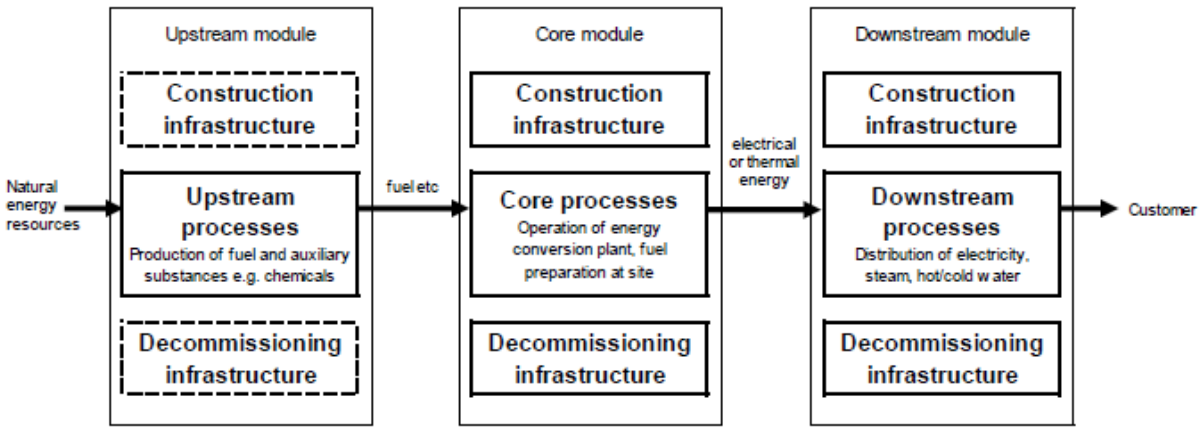

Figure 1 Illustration of the life cycle structure and rough system boundaries. Rectangles with extended lines show processes that should be included, dashed lines show processes that could be included. Construction includes necessary renewals during the technical lifetime, decommissioning includes demolition and treatment of the various waste fractions according to the polluter-pays principle (cf. PCR CPC 17 2007).

3.2 Issues identified

1. The PCR requests a distinction of upstream, core and downstream processes as described above. No clear guidance was given, if and how e.g. a lubricant used for maintenance of the turbine should be allocated to the upstream or core process. In theory, according to the structure in Figure 1, production and emissions related to production of the lubricant should be allocated to the upstream process and emissions caused in the use phase during the processing of the turbine should be allocated to the core process. Unfortunately, in several commercially available databases only "system processes" are included. They show cumulated results of the lifecycle inventory of processes and products. Therefore, it is not possible to distinguish the share of emissions from production and other upstream processes from emissions occurring during the use phase. On the other hand, also in unit processes often there is a lack of direct emission data, so these emissions would need to be assessed in an additional model.
2. Some indicators do not follow customary practice and logic of LCA, e.g. the PCR requests statements on which parts of resources are used for materials. In lifecycle inventory data, resources are accounted for in the first stage of a production process. It is not recorded for which

purpose the derived materials (e.g. mineral oil products in the production of lubricants) are used finally. From an environmental point of view, when only looking at resources, there is no difference if a resource is consumed for the provision of energy (e.g. combustion of mineral oil) or the production of a material. (e.g. use of mineral oil as ingredient substance of the lubricant). Issues of accompanying emissions etc. are covered by other indicators than the resource use. Also, the PCR requests reporting on the level of different waste categories. This is also not state of the art in the LCA practice. There, all emissions of waste treatment should be tackled in process stages looking at the waste treatment. Reporting on the amount of waste per se is not an environmental indicator as the relevance for the environment can only be assessed when knowing more about the further treatment of it (e.g. type of filters used in incineration plants, landfill sealing, recycling shares).

3. For the commissioner and especially the final target group of a report (customers of the product under study), it is difficult to set findings in perspective as they are not used to the metrics of LCA and have no feeling what the consequences of the release of e.g. 1 kg of CO2-eq would be. With bare numbers on several single emissions, the values give no order of relevance and little encouragement for improvement. The PCR and the ISO-standards give no indications on how to foster such an encouragement.

3.3 Solutions

1. For the project at hand ecoinvent unit processes were screened to determine direct emissions to the environment for lubricant oil and paint used in infrastructure and core processes. Where the emissions made more than 2% of total process related emissions according to the assessment criteria, they were included in the parameter model.
2. To get the indicator results requested according to the PCR, information was exported from the life cycle inventory data and hand-picked to be presented together with the impact assessment. To improve workflows in other consulting companies, this lack of user-friendliness was reported to the developer of a common LCA-software. They agreed to provide a more comprehensive EPD methodology with their next release. Nevertheless, it is also questionable if an extensive list of single emissions reported in an EPD can lead to better choices by the decision maker. Also, here more guidance by PCR developers would be necessary.
3. To set things in perspective it could be helpful to show results in comparison with best available technology, average technology and on an individual as well as on a national or global scale.
4. Developing a key parameter model proofs to be a valuable tool for simplifying the work on EPD for several similar products in one product group.

4. Suggestions for general improvements

It is suggested, that product category rules (PCR) include more detailed, practical guidance on how to fit a certain process into the life cycle structure as shown in Figure 1. Additionally, it is suggested, that providers of LCA software include an LCIA methodology to easily access all indicator information requested by the EPD-framework.

The PCR ideally also provides sources for information on how to put EPD results in perspective. Such sources could include a list of former EPDs and links to international environmental target values.

So far PCR do not deal sufficiently with the requirements for such simplified tools. Requirements for the review of the tool and the publication of results should be integrated in the PCR.

5. Discussion

The purpose of this paper and conference presentation is to show some shortcomings in common PCRs and initiate a discussion about the usefulness of EPD. It contains only some subjectively selected examples. The authors neither claim to deliver a comprehensive paper nor a perfect solution. In the best case, the here mentioned examples are useful as a starting point for further discussions and improvements in the general PCR-framework.

Abstract. This paper will present objectives and first results of the research project entitled "Large Scale Smart Meter Data Assessment for Energy Benchmarking and Occupant Behaviour Profile Development of Building Clusters," implemented in the geographical scope of Hungary. The project seeks to utilize a new and unique opportunity for accessing and processing an enormous dataset collected by smart meters. Recently in Hungary, nearly 10 000 buildings have been equipped with smart meters within the "Central Smart Grid Pilot Project". By means of advanced data analysis techniques, consumption trends and motivations of building users are being investigated. The aims are to help building designers and engineers design more energy efficient buildings at lower investment costs by avoiding system oversizing, and to obtain better knowledge about hourly, daily and monthly energy consumption trends. Furthermore, standard net demand values for normative energy calculations can be updated and specified more precisely since consumption habits change with time and depend on the region.

1. Introduction

There are two principal ways to analyze the energy performance of buildings. First, the asset method, which applies calculation principles and modelling tools based on the physical characteristics of buildings such as geometry, building shell attributes, features of technical systems and occupant's behavior. The asset method provides transparent information on performance indicators and details. However, it is sensitive on the reliability of input data, and information on user behavior is often missing; thus, standardized data are used instead of actual users' performance. The second, so called operational method, is based on real energy consumption analysis, which gives a reliable picture about the energy performance of a building, but only for the analyzed period under specific circumstances.

To perform energy analysis for a large number of buildings, both methods are applicable and relevant. In Hungary, there is greater proficiency in building stock analysis using the asset method, particularly in the housing sector. In 2013 the National Building Energy Strategy (NBES) [1] was expanded based on modeled building archetypes. Additionally, Hungary has joined the Tabula/Episcope project, supported by the Intelligent Energy Europe Programme. In this project, building typologies have been developed for 18 EU countries, Norway and Serbia [2]. The work was further developed within the KEOP-7.9.0/12-2013-0019 project in 2015, when a representative sample of 2 000 residential buildings [3] were selected and on-site surveys were carried out by accredited experts. As a result of the work, a national level extrapolation was implemented and energy saving scenarios were proposed for policy developers.

However, these projects did not consider real occupants' behavior, and certainly a set of simplifications were applied in the analytical model. Real energy performance can only be monitored based on the operational model, although this method does not give any information about factors influencing performance and is not applicable for modeling energy saving. Nevertheless, both discussed methods have relevance and can provide supplementary information to each other.

1.1. Brief Review on Smart Meters

Smart meters (SM) are electronic devices that record occupant energy consumption and share this information with utilities, allowing two-way communication between consumers and providers [4]. At the end of 2016, there were 700 million smart meters installed globally, with over half of those in China [5]. Aside from China, Europe is a global leader in SM implementation; a European Union directive has an 80% customer penetration goal by 2020 [6]. Additionally, from 2016 – 2020 European utility companies will invest €33.4 billion to install 182 million smart meters [7].

Given the massive uptake in SM technology, methods for analyzing such data are crucial, and there is an increased focus on profiling occupants to better understand their energy behaviors. Many researchers have begun using a data mining technique known as clustering to group occupants by similar temporal (i.e. daily, weekly or seasonal) energy use patterns [8–10]. Research in this area also supplements SM data clusters with socio-demographic data to determine how factors like age, income, employment status, appliances and building retrofit, among others, influence energy use patterns [11–14].

It is also important to note that consumers have expressed privacy concerns with SM technology. Such concerns are energy data being sold to third parties like advertisers or law enforcement, decreased privacy inside households (such as family members monitoring each other's activities), or that criminals could hack SM information and determine when residents are not at home [15,16]. Recent research also suggests that social-psychological factors like trust in utility companies, perceived usefulness of the technology and perceived risk to privacy may directly impact SM support [17]. Therefore, it is important to continually refine data analysis techniques while also addressing consumer concerns as SM use surges worldwide.

1.2. Central Smart Grid Pilot Project in Hungary

Article 8 of the Energy Performance of Buildings Directive (2010/31/EU)claims that the Member States shall encourage the introduction of intelligent metering systems whenever a building is constructed or undergoes major renovation, and the Member States may furthermore encourage, where appropriate, the installation of active control systems such as automation, control and monitoring systems that aim to save energy. Furthermore, directive (EU) 2018/844 of 30 May 2018 amending Directive 2010/31/EU on the energy performance of buildings, prioritizes smart buildings and introduces the new smartness and smart readiness indicators.

Legislation related to the Third Energy Package of the EU, such as 2009/72/EC [6], and 2009/73/EC [19] required Member States to prepare an economic assessment of long-term costs and benefits of electricity and gas smart metering by 3 September 2012. In cases where the cost-benefit analysis (CBA) is positive, there is a roll-out target of 80% market penetration for electricity by 2020. The results of the CBAs are as follows [20]: for electricity smart meters, 16 states from the EU-27 have decided to roll-out smart meters by 2020, in seven states the CBAs were negative, and in four states the CBAs or roll-out plans have not been prepared; for gas smart meters, five states from the EU-27 will proceed with large-scale roll-out of smart meters by 2020, two states have plans to proceed with a large-scale roll-out but have yet to take official decisions, in 12 states the CBAs were negative, two states have no gas network at all, and in six states the assessments have not been prepared. Overall, 72% of EU consumers are expected to have smart electricity meters and 40% smart gas meters.

In Hungary, the Central Smart Grid Pilot Project (KOM) was established in 2016 to assess the possibilities of a national smart monitoring system. Within the framework of the project, 139 901 smart metering devices have been installed throughout the country in residential, public, commercial and industrial buildings. Emphasis was placed on the representativeness of settlement and building types during the selection. The evaluation of energy consumption was not an objective in the demonstration project, only installation, maintenance and continuous data collection during a 5-year period ending in 2023. Therefore, another project entitled "Large Scale Smart Meter Data Assessment for Energy Benchmarking and Occupant Behavior Profile Development of Building Clusters" was initiated by BME in October 2018 to benefit from the opportunity by accessing and processing this enormous, representative dataset.

In the past, only some segments of the building stock and building users' energy performance could be analyzed in the country due to the lack of consumption-related information. This high-resolution, detailed dataset opens new perspectives to supplement and complete the existing national building typology; it also provides building use schedules for different purposes such as building energy simulations or energy certifications using more reliable input data on users' profiles.

1.3. Objectives

The main objective of this research is to evaluate the dataset collected by the smart meters installed across Hungary within the Central Smart Grid Pilot Project. This enormously rich source of information opens new perspectives in energy pattern evaluation on a building stock level. Our intention is to obtain more advanced knowledge in the following aspects:

- a more precise picture about the real energy consumption of Hungarian building stock,
- a comparative analysis can be carried out between measured and building typology based modelled data, and hence a supplement and completion in national existing bottom-up building stock modelling,
- by means of advanced data analysis techniques it is possible now to cluster building types and occupant types to determine user profiles and energy consumption patterns,
- energy demand profiles can be developed on a large scale and utilized by energy supply and utility companies to improve their production profiles by demand side management (DSM); thus, the smart-grid concept can be realized, resulting in energy savings by peak-shifting on a national level.

The current research ("Large Scale Smart Meter Data Assessment for Energy Benchmarking and Occupant Behavior Profile Development of Building Clusters") started in October 2018 and is still in an early phase: we are working on data verification and cleaning; evaluation algorithms are being developed and tested on a small sample and supplementary data on buildings are being collected. Present paper presents the first experiences, challenges and difficulties we have faced so far.

2. Methods

2.1. Time Series Datasets

In the early stages of the project, it was decided that residential buildings would be in the focus of the research. First, the device database was filtered in order to identify the smart meters installed in residential buildings. The second step was to categorize the selected smart meter database. In the categorization process the following were considered:

- geographical diversification,

- type of settlement,
- meter type / measured consumption.

For the analysis of geographical diversification, a map was created indicating locations of installed sensors, which can be seen in Figure 1. It is apparent that the meters were mostly installed in Central Hungary and the Southern Great Plains; further, it is important to note that while there were a significant number of smart meters also installed in Northern Hungary and the Northern Great Plains, they were only in two cities (Nyíregyháza and Miskolc).

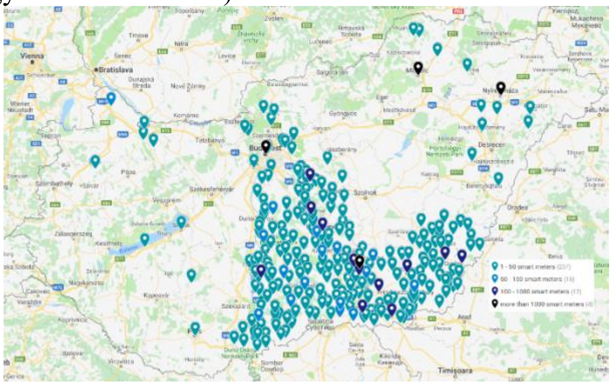

Figure 1., The geographical distribution of the installed smart meters.

The distribution of settlement types was better than the geographical distribution, which can be seen in Figure 2. While the distribution of buildings by settlement type was uniform, the number of installed smart meters by settlement type shows an uneven distribution in favour of larger cities.

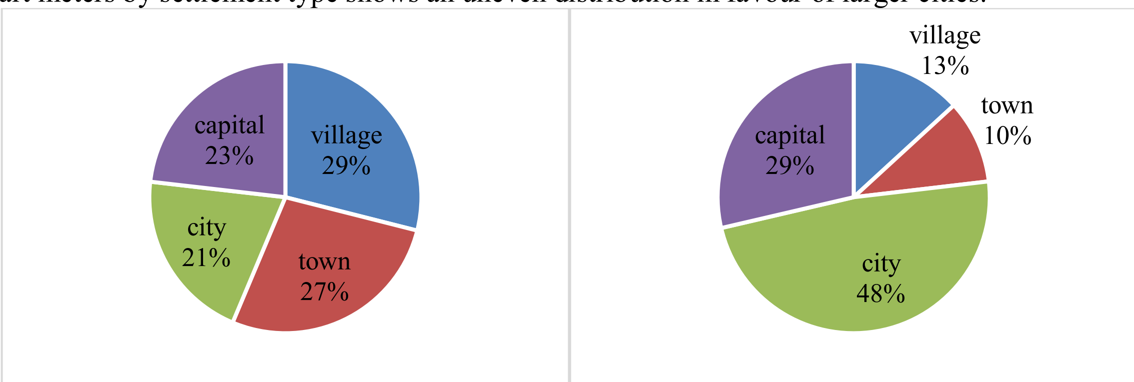

Figure 2., Distribution of residential buildings in Hungary (left) and the installed smart meters (right) by settlement type

In residential buildings a total number of 33761 smart meters were installed, measuring gas (5614), electricity (10368), heat (11715) and water (6064) consumption.

The meters were in operation between the years 2016 and 2018. For most of them, the dataset is limited to dates between 2017 and 2018 or only 2018.

It should also be noted that, depending on the sampling frequency, the possible data usage can be limited. For some meters, the sampling time was as low as 300s, but there were meters with sampling times as high as one week. Obviously, the more frequently recorded data is more suitable for daily profiles, whereas the usage of time series with high sampling time is restricted to weekly or monthly profiles. Communication problems between the smart meters and the servers result in data loss and this degrades the quality of the data. Long outages make it impossible to derive relevant observations.

2.2. Statistical Significance and Representative Sample

It is essential to ensure the validity of the results obtained from the dataset described above. In order to formulate statements on Hungarian building stock, two statistical parameters have to be investigated to determine appropriate sample size and distribution.

Firstly, the population groups were determined with the aim of having results with statistical significance. In the first round of analyses, residential apartments were tackled. Group-defining variables were: size of settlement and geographic regions of the country (see Table 1).

Table 1 - Residential apartment-based population groups used for sample-size calculations

Size of town	Nr. of apartments	Geographical region	Nr. of apartments
Villages and towns	1 227 110 (23%)	Southern Great Plain	602 819 (11%)
Cities	1 370 964 (26%)	Southern Transdanubia	409 265 (8%)
County-seat cities	925 730 (17%)	Northern Great Plain	624 091 (12%)
Capital	1 832 310 (34%)	Northern Hungary	509 790 (10%)
		Central Hungary	2 318 556 (43%)
		Western Transdanubia	435 697 (8%)
		Central Transdanubia	455 896 (9%)

Based on a national statistical dataset [21], the population of each statistical group was determined based on the number of apartments. The necessary sample size to ensure statistical significance in each group was calculated using Eq. 1 [22].

$$Ns = \frac{(Np)(p)(1-p)}{(Np-1)\left(\frac{B}{C}\right)2+(p)(1-p)} \qquad (1)$$

Where Ns = completed sample size needed (notation often used is n)

Np = size of population (notation often used is N)

p = data diversity: 50% or 0.5 is most conservative

B = acceptable level of sampling error (0.05=±5%; 0.03=±3%)

C = Z statistic associate with confidence interval (1.645=90% confidence level; 1.960=95% confidence level; 2.576=99% confidence level)

For the sample size calculations, a sampling error of 3% and 95% confidence level were assumed.

Secondly, the representativity of the sample was ensured by preserving the ratios of population groups. For example, in Hungary, 26% of apartments are located in cities. Therefore, in this project's sample, 26% of the apartments investigated were from cities.

2.3. Qualitative Information Assigned to Smart Meter Data Points

Analysis of the measured data requires some information from the buildings where the meters were installed. First, the function of the building is relevant, but parameters such as the size or construction type influence the energy consumption and may help with further analysis. Unfortunately, such data were not recorded in the measurement campaign and only the address of the buildings were available.

For compiling further building parameters, we decided to apply a 'manual' approach. As the number of meters and the number of buildings is large, a compromise had to be found between the accuracy and the time spent for data acquisition. Physical observation of the buildings would give highly reliable data, but it would take too much time as the meters are scattered all over Hungary. Using GIS mapping tools provides a relatively fast method for data collection. Based on the address, an expert identifies the building and collects relevant information by observation and some measurements.

First, we identified the relevant parameters that are important for the characterization of a building. The necessary parameters include the building function, building type, covered area, number of stories, general condition of the building, visible retrofit measures (change of windows, additional insulation on façade), type of roof (flat roof, pitched roof unused or used) and the presence of solar panels/ collectors. Buildings are first classified based on the building function: residential buildings, offices, sport facilities, restaurants, educational, healthcare, cultural, industrial, commercial, religious or agricultural buildings. There are further subcategories available, for example, educational buildings are classified into kindergartens, primary and secondary schools, universities, etc. So far, only residential buildings were examined.

As most of the measured data are from residential buildings, a more detailed subcategorization based on building archetypes developed in the framework of the KEOP-7.9.0/12-2013-0019 project was applied [3]. In this project, 23 residential building types were established and for each building type, the most typical construction materials, heating systems, typical energy consumption, etc. were provided. However, it was soon realized that such a detailed classification is difficult without further information sources, so certain categories were merged. Finally, a simplified typology with 10 classes was applied, based on the type of the residential building (detached house, small apartment building, large apartment building), the approximate date of construction and the construction type (prefabricated concrete panel or not).

According to the first experiences, this process generally worked well and fast enough to identify and classify a large number of buildings in a reasonable time frame. A major problem encountered was that streetview images are not available is some villages and in some smaller streets. Such buildings were removed from the sample and substituted with new ones. Also, the identification of the building based on the address was sometimes difficult, and external obstacles such as trees blocked the view in some cases.

2.4. Time-series Data Analysis

The preliminary analysis of the data started on the time series showing the incremental natural gas consumption of different residential buildings. It is vital to discard the unusable or false datasets as they would corrupt the conclusions of the future analysis. Therefore, some series were manually analyzed to identify the typical errors. By using the findings of these investigations, algorithms will be developed to automatically categorise the time series from the different meters and only manually investigate the minimal number of datasets.

For instance by analyzing the electricity measurements time series of the energy usage measured in kWh-s was different from the same energy usage obtained from integrating the mean power measured by the same meter. The mean power values were zero sometimes, which can be the result of some software or database failures. Thus it’s vital to check smart meter data carefully before any conclusion can be drawn.

2.5. Questionnaires and Interviews

In this project, time-series datasets are supplemented with socio-demographic data collected by questionnaires and interviews.

The following table contains independent variables derived from four models commonly used to determine social-psychological determinants of energy efficient technology acceptance. We have selected the variables from each model most relevant to our project. Each variable will be measured using reliable, previously-validated survey questions. (See Table 2)

Table 2 – Social-Psychological models and survey measures used in the project

Model	Reference	Variables
Theory of Planned Behavior	[23]	**Attitude** towards the technology

Technology Acceptance Model	[24]	**Perceived usefulness** **Perceived ease of use**
Norm Activation Model	[25]	**Personal norms (**moral obligations)
Sustainable Energy Technology Acceptance (SETA)	[26]	**Trust in technology providers** **Knowledge** **Perceived risk to privacy** **Problem perception** (awareness of consequences)

These survey measures will be supplemented with dependent, demographic variables such as age, gender, occupation, education level, perceived material status and building characteristics and retrofit. Additional dependent measures such as support for SM technology, intention to adopt SM and continued SM use in the future will also be utilized.

This forthcoming part of the project will be split into three rounds of data collection with three different categories of participants:

1. Building operators in public buildings where SM technology is not yet installed.
2. Assigned "sustainability champions" in smart buildings and potentially users who interacted with SM in their buildings.
3. Residential households with recently-installed SM.

3. Preliminary Results

3.1. Data quality check

At the present stage of this project, three common error types were found and defined. These errors will be the basis of automatic data filtering procedures.

- Type A: the sampling time is longer than a user defined value in one or more points.
- Type B: no usable data is available (the meter did not record any data, or the change in the data is almost zero –probably the building was not used).
- Type C: small or large breaks in the time series.

One example for type A errors can be seen in Fig. 3.

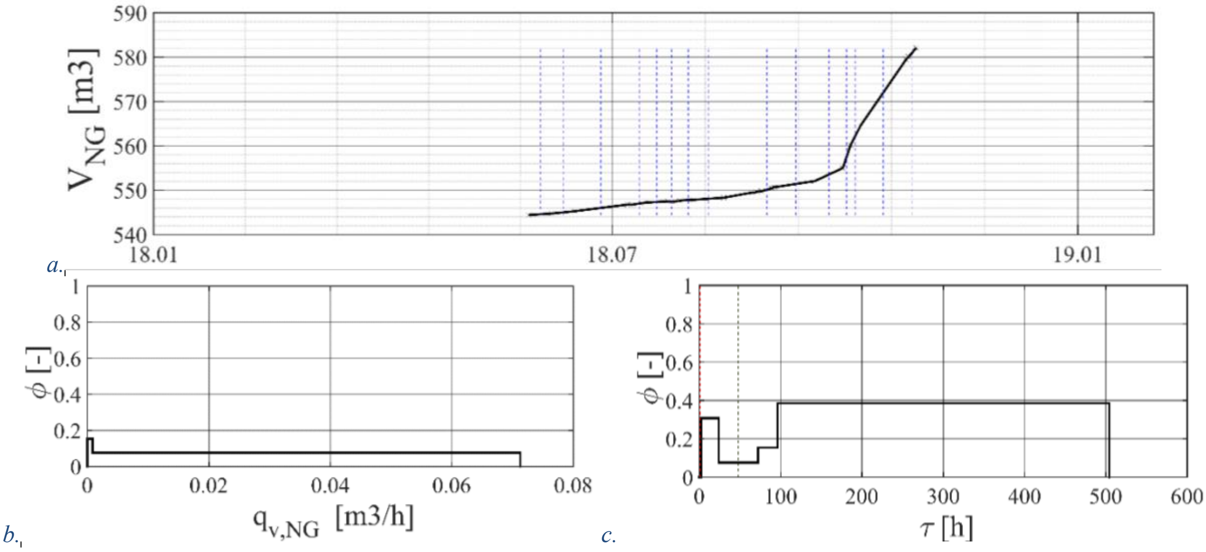

Figure 3., a.: time series, b.: histogram of $q_{v,NG}$, c.: histogram of τ. for the location code named as C00023827.

V_{NG} the incremental gas volume flown through the meter, $q_{v,NG}$ is the mean flow rate between two adjacent samplings, ϕ is the relative probability density, τ is the sampling time (the time between two adjacent points). The criteria for sampling time was 48h in this case, and at the locations where actual sampling time was higher than this value, vertical blue dashed lines were drawn at the middle between the two adjacent points (Fig. 3.a).

Fig. 3.b shows a histogram created by using the Eq. 1. $q_{v,NG,i}$ is the mean flow rate between the data point i and i+1, $V_{NG,i+1}$ and $V_{NG,i}$ are the incremental gas volumes flown through the meter at the ith and (i+1)th measurement points and τ_i is the difference in time between the two points (sampling time).

$$q_{v,NG,i} = \frac{V_{NG,i+1} - V_{NG,i}}{\tau_i} \tag{1}$$

Fig. 3.c shows a histogram of τ. It can be seen, that this time series is not suitable for any further analysis, as many points are missing.

Type B errors can be identified by only using the time series diagram. Fig. 4. show one example, for which data was transmitted, but apparently either no gas was consumed or instead of the correct numbers only zeros were recorded.

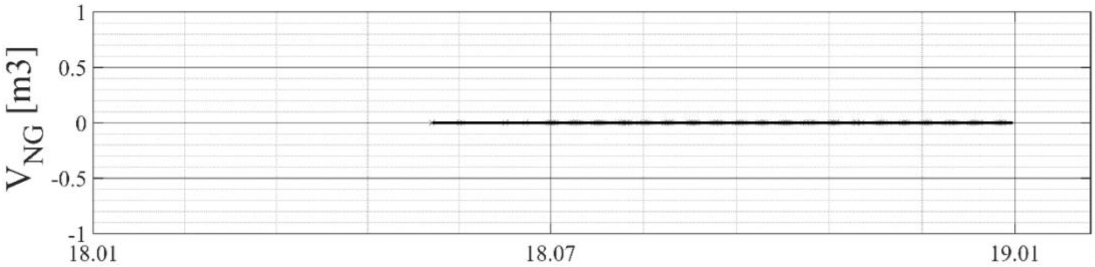

Figure 4., Time series for the location code named as C00023827.

For type C errors Fig. 5. is a good example. In this case the break or jump in the times series data can be the result of meter replacement.

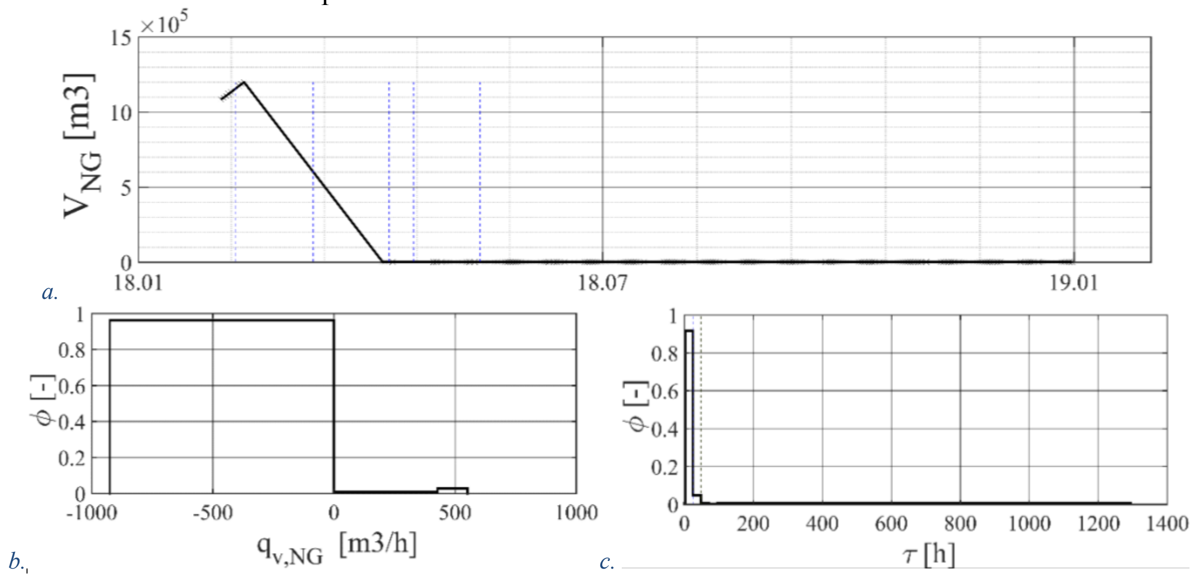

Figure 5., a.: time series, b.: histogram of qv,NG, c.: histogram of τ. for the location code named as C00028711.

Type A and C errors can most likely be corrected in some cases, but type B errors make the dataset unusable. The development of correction methods can be the subject of further research.

3.2. Natural Gas

As a preliminary step a basic gas consumption analysis has been carried out for a small selection of buildings. By carefully filtering out the datasets containing errors presented in Section 3.1, it was possible to examine the monthly natural gas consumption in 11 different locations. Fig. 6 shows locations where no gas was used during the summer season; so, it can be concluded that for cooking and domestic hot water (DHW) production electricity is used. The monthly consumption numbers were divided by the annual consumption ($V_{NG,a}$), so results are presented on a relative scale. It can be observed that the trends are within a narrow range.

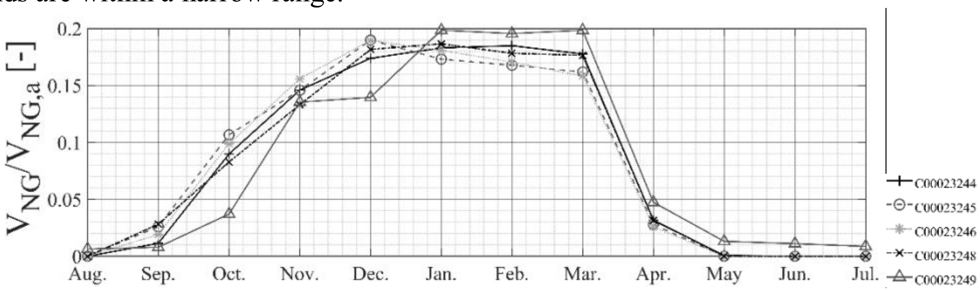

Figure 6., Monthly natural gas consumption for profiles for five different locations with almost zero consumption in the summer.

Fig 7. shows six more locations where DHW production and possibly cooking was also natural gas based, as around 12% percent of the annual gas consumption was used between May and August.

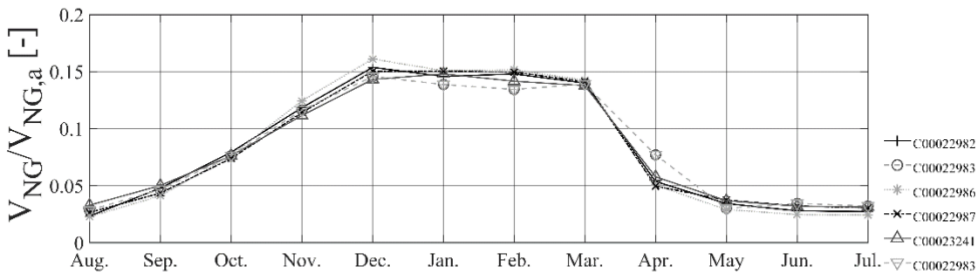

Figure 7., Monthly natural gas consumption for profiles for five different locations with gas based DHW production and cooking.

4. Conclusions and future plans

Statistical methods showed that the large dataset is suitable for selecting a sample from the smart metered buildings that produces representative results for settlement categories and building types, but not for geographical distribution, as most sensors were installed in the South-Eastern part of Hungary. The representative selection can be realized despite data errors in case of a significant number of sensors.

Data are handled with respect towards privacy issues, although GDPR rules makes it challenging to collect qualitative supplementary data about the sample buildings. All results will be anonymised.

The data evaluation process is still in the phase of methodological development and data filtering, although qualitative data collection is ongoing. Results on residential building stock is expected by the end of 2019, then public and other building types will be analyzed. In addition, there is a significant number of large residential buildings where heat cost allocator data are collected, which will be analyzed for a selected smaller number of buildings with a different, more detailed approach in cooperation with housing associations. For public buildings, GDPR is not a problem; thus, more precise supplementary data collection will be possible.

An additional part of the project will be social-psychological research based on questionnaires and interviews focusing on users' habits in approximately 20-30 public buildings in cooperation with Hegyvidék Municipality, 12th district of Budapest.

The project runs until September 2021.

Acknowledgments

Results and the determined trends are being fine-tuned and extended for other building types with a geographic scope of Hungary in another research project entitled “Large Scale Smart Meter Data Assessment for Energy Benchmarking and Occupant Behavior Profile Development of Building Clusters“. Furthermore, methods and approaches developed in the current work are being further developed for large scale data analysis. The project (no. K 128199) has been implemented with the support provided from the National Research, Development and Innovation Fund of Hungary, financed under the K_18 funding scheme.

The monitoring data subject to analysis is being collected within the "Central Smart Grid Pilot Project" by KOM Smart Meter Ltd.

The research reported in this paper was also supported by the Higher Education Excellence Program of the Ministry of Human Capacities in the frame of Artificial intelligence research area of Budapest University of Technology and Economics (BME FIKP-MI).

The authors wish to acknowledge a Fulbright Visiting Student Researcher Award from the Fulbright Commission for Educational Exchange which enabled scientific exchange between Budapest University of Technology and Economics and University of Tennessee.

martin.beermann@joanneum.at

Abstract. The objective of this paper is to present real-world energy monitoring and sustainability assessment results of innovative energy-efficient service buildings in Austria. In the investigated buildings, the energy flows for the supply and distribution of heating, hot water and cooling energy, the object-related electricity consumption and, if available, energy generation with PV and solar thermal systems were recorded during a period of at least twelve months. The room parameters temperature and relative humidity, and in some cases the CO_2 content were also monitored. The use behavior was described based on the users of the building as well as on the operation and parametrization of mostly fully automated energy facilities. The buildings were classified in a sustainability assessment according to the Austrian Total Quality Building (TQB-) system. The buildings investigated are three office buildings, a research laboratory building, a supermarket, a hotel, a nursing home, a culture and event center and a student dormitory. The main findings presented in this paper include energy efficiency potentials identified in the automated operation of the energy facilities in the investigated service buildings. Recommendations also relate to challenges of energy monitoring itself.

1. Introduction

In Austria numerous innovative, energy-efficient buildings have been built in recent years and existing buildings renovated. Such buildings are characterized by requirements as lowest energy use, use of onsite renewable energy sources or waste heat, use of ecological building materials, ensuring adequate room comfort parameters and all this at life cycle costs comparable to conventional building concepts.

The realization of such buildings, in particular larger service buildings, includes the planning and operation of sometimes complex technical systems for heating, cooling and ventilation (HVAC). Although the planning process of complex building systems is increasingly supported by digital working methods aiming to integrate the design of buildings and their conditioning concept, the real world performance of energy efficient buildings also depends on the parametrization of mostly automated HVAC systems in larger service buildings, and on actual user behavior which can significantly deviate from standard user profiles applied in the planning phase.

Previous investigations of planned and real energy consumption of several demonstration buildings in Austria [1], [2], [3] have resulted in deviations to a varying extent. The objective of this paper is to present additional nine service buildings in Austria and to make the potential of innovative building concepts and technologies visible, but also point to possible areas of concern. The monitoring and assessment results shall serve future building projects to realize the optimization potential with regard to energetic, ecological and social aspects.

The following table 1 and figure 1 present an overview of the investigated service buildings and the main technical elements of the HVAC systems.

Table 1: Overview of the investigated service buildings

2. Methods

In all buildings, the generation and distribution of heating and cooling energy and hot water, the electricity demand of the HVAC system and its subsystems (e.g. heat pump, ventilation) and of other electricity consumers such as lighting were measured by using heat flow and electricity meters. The monitoring period was at least 12 months, thus covering all seasonal climatic differences, all values were recorded as 15 minute-mean values. Data management and visualization was supported by a web- and server-based professional hard- and software solution with universal interfaces to any energy and flow meters. The measurement data were evaluated in plausibility tests, specific attention was paid to the heat measurement data. Heat energy data are based on the measurement of the heat medium volume flow and the difference of flow and return flow temperatures. The measurement of small temperature differences of a few degrees, e.g. at heat pumps, is very sensitive to measurement errors of a few tenths of degrees within the class inaccuracy of the meter, which already have a major impact on the measured heat energy. Systematic errors therefore need to be corrected with appropriate factors.

Based on the measurement data, energy indicators were calculated: heating energy consumption (ambient temperature adjusted by heating degree days), warm water consumption, cooling energy consumption and final energy consumption, which is the energy supplied to the building to cover the demand of the HVAC system and of general consumers as lighting (free energy supplied by environment as solar energy, PV electricity or geothermal energy is per definition not considered as final energy).

The comfort parameters temperature, relative humidity, and in some cases the CO_2 content were measured in at least 3 rooms per building with different exposures to solar radiation. The use behavior was evaluated based on the use category of the building as well as on the operation and parametrization of mostly fully automated energy facilities.

All buildings were assessed with the Austrian sustainability rating system Total Quality Building (TQB). This rating system is based on five equally weighted criteria groups: location and facilities, economy and technical quality, energy and supply, health and comfort, resource efficiency. Criteria assessment was based on information provided by the building operators and, where available, on monitoring data. Two ecological indicators as part of TQB are explicitly presented in the results table 2 below: the life-cycle based OI3-indicator, combining global warming potential, acidification potential and non-renewable primary energy demand of the materials used in the building (system boundary BG1), and the disposal indicator EI, weighting the volume of building materials by its utilization potential after end-of-life. Detailed information on the TQB-method is provided in [4].

3. Results

Results are presented below in table 2 for the energy indicators, the comfort parameters, the TQB scores and ecological indicators. Due to the different use categories of the buildings, a comparison of results is only feasible for the three office buildings. For the other buildings the results are commented individually.

Table 2: Results of monitoring

	Office building 1	Office building 2	Office building 3	Laboratory building	Nursing home	Super-market	Hotel	Cultural and event center	Student dormitory
Gross floor area [m²]	13 051	5 535	4 878	918	3 727	1 236	1 449	1 538	1 456

EI (V1, 2012)	2.6	2.3	2	2.3	1.8	1.7	1.3	2.6	2.6

3.1. Office buildings

The three office buildings 1, 2 and 3 (OB 1, 2 and 3) have similar HVAC concepts, but completely different building shells. All three buildings supply heating energy demand by heat pumps, in OB1 using waste heat from neighboring water turbine generators, in OB2 and OB3 using groundwater, in OB3 in combination with district heating. Cooling energy is supplied by free cooling, at OB1 with water from the neighboring reservoir and in the other two buildings OB1 and OB2 with groundwater. Heating and cooling energy is distributed in OB1 by floor heating and cooling ceilings and in OB2 and OB3 by concrete-activated ceilings. The building shell of OB1 is a wood-concrete hybrid construction, and in OB2 and OB3 massive concrete construction. OB3 also has a unique stamped concrete façade. This is reflected in the average building U-value, which is particularly low for OB3 with 0.24 W/m²K compared to OB1 and OB2 with 0.33 and 0.38 W/m²K. OB1 in turn is a very compact building with an A/V value of 0.29 1 m compared to 0.42 for OB2 and 0.81 1/m for OB3.

Ambient temperature-adjusted heating energy consumption is 17 kWh/m²a for OB1, 25 kWh/m²a for OB3 and 44 kWh/m²a for OB2. In addition to the building shell characteristics U-value and compactness, solar radiation as well as the average room temperature in the heating season have an influence on heating energy consumption. Impact by solar radiation is higher in OB1 and OB2 due to large windows (east and west oriented). OB3 has smaller windows as well as the additional storage mass of the stamped concrete façade, which reduces the transmission losses of the building shell. The average room temperature during the heating season is lowest with 22.8 ° C in OB1, 23.5 ° C in OB3 and 24.1 °C in OB2.

Cooling energy consumption at OB1 is 12.9 kWh/m²a, at OB2 20.1 kWh/m²a and at OB3 9.2 kWh/m²a. The average room temperature in the summer in OB1 and OB3 is on average 24 ° C, in OB2 24.8 ° C. The percentage of overheating hours (> 26 ° C in the summer) is 0% in OB1, 0 to 8.6% in OB3 and between 3 and 11% in OB2. OB1 has overhangs in the façade on each floor as shading elements as well as daylight-controlled automated exterior blinds. In OB3, the deep, narrow window areas reduce the solar input, while the stamped concrete façade reduces the transmission losses of the building shell also in summer. In OB2, both daylight-controlled exterior blinds and specific foils on the windows provide the necessary shade.

The results of final energy consumption focus on the HCAC-systems of the buildings. Electricity consumption is 21.4 kWh / m²a in OB1, 19.7 in OB2 and 37.9 kWh / m²a in OB3. The seasonal performance ratio of the heat pumps are 3.8 in OB1, 3.7 in OB3 and 3.1 in OB2. The lower ratio at OB2 is due to a non-optimal parameterization of the heat pump in combination with district heat.

With regard to relative humidity, the measured data show the expected result that compliance with the comfort range in winter can only be ensured by air humidification in the ventilation system. In OB1 steam humidifiers are installed, resulting in an average relative humidity of 47% respectively in winter. In the other buildings, relative humidity is on average 30-34% in winter and below 20% with ambient temperatures below 0°C. However, steam humidifiers have a high power consumption, in OB1 with the highest share of household electricity consumption throughout the entire year (8.3 kWh/m²a). Electricity consumption of the steam humidifier increases the annual electricity consumption of the HVAC-system in OB1 by approximately 64%.

The range of the TQB-scores result in 800 to 900 points for OB1 and OB3 and 700 to 800 for OB2. The sub-scores for the criteria groups “location and facilities” and “economy and technical quality” are close to the maximum points in all three buildings, the differences can be found in the criteria groups “energy and supply” (described above), “health and comfort” and “resource efficiency”. The OI3-indicator is lowest (best) for OB1 with a high share of wood as construction material, whereas the massive concrete building shells of OB2 and OB3 have high OI3-indicators. The disposal indicator EI largely depends on the choice of insolation material, synthetic materials as XPS and EPS have higher (worse) results than mineral materials.

3.2. Other buildings

Results for the other buildings are commented in the following to a lesser extent than the office buildings.

A very special use category is the laboratory building. The ambient temperature-adjusted heating energy consumption is 163 kWh/m²a, cooling energy consumption is 102 kWh/m²a, final energy consumption is 370 kWh/m²a. These values result from special laboratory requirements related to room conditioning, room temperature and relative humidity must be kept in defined and very narrow ranges. Laboratory operation also requires high air exchange rates for safety reasons, resulting in additional energy consumption for the conditioning of the supply air. Steam humidification has the highest share of final energy consumption of the HVAC system (yearly average 45%, in the months of October to April up to 58%), followed by ventilation (40%). The sophisticated operation of the ventilation system with steam humidification, cooling and pre-heating and post-heating registers can therefore not be compared with other buildings and use categories. This building is nevertheless an interesting example of a building and of the high “energy investment” required to keep the room parameters within predefined and very narrow ranges throughout the year under changing ambient conditions.

The nursing home has the simplest HVAC concept in the project. The heating energy is supplied from September to May by district heating, in the remaining months by an electric boiler. The ambient temperature-adjusted heating energy consumption is 47 kWh/m²a. Compared to empirical values in the literature [5] this value is more than 50% lower calculated per care place. The relatively high average room temperatures during summer and the high proportion of overheating hours can be expected in a building without active cooling system. The supply air of the ventilation system is pre-cooled by underground collectors, which results in room temperatures of about 2-3°C lower than ambient temperatures above 30 ° C in summer.

The supermarket is another special use category. This building is known as second passive house supermarket in Mid-Europe. The heating energy consumption is 32.7 kWh/m²a. This value is higher than the maximum heating demand of 15 kWh/m²a for passive houses according to the Passive House Planning Package (PHPP-certification). However, the maximum heating demand in the PHPP refers to the energy balance of the building shell including ventilation, not including the extraction of heat by the refrigerated units. The internal heat sources are negative in this supermarket, which means that the heat extraction is higher than the internal heat sources (resulting in a so-called "cold market"). Therefore, heat needs constantly to be supplied to the building, otherwise the market would cool down. The key finding of this supermarket is that, unlike conventional supermarkets, it can be heated only with the waste heat of the refrigeration system and the compression cooling machine without using a technical heating system.

The hotel is the only renovated building presented in this paper. During renovation, the oil burner was extended by a geothermal heat pump. The monitoring result showed a surprisingly high share of 67% heat supplied by the oil burner for heating energy and warm water. It is interesting to discuss the reason as it represents a basic problem often found in heating systems that combine heat pumps with a second heating system: the heat pump feeds an energy store, which supplies the heating circuits as well as the hot water boiler. Thus, the energy storage must be maintained at the temperature level of the hot water boiler of 70 °C. In consequence the heat pump operates with a very high temperature difference between 2-3 °C temperature of the geothermal source in the primary circuit and 54- 59 °C in the secondary circuit. This results in a low efficiency of the heat pump (seasonal performance ratio 3.1). In order to keep the temperature of the energy storage at the required level for the hot water of 70 °C, the oil burner feeds the energy storage at certain times. During the time the oil burner operates, the heat pump is switched off. This is problem number two: switching on and off the heat pump leads to a lower efficiency of the heat pump, and the potential heat energy that could be generated is only half exploited, thus increases the oil consumption. The conclusion is that the heating and hot water circuits should be separated, in order to keep the temperature requirement of the heating energy storage low and to operate the heat pump with a lower temperature difference efficiently and constantly.

The cultural and event center is an interesting building since the heating energy is supplied by the solar collectors on the roof of the building throughout the year, besides one or two cold months in winter when heat is additionally supplied by the neighboring biomass heating plant of a hotel. Solar energy not consumed by the building is supplied to the neighboring hotel, and electricity from the PV plant also installed on the roof of the building is fed into the grid. Cooling energy is supplied by free cooling with water from a rainwater pool. The annual balance of energy generated by the building and final energy supplied to the HVAC system shows a surplus of 42% which is supplied to the neighboring hotel and the electrical grid.

The last building, a student dormitory, consists of 10 wood containers arranged in two floors around an atrium covered by a roof. Each box has 4 living units. Heating, cooling energy and ventilation is supplied by a combi heat pump. Heating energy demand is 30.1 which is higher than the maximum heating demand of 15 kWh/m²a for passive houses according to the Passive House Planning Package (PHPP-certification). Since the room temperature, especially in the atrium, has been relatively high with more than 23°C in winter time, there is a potential to optimize the parametrization of the HVAC system and the heating energy consumption could be reduced by about 50%.

4. Conclusions and recommendations

The following recommendations focus on project results related to the operation and parametrization of HVAC systems as well as on measurement errors of energy meters. These recommendations are relevant for building operators and owners as well as for planners and maintenance companies.

4.1. Heat pumps - temperature level and operation in an integrated HVAC system

Frequently heat pumps feed into a heat storage in conjunction with other heat generators (gas heating, solar thermal systems, district heating, etc.) to supply both heating energy and hot water, as observed in the monitored hotel and in office building 2. Due to the temperature requirement of the hot water up to 70 to 80 °C, a high temperature level is maintained, although low-temperature heating systems (underfloor heating, component activation, etc.) are frequently installed in energy efficient buildings. As a result, the efficiency of heat pumps decrease, thus losing their advantages as heat generators for low temperature heating. In integrated HVAC systems where other heat generators (for example district heating) operate to cover peak loads or extreme days parallel to the heat pump, heat pumps are often completely switched off. Thus, the heat pump does not reach the possible operation time, and the full potential of energy generated by the heat pump is not used. The recommendation is thus to disconnect high and low temperature storage tanks and maximize heat pump operating time.

4.2. Ventilation -air exchange and humidification

Excessive air exchange provides fresh air, but has the disadvantage that indoor air dries out without humidification, down to 15% relative humidity (45% would be ideal). The installation of humidifiers, especially of commonly used steam humidifiers, however, results in a very high power consumption, in the two investigated buildings in this project (in office building 1 and in the laboratory building) with the highest shares of final energy consumption. Fans for the supply and exhaust air are often operated with only one or two fixed volume settings and cannot be optimally regulated. The recommendation is to control the air volume based on CO2, adapted to the number of persons. Priority should be given to spray humidification instead of steam humidification, and retrofit frequency converters for adapted fan speed.

4.3. Pumping capacities

Frequently pumps in heating circuits are operated at constant power without taking into account the actual heat demand, as observed in office building 3. Also pumps for well water extraction for heating and cooling are often operated continuously. The result is an unnecessary power consumption for pump performance. The recommendation is to install pump controllers.

4.4. Measurement errors of heat energy meters

Heating and cooling energy meters are based on flow and return flow temperature sensors as well as on pulse or ultrasonic flowmeters. The pulse transducers are designed for different heat transfer flow rates, which results in data acquisition in too large steps if the choice is not optimal. This is a challenge for accurate heating and cooling energy measurement based on quarterly hour resolution. Another challenge is the class inaccuracy of temperature measurement in the range of 10%. With small temperature differences of flow and return flow temperatures of a few degrees (e.g. groundwater, heat pump), small measurement errors of a few tenth degrees already have a major impact on the heat energy measurement results. It is therefore important to pay attention to ambient influences on the temperature sensors, especially in retrofitted ultrasonic (clamp-on) heat meters which are externally applied to the heat pipe. For meters that can measure both heating and cooling energy, the differentiation between heating and cooling energy in the energy meter calculator is based on a minimum temperature difference of about 5 ° C (manufacturer-specific). However, with the same temperature levels in both heating and cooling energy flow (e.g. groundwater, heat pump), the heating and cooling energy needs to be calculated manually from the flow rate, flow and return flow temperature measurements. The recommendations are: careful choice of measuring instruments, installation of sensors according to standards, avoidance of external influences by insulation, plausibility check of measured data for heating and cooling energy quantity by manual recalculation based on temperatures and flow rates in the lowest possible temporal resolution, and if necessary calculation of correction factors for the temperature measurement data in the context with other measured values.

4.5. Energy monitoring

The HVAC systems are becoming increasingly complex. Often the systems are parameterized and operated based only on general knowledge regardless of the use of the building or the interaction of the technical subsystems. The result is often unnecessary over-conditioning and energy consumption, late detection of errors, as observed in most of the buildings in this project. The recommendation is to use web-based monitoring systems with automated energy reports.

Abstract. A lot of research is currently focused on studying user behavior indirectly by analyzing sensor data. However, only little attention has been given to the systematic acquisition of immediate user feedback to study user behavior in buildings. In this paper, we present a novel user feedback system which allows building users to provide feedback on the perceived sense of personal comfort in a room. To this end, a dedicated easy-to-use mobile app has been developed; it is complemented by a supporting infrastructure, including a web page for an at-a-glance overview. The obtained user feedback is compared with sensor data to assess whether building services (e.g., heating, ventilation and air-conditioning systems) are operated in accordance with user requirements. This serves as a basis to develop algorithms capable of optimizing building operation by providing recommendations to facility management staff or by automatic adjustment of operating points of building services. In this paper, we present the basic concept of the novel feedback system for building users and first results from an initial test phase. The results show that building users utilize the developed app to provide both, positive and negative feedback on room conditions. They also show that it is possible to identify rooms with non-ideal operating conditions and that reasonable measures to improve building operation can be derived from the gathered information. The results highlight the potential of the proposed system.

1. Introduction

Energy efficiency plays an important role in the building sector. Aspects such as user behavior [1] or optimal operation of heating, ventilation and air-conditioning (HVAC) systems [2] have a significant impact on the energy consumption of buildings. Moreover, achieving a high level of user satisfaction is an important goal of building operation. Although standardized comfort models (e.g., Fanger [3]) provide a basic framework for the operation of HVAC systems, meeting the specific needs of building users is often a tedious and time-consuming process. In many cases, user dissatisfaction goes hand in hand with inefficient operation of building services, for example, if HVAC system set points or control strategies are wrong. In such cases, it is beneficial to determine optimum system settings in order to achieve both, a high degree of user satisfaction and energy-efficient operation. While many research activities focus on the analysis of sensor data to optimize building operation, so far only limited attention has been given to the immediate capture of user perceptions by means of individual user feedback and the use of such feedback for optimizing building operation. Field studies of mood-tracking applications have shown that techniques for reporting mood feedback are well accepted and can improve performance if the application is well integrated into the work processes [4]. For this reason, the research project FEELings (User Feedback for Energy Efficiency in Buildings) aims to develop an integrated user feedback system which allows building users to report their mood and personal perception of room conditions via a mobile app. In this paper, we will introduce the basic concept of the novel user feedback system and the design of the developed user feedback app. We also present initial results obtained from a first test period (roll-out phase), which show that the system provides the necessary functionalities to capture user feedback and to deliver relevant information to improve building operation.

2. Description of the integrated user feedback system

2.1. Overall system design

Figure 1 shows the overall concept and structure of the investigated user feedback system. The main system components are a mobile app representing the interface to building users and a database for storing the feedback along with measurement data.

Users are able to give feedback on room conditions via the app by specifying their mood and comfort level. Each feedback is tied to a specific location or room in the building. Users can set a default location such as their own office. If users want to give feedback on other rooms or buildings, they can enter a different location manually or semi-automatically via a QR code. In the future, localization may be done automatically by means of indoor positioning.

The user information is stored in a database together with measurement data (temperature, humidity, CO_2 concentration, light intensity etc.) and building service system data (HVAC operation parameters) of the corresponding room. Data analysis methods are subsequently used to identify room and operating conditions which are perceived as pleasant. In a first step, favorable conditions are reported to facility management staff who can manually adjust settings of building services systems for the rooms. In an advanced stage, the adjustment should be done automatically. This would lead to building services systems adjusting themselves according to the user feedback, meaning that system operation matches the user needs.

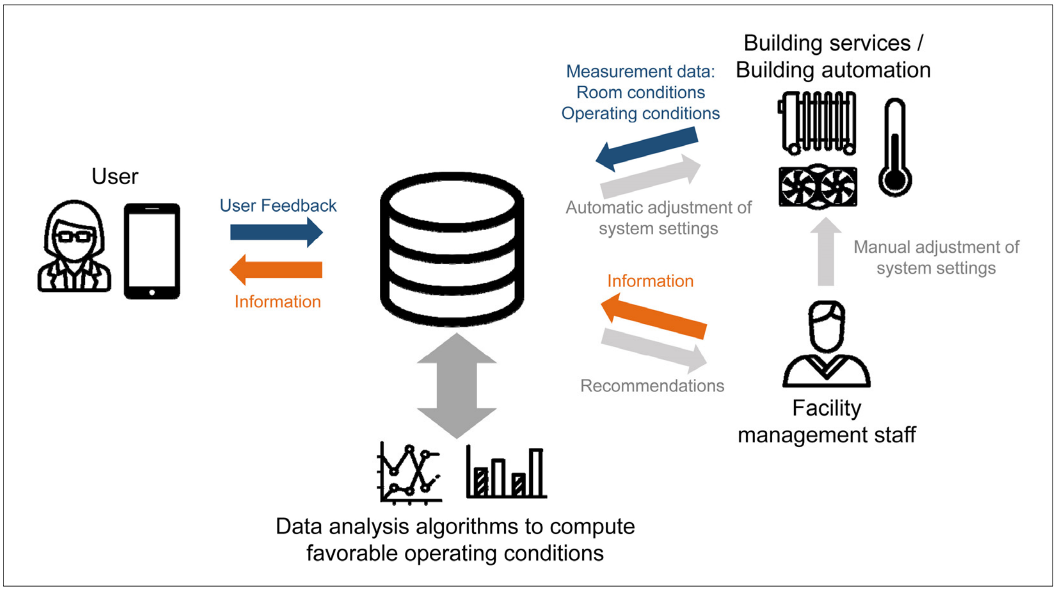

Figure 1. Concept of the user feedback system connecting building users, building services and facility management staff by means of data analysis.

Besides mood and comfort reporting, the app also provides additional functionalities in order to motivate people to use it. Users can report issues such as damages or failures of technical equipment to facility management staff (e.g., power or water failure, broken heating or air-conditioning etc.). In addition, the app can be used by facility managers to communicate with the building users, for example, to announce maintenance works. Finally, users can access statistical information based on the obtained feedback (e.g., frequency of feedback, building rating based on the feedback etc.). This information is very important to keep people interested in the app and consequently keep them as active users.

So far, the mobile app, a web portal and the database for storing user feedback and measurement data have been implemented and evaluated in an initial test phase. The development of data analysis algorithms to automatically detect preferable operating states has not yet started and is subject of the second phase of the FEELings project.

2.2. Design of the user feedback app

The developed user feedback app was implemented using the Ionic HTML5-based cross-platform framework [5]. Ionic was selected to cover Android, iOS and the desktop browser with one code base, drastically reducing development effort of the app.

After installing the app on a smartphone (or after opening the app in a desktop browser), users register with their e-mail address and select a default location by choosing the building and the room from a pull-down list or by scanning a QR code at the room entrance. Once registered, users can submit mood and comfort ratings and report issues.

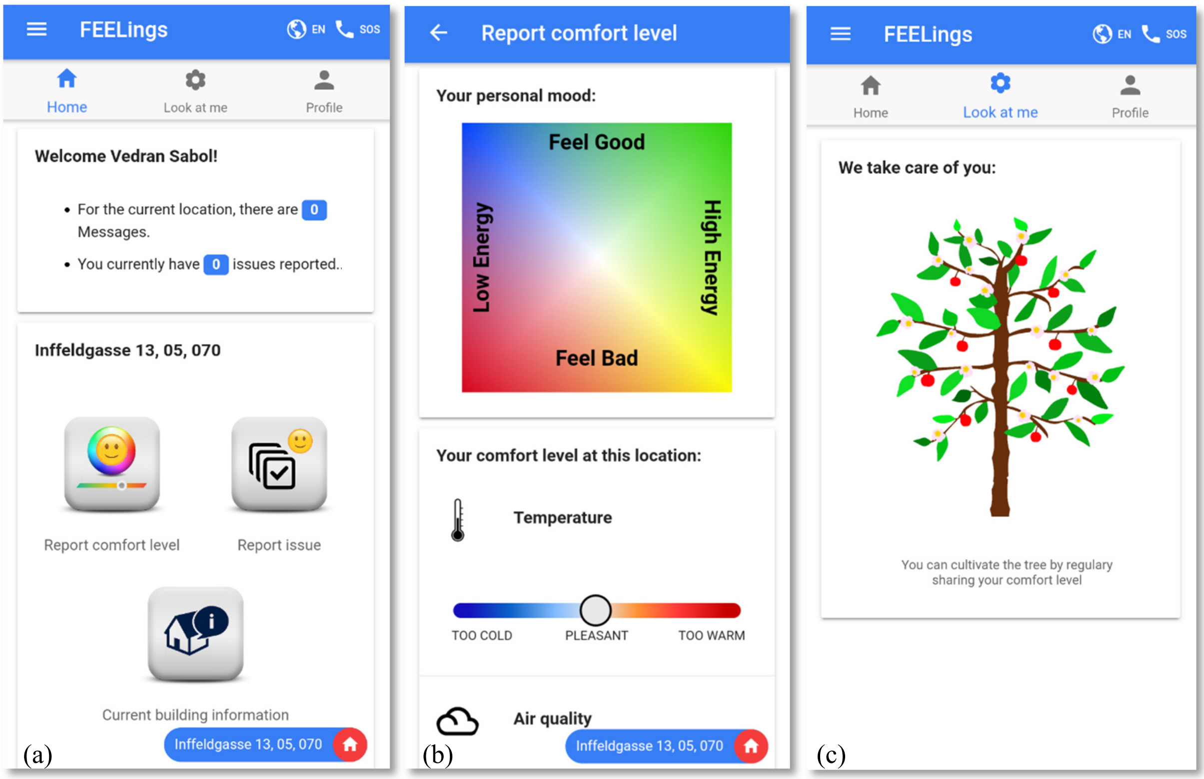

Figure 2. Design of the app: (a) home screen for navigating the app; (b) mood map and sliders for reporting user's comfort level; (c) a motivational widget which responds to the user's activities of submitting feedback.

Figure 2a shows the home screen displaying the user's name, the location, the number of reported issues and the number of messages from facility management related to the user's building. From here, users can select one of the three major functionality blocks of the app: (1) submit the current mood and comfort level; (2) report an issue specific to the room, building or environment; (3) obtain information on reported issues concerning the user's building.

Figure 2b illustrates the screen for submitting the personal mood using a mood map. The mood map is a rectangular area where the y-axis corresponds to how the user currently feels (*bottom – feel bad, top – feel good*), while the x-axis represents the user's energy level (*left – low energy, right – high energy*). By simply touching (or clicking) a specific position in the mood map, users can express their mood along these two dimensions. Furthermore, the comfort level can be specified more precisely using sliders representing temperature (*too cold – pleasant – too warm*), air quality (*fresh – ok – bad*), noise level (*quiet – lively – noisy*), light intensity (*too dark – pleasant – too bright*) and the type of activity (*sitting, standing or moving*). Optionally, users can submit a short message of up to 300 characters.

Figure 2c shows a motivational widget in the form of a tree: if a user submits feedback frequently, the tree will grow green; otherwise the tree starts losing leaves until the branches remain naked. We believe that using a natural metaphor, such as a growing tree, could motivate users to nourish the tree by reporting their mood and comfort level more frequently. Moreover, users may opt to receive bi-weekly or daily reminders to submit feedback.

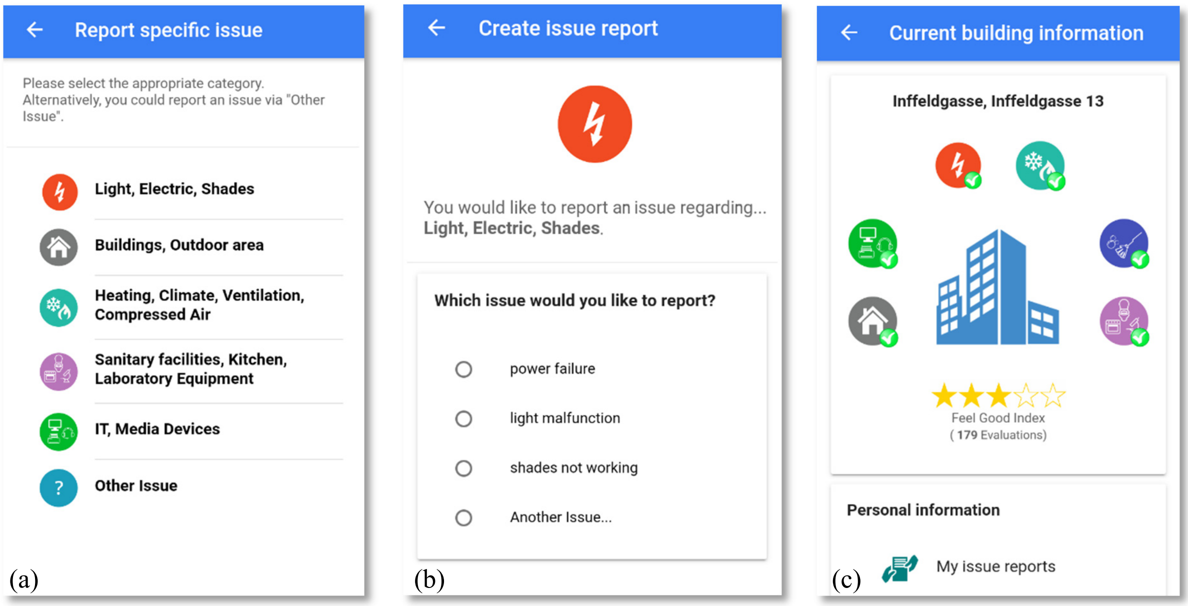

Figure 3. Mechanism for reporting issues: (a) selection of issue category; (b) more detailed specification of the problem; (c) overview of the state of a building in six categories.

Figure 3 shows the possibilities to report and monitor issues related to the room, the building or the outside environment. After selecting an issue category (figure 3a), users can choose from a list of predefined options to specify the issue in more detail (figure 3b). If no option describes the issue well enough, users can select the option "Another issue…" where it is possible to provide a textual description and to upload a photo of the problem. For later reference, users have access to all issues they reported. A reported issue is immediately sent to the maintenance service per e-mail, including a link to a web page containing all information submitted for that particular issue. The maintenance team can take action or, if necessary, request further information from the user.

Finally, figure 3c shows a status overview of the user's building for each of the six issue categories and a star rating calculated based on the submitted mood and comfort ratings.

3. Initial test results

3.1. Description of the first use case

The novel user feedback system is evaluated over a period of one year in four different use cases. A use case represents a monitored building in which users are asked to use the app. The use of the app, and therefore participation in the project, is voluntary. A building at the campus of Graz University of

Technology was selected as first use case. The seven-story building was put in operation in 2012 and accommodates offices, laboratories and seminar rooms. About 250 people currently work in this building. The building is equipped with a floor heating system operating in heating mode in winter and in cooling mode in summer. The temperature is controlled via four zones on each floor (i.e., no single room control). While a central ventilation system is available in all laboratories and seminar rooms, the ventilation of office rooms takes place manually by means of window ventilation.

The roll-out of the user feedback system for this first use case took place in December 2018 with an information event for the building users. The first two and a half months of operation are used as trial phase in order to test the basic functionality of the system, to get user feedback to improve the app and to eliminate bugs. After successful completion of this initial test phase, the system will be rolled out to the other use cases. The following results were obtained from this initial test phase which lasted from December 10, 2018 until February 28, 2019. A total of 55 users, i.e., about 20% of all building users, participated in this initial test phase.

3.2. Frequency of comfort ratings

Figure 4 shows the accumulated number of comfort ratings over time; sections with a high growth indicate an active use of the app, while constant sections correspond with no use (e.g., Christmas break with no app usage at all). Sharp increases correspond with information events (e.g., during roll-out) and e-mail reminders (e.g., on January 24, 2019) or with times with poor room comfort.

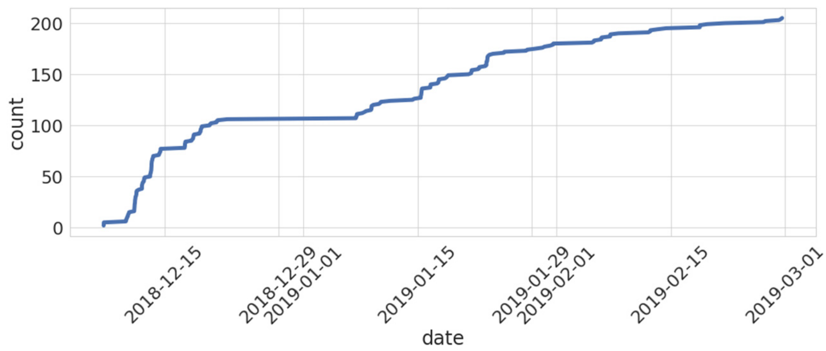

Figure 4. Accumulated number of comfort ratings over time.

The total of 205 app ratings can be broken down into specific feedback categories as shown in table 1. Part of the feedback was sent with default values preset by the app. There are two possible explanations for this. First, the default value matches the user's perception, or, second, the user did not want to provide feedback in a specific category and simply kept the default value. The number of default values varies significantly between the different categories. Table 1 shows that the mood map most often has a value different to the default setting, followed by air quality, temperature, noise, light and the work profile.

Table 1. Number of non-default feedback values per input category. Percentages relate to the total of 205 comfort ratings.

	Mood	Air Quality	Temperature	Noise	Light	Work Profile
Count	167	148	111	106	57	39
Percentage	81%	72%	54%	52%	28%	19%

3.3. Distribution of mood ratings

The feedback from the mood map (figure 2b) provides a first indication about the well-being of building users. Figure 5 shows the result (i.e., non-default feedback values) obtained for the selected use case building during the initial test period. The two-dimensional mood map was divided into nine areas of equal size in order to categorize and compare the user ratings. The overall mood feedback for the use case building is positive. A total of 114 mood ratings have at least a rating of *FEEL OK* and *ENERGY OK,* which corresponds to 68% of the overall number of non-default ratings. Moreover, 61 ratings belong to the *FEEL GOOD* and *HIGH ENERGY* group (upper right corner). On the other hand, 15 reported mood ratings fall into the *FEEL BAD* and *LOW ENERGY* category (lower left corner). A more detailed look at the data shows that the poor mood ratings come from eight specific rooms. An obvious conclusion from this result is that people generally feel comfortable in the building except certain rooms. The user feedback from these rooms was thus analyzed in more detail. First results for one particular room are presented in the next section.

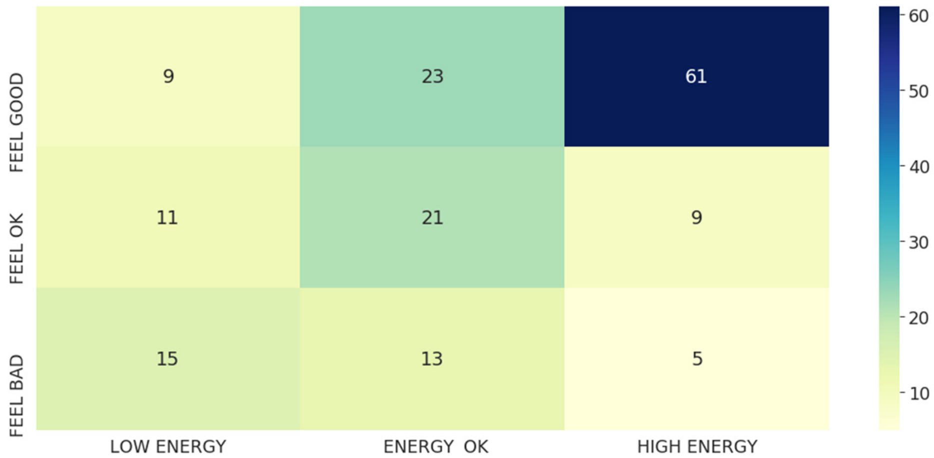

Figure 5. Heatmap encoding the number of ratings for nine mood groups of equal size.

3.4. User feedback on room temperature for an office room

Figure 6 shows the measured room temperature and the reported room temperature feedback over the initial test period for an office room with 14 occupants. The mood map feedback for this room was poor (FEEL BAD and ENERGY LOW) in comparison with other rooms. The room is equipped with two sensors (brand Tinkerforge, type Temperature Bricklet v1.1) positioned in the longitudinal axis of the room at one-third points at a height of approximately 1.4 m. The upper part of figure 6 shows the temperature profile measured by one of the sensors. Temperature values are recorded every five minutes. User feedback is illustrated in the lower part of figure 6. Each point corresponds with a reported temperature feedback using the temperature slider of the app (see figure 2b). The points' vertical positions in figure 6 coincide with the slider positions, covering the range *too cold – pleasant – too warm*. Five of the 14 room occupants participated in the test and provided feedback. One user only submitted one rating; the other users gave multiple ratings over the test period.

The average room temperature is around 26 °C as apparent from the temperature profile. This is a comparatively high value in winter months. The profile has downward spikes showing significant temperature decreases for short times. These spikes are caused by manual room ventilation. People who work in the office regularly open the windows when they arrive in the morning. This explains the absence of spikes during the Christmas break from December 22, 2018 until January 6, 2019 when the office was not occupied.

The amount of feedback of the four users is declining over time as figure 6 shows. While 25 room temperature ratings were received between December 10 and 22, 2018, only 15 ratings were received between January 6 and February 28, 2019. One possible reason is that people lost interest in the app, potentially because no action was taken to improve the temperature level in the room.

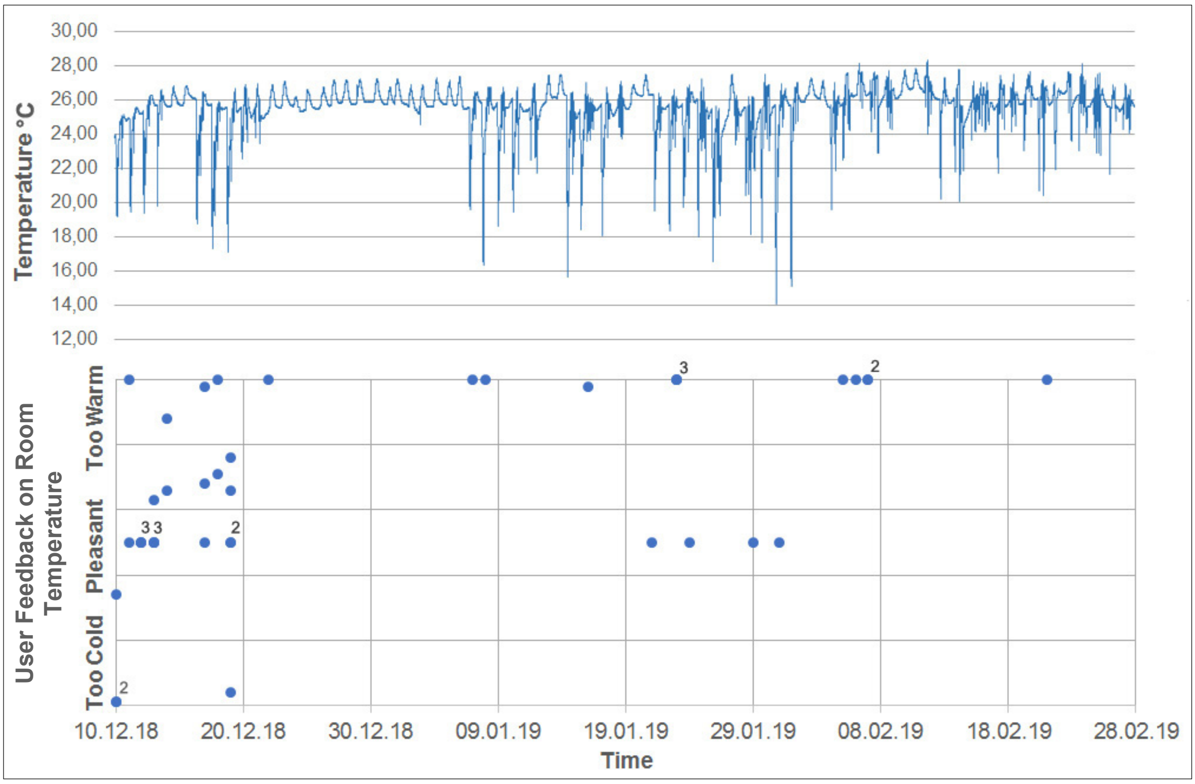

Figure 6. Measured room temperature and reported feedback on the temperature for an office room.

Figure 7 shows the temperature ratings against the measured room temperatures at which these ratings were submitted. Temperatures above 26 °C are rated as *too warm*. Ratings submitted between 25 °C and 26 °C vary between *pleasant* and *too warm.* The majority of ratings in the temperature range between 20 °C and 25 °C is *pleasant*.

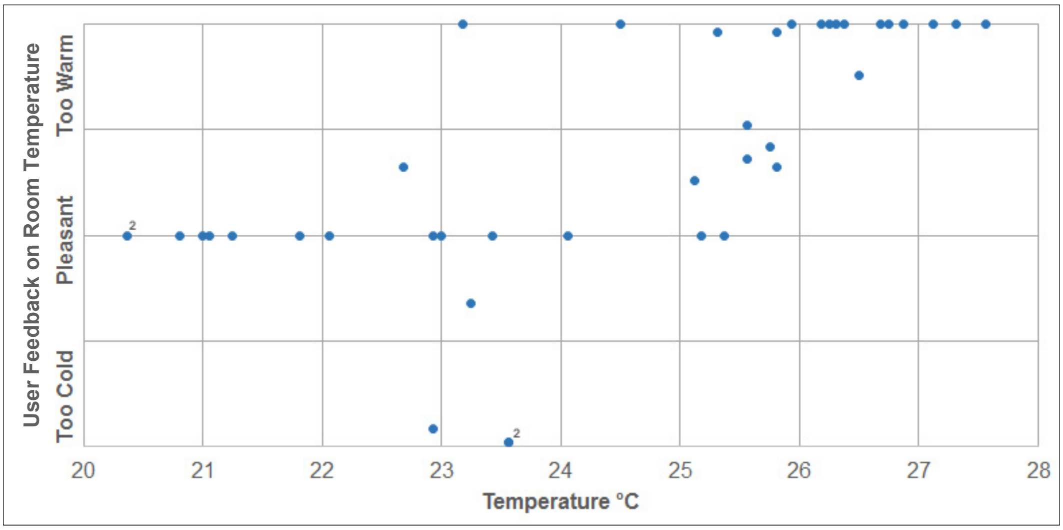

Figure 7. Feedback on the room temperature vs. measured room temperature for an office room (data from the test period between December 10, 2018 and February 28, 2019).

The results presented in figure 6 and figure 7 indicate that the average room temperature of around 26 °C is too high. A reasonable measure would hence be to adjust the set point of the heating system in order to reduce the temperature of this room. Such an adjustment would also reduce energy consumption for room heating. The practical implementation of this measure will be evaluated with the facility management staff. The impact of this step on the personal sense of users' comfort can in turn be monitored with the app. These initial results already highlight the potential for identifying non-ideal room conditions by using the proposed user feedback approach.

4. Conclusion and outlook

In this paper, we introduced a novel feedback system for building users and presented results of its initial test phase. The principal idea is to capture perceptions of building users about room conditions with an app and to compare the obtained user ratings with measurement data. The immediate user feedback makes it possible to determine whether given room conditions correspond with user requirements. The generated information is used to optimize the operation of the building with respect to both, user satisfaction and efficiency. In a first phase, the overall system was designed, set up and evaluated in an initial two-and-a-half-month test in order to prove the basic functionality. The results of this initial test have shown that users utilize the app to report both, positive and negative feedback. Based on this feedback, it was possible to identify rooms with non-ideal room conditions. In one example, users rated room temperatures during winter months as too high. This is an indication for facility managers to reduce the room temperature by adjusting the heating system. This example shows that the generated information can support decision making of facility managers. It can be concluded from the initial test results that the system provides the basic functionalities for capturing user feedback and delivering relevant information to improve building operation. In a next step, data analysis methods will be developed in order to automatically detect non-ideal room conditions. Information about such conditions will be provided to facility managers so they can optimize system settings. In an advanced stage, this optimization process should be done automatically by computing set points based on data analyses and by directly applying them to building automation systems. The proposed approach should help to increase the efficiency of building operation and the quality of building use.

Abstract. The Hook-and-Loop fastener (better known for its commercial name Velcro®) is omnipresent in many fields today. Astonishingly it is far from utilizing its full potential in the construction industry although its properties could have a variety of positive effects on the industry.

Contents and Objectives

Commonly the building installation lines (such as electricity, water or ventilation, to name just a few) are walled-in, screwed, or glued at the construction site. Would these instead be assembled and mounted using the hook-and-loop similar fasteners, the following effects with corresponding consequences could arise:

- Simplified assembly processes: They would decisively accelerate the construction phase of a building and would additionally be less prone to performance-related quality deficiencies.
- Flexible mountings and adaptability: They would enable the building to react to short-notice planning changes as well as to adapt to a new spatial program more efficiently.
- Damage-free connections - both for the base-surface and for the component to be fastened to it - would enable a pure separation of different materials and thus easy re-use. The possibility of easy re-use of specific components could prolong the component's in-use phase of the lifecycle, which would contribute to sustainable usage of resources.

The aim of this exploratory project was thus to develop concepts for the production of surfaces with hook-and-loop-compatible surfaces in buildings, which could serve as a base-surface for simplified mounting of building`s installation lines.

1. Starting point/Motivation

The Hook-and-Loop fastener (better known for its commercial name Velcro®) is omnipresent in many fields today. Its potential lies in the astonishing strength of the bond between two compatible layers, which can in addition be loosened and re-fastened tool-free for several hundred times with very little influence to its strength and durability. Astonishingly it is far from utilizing its full potential in the construction industry although its properties could have a variety of positive effects on the industry.

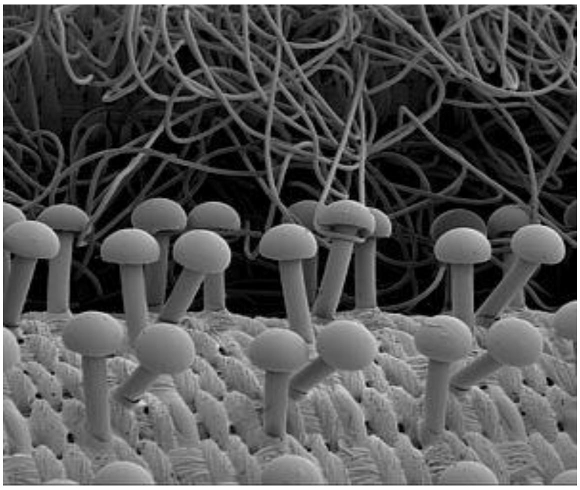

Figure 1. Hook-and-loop fastening principle [1].

The project facade4zeroWaste which includes the development, architectural design relevance, grants of patents, results of pre-certification testing's and the product publication in the time frame from 2009 till now ongoing. Aim of the research project facade4zeroWaste was the idea of a recyclable facade insulation system that can easily be dismantled after its lifetime and reused thanks to an innovative grip fixing system consisting of mushroom-shaped heads and loops - Grip fixing instead of adhesive. The project won numerous prices and awards like the EQAR - Recycling Prize 2015 or the Innovation Award for Architecture and Building 2017. The project is a contract research project tasked by Sto SE & Co. KGaA, Germany and Sto GesmbH, Austria and the Institute of Architecture Technology, Austria. The façade system was presented to the public in January 2017 as the product Sto Systain R (R = render: seamless plaster layer surface) on the building fair BAU 2017 in Munich. StoSystain has been developed by the authors of this paper.

3. Methods

The exploratory project was not limited to the consideration of a single material or a trade, but aimed at the widest possible field of view in order to uncover potentials that could lead to more extensive and more product-specific research projects in the near future.

The development of conceptual connections between different construction base-surfaces and hook-and-loop components was carried out by a thorough investigation and professional assessment of existing connections. Two innovation matrices were created. The developed concepts were then evaluated by means of evaluation sheets and team discussions. Promising concepts have been physically tested by the Laboratory of Structural Engineering at Graz University of Technology.

A – Shell Construction Material				
wood	concrete		steel	brick
H1.8 - Fasern 	B1.1 - Kleben 	B3.5 - Einlegen 	S2.2 - Klemmen 	Z3.4 - Einspannen Substance to substance bond	Substance to substance bond	Frictional connection	Interlocking connection	Frictional connection

Figure 11. Promising concepts - Connections between different construction base-surfaces and hook-and-loop components [9].

Figure 12. Experimental Setup of the peeling and pull-out tension test with Loop-Fastener. The width of the test strip is 5 cm. [10].

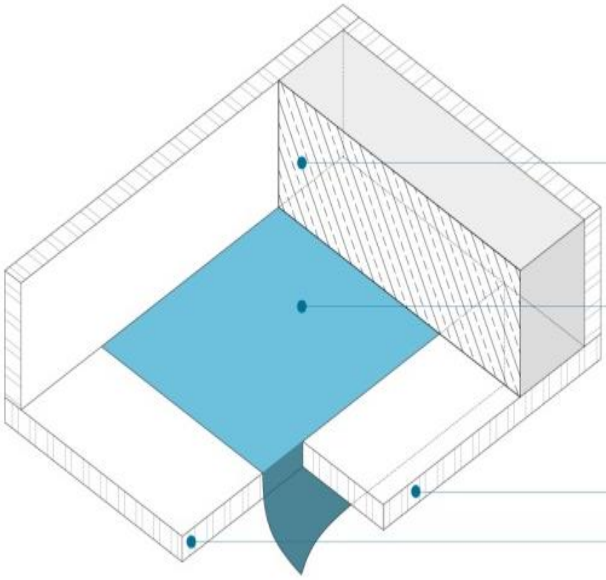

Figure 13. Testing concept, Fixations of the inserted Hook-and Loop-fastener [11].

4. Results

Based on the innovation matrix, a total of 143 concepts for connections between Velcro and building materials were developed. Due to their particularly high innovation content, five of these concepts were handed over to the Research & Technology House at the Graz University of Technology, which is currently examining their patentability.

Two key findings form the basis for further research projects. On the one hand, to achieve the envisaged flexibility, the aim is to provide a large hook-and-loop-compatible base-surface of a building (e.g. wall or slab). To achieve the hook-and-loop compatibility, the material of choice here would be either velour or fleece, because they are both webbed materials and thus more economical and available in large rolls. The specific properties of the material and its processing specifics must be taken into account for further development.

Secondly, the timing of production of hook-and-loop-compatible base-surfaces is of crucial relevance. Whether during prefabrication, during the construction phase, or during reconstruction / remodelling, each intervention requires a different approach.

During the construction phase of reinforced concrete walls or slabs for example, the hook-and-loop-compatible base-surface could be achieved in a variety of ways. Following the manufacturing logic of reinforced concrete, velour or fleece mats could be inserted into the formwork before the concrete is poured. Challenges, such as precise position fixation during the pouring process, or the protection of mats from contamination, need to be addressed. However, completely different approaches are required when the load-bearing construction is already finished or when refurbishment of an existing building is in question. In the last two cases, largely independent of building materials, we found out, that production of hook-and-loop-compatible base-surfaces is the most efficient when it is done with one of the various available gluing techniques. They are relatively easy to handle, but with disadvantages when it comes to dismantling a building. Namely, the ability to separate building materials at the end of their life-cycle (ideally the velour or fleece mat could be completely separated from other materials), is of great importance for the evaluation of the different concepts.

In addition to these considerations, building materials and construction composites were examined for their potentially inherent hook-and-loop compatibility. First and foremost, these include various fibrous materials which, due to their structure, could under certain circumstances form loops. Such concepts are convincing in terms of material homogeneity and thus complete purity. Nevertheless, tests have shown that the strength of such bonds is far from that of commercially available hook and loop fasteners, which limits, but does not preclude their potential use and development.

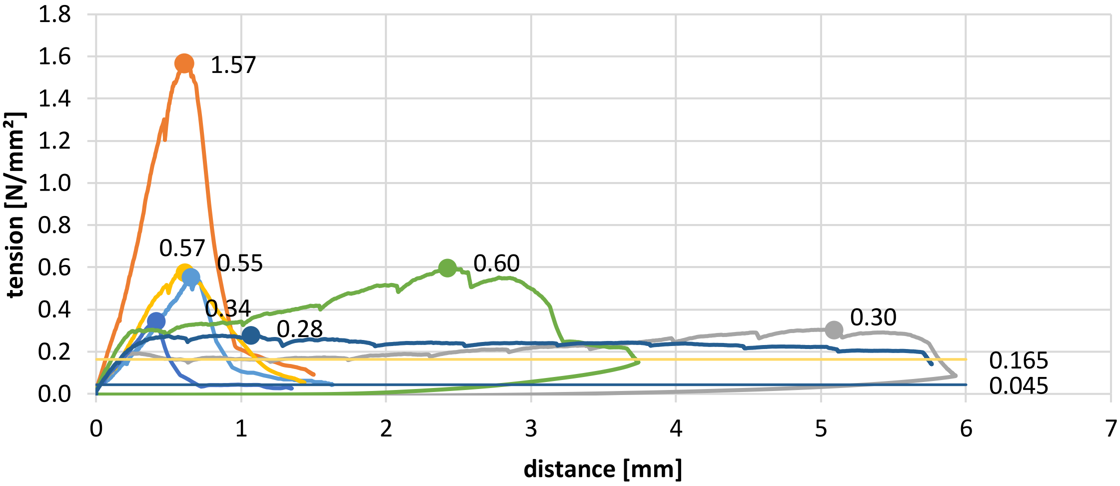

Figure 14. Complete overview of the results pull strength test „Insert Loop-fastener into concrete" [12].

5. Prospects / Suggestions for future research

The exploratory project has shown that it is possible to produce large hook-and-loop-compatible base-surface areas in buildings. This represents a solid foundation for the future achieving of the formulated objectives. Within the institute an in-depth basic knowledge has been created, which provides optimal conditions for further research and development work on the way to the damage-free assembly and disassembly of building's technical installations. The entire project team gained new knowledge in the field of building services, connection and fastening types, and the production & application of hook-and-loop products.

Great potential lies in the exploration of the following topics: Concrete and hook-and-loop surfaces, hook-and-loop-compatible fiber insulation, and alternative connection systems for conventional hook-and-loop-fasteners. The further development either in the form of a state-funded project or together with corresponding and well-known partner companies will therefore be the focus of the future research work of the Institute of Architecture Technology.

Image-obfuscation as a means for privacy-conscious visual data acquisition from building systems

Subramaniam S[1], **Hoffmann S**[1]

[1] Department of Civil Engineering, Technische Universität Kaiserslautern, Germany

sarith@rhrk.uni-kl.de

Abstract. In the last two decades, numerous studies have demonstrated the viability of using High Dynamic Range Imaging (HDRI) to quantify lighting conditions in the built environment. Several human factor studies have demonstrated correlation between visual comfort perceived by occupants and glare metrics calculated by analysing HDR images. However, the use of HDRI in real-world applications has been severely limited owing to privacy concerns. This research investigates the feasibility of employing obfuscated (i.e. deliberately distorted) HDR images for analysing glare. The authors present a pilot study where visual conditions inside an office-space were simulated and captured as HDR images using a validated, physically-based renderer. The images were then obfuscated to various degrees by application of blur filters. Glare metrics calculated for the obfuscated images, when compared with the metrics generated for the original HDR images, were found to be within 2%-12% relative error. The proof-of-concept demonstrated through this study provides the framework for field-testing of an HDR-based lighting control system in a real office space.

1. Introduction

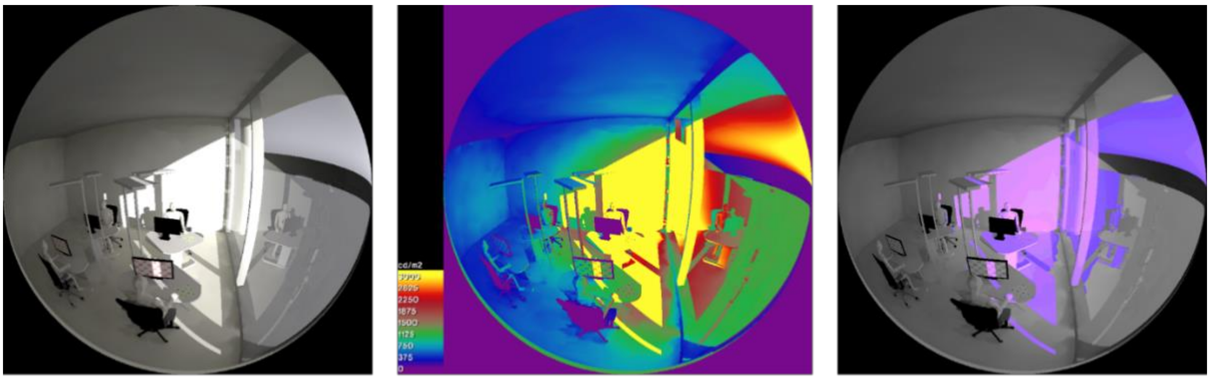
The availability of daylight in commercial workspaces has been associated with improvement in occupant well-being and productivity. In surveys, occupants have indicated a preference for locations with a view of the outdoors than in closed spaces with no external views[1, 2].

An effective daylight control strategy is one that will ensure task-adequate brightness inside a space and minimize visual discomfort due to glare [3]. Active strategies for glare control include the use of devices such as blinds, adjustable shades, and more recently, electrochromic glazing. Owing to the temporal variations in daylight during a typical day, such devices need to be adjusted periodically to minimize glare and optimize useful daylight. While automated lighting control systems have been commercially available for many years, there exists a gap between the purported and actual performance of these systems. Studies have shown that in spaces where such automatic systems are installed, the automatic control is often overridden by the occupants. Additionally, meta-analyses have indicated a significant disparity between the projected and realized benefits of daylighting control systems [4, 5].

The shortcomings in the performance of daylight responsive lighting control systems are attributable to the way in which they estimate the lighting conditions in a space. These devices are automatically actuated by microcontrollers or building management systems whose control algorithms rely on photosensor-derived vertical and horizontal illuminance/irradiance measurements to account for lighting conditions in a space [6-8]. Illuminance, especially of a single representative location in space, while easily measurable, is not always a reliable predictor of visual comfort. The lighting metrics that have demonstrated high correlation with perception of visual discomfort typically take into account luminance of potential glare sources, their size and vertical illuminance[9]. Several field studies conducted since early 2000s have demonstrated that images acquired from commercial cameras can be reliably employed to measure luminance and illuminance data through High Dynamic Range Imaging (HDRI) [10-13]. The process of image-acquisition involves capturing multiple images at different exposure levels and then fusing them together to create a High Dynamic Range image. Unlike standard image formats like JPG or PNG, which usually store 8-bit data per pixel, HDR images store between 24 to 48 bytes per pixel, thus facilitating the storage of a wide range of brightness values encountered in natural lighting conditions [14-16].

HDR images can also be generated through physically-based rendering engines like Radiance. Radiance, a command-line ray-tracing tool developed primarily by Greg Ward at the Lawrence Berkeley National Laboratory [17]. It employs a 32bit/pixel RGBE data format capable of storing the wide range of luminance values encountered in daylit spaces. Based on the numerous validation studies conducted on the accuracy of Radiance in simulating daylighting conditions, and resulting glare, the use of Radiance for predicting glare through HDR images during design stages is widely advocated and practiced [18-21].

Currently, the most commonly used tool for glare assessment from HDR images is a command line program called Evalglare [22-24]. Among the several glare-based metrics calculated by Evalglare, Daylight Glare Probability (DGP), is the most prominent and is widely used [25-27]. Evalglare requires fisheye HDR images for analysing glare. Figure 1 shows a scenario where the luminance captured through an HDR image has been evaluated using false-colour mapping as well as Evalglare.



(a) (b) (c)

Figure 1. Image (a) shows an HDR image generated through Radiance. Image(b) shows the corresponding false colour mapping of luminance values and image (c) shows the location of potential glare sources identified by evalglare. The colours assigned to the glare source by evalglare are arbitrary.

2. Motivation and working hypothesis

Although HDRI has proven to be a reliable means of acquiring data that can be used to quantify the luminous conditions existing in space, its applications in real-world applications have been limited. The photographs captured for generating HDR images can compromise the privacy of individuals and/or reveal sensitive information about the photographed space [28-30].

The research underlying this paper investigates whether glare analysis of low-quality or deliberately distorted HDR images can produce results comparable to those obtained through high resolution HDR images. The rationale behind distorting the HDR images is to obscure the activity and identity of occupants, thus alleviating, to some extent, privacy-related concerns. An example of distortion using blur filters is shown in Figure 2. The authors hypothesize that, if an obfuscation technique is uniformly applied across the entire image, the values of DGP derived through obfuscated HDR images will be comparable to those derived through original HDR images. The subsequent sections describe the methodology and results from a simulation-based pilot study conducted for testing this hypothesis.

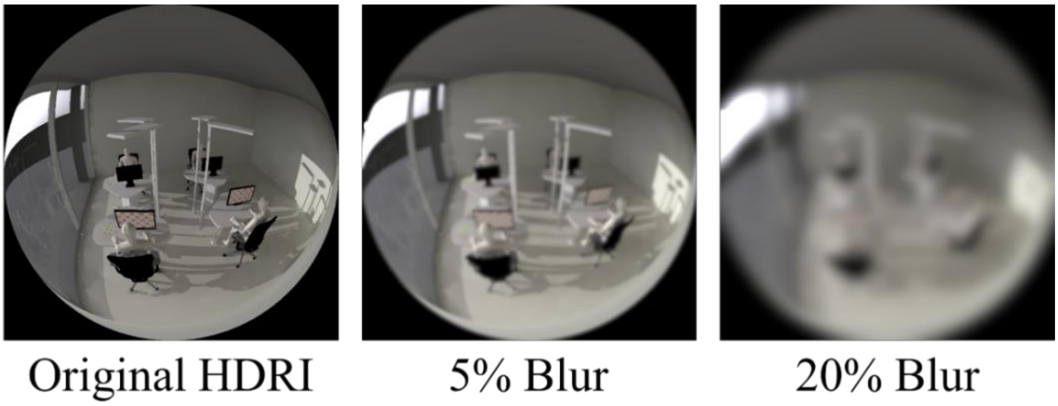


Figure 2. Obfuscation of an HDR image using Gaussian blur filters.

3. Methodology

The goals of the pilot study described in this paper are to identify an obfuscation method that allows for progressive distortion of HDR images, establish automated glare analysis workflows from images and finally ascertain the feasibility of such images as a replacement for standard HDR images.

Figure 3 shows the room considered for the simulations. This room, which is modelled after an actual office space in Germany, consists of a south-facing full-height glazing. The occupants are subject to direct insolation, and consequently visual discomfort, especially during the winter months when the solar profile angle is low. The 3D model shown in Figure 3 was created in SketchUp® software from physically measured dimensions at the site. The model was then exported to a format compatible with the Radiance rendering system using a plugin called Su2Rad [31].

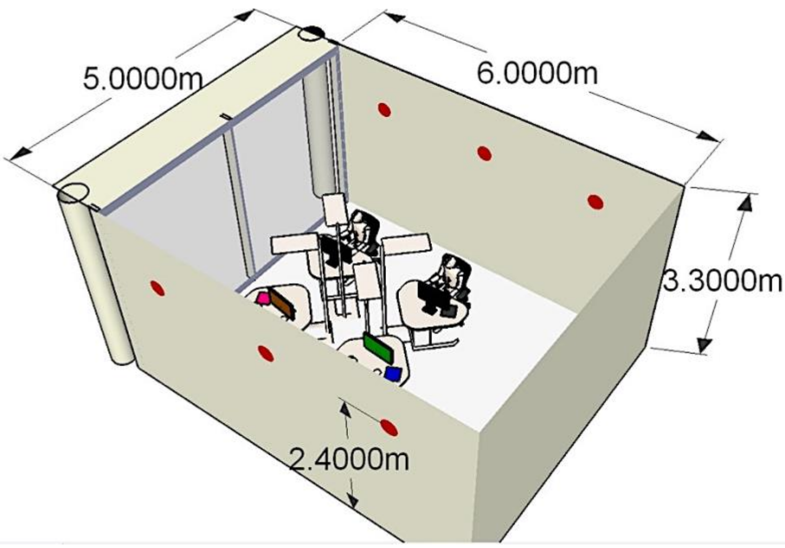

Figure 3. Overall dimensions of the space modelled for the study. The glazing faces towards south. The six virtual cameras used to generate HDR images were placed 2.4 m above the floor level and are highlighted with red circles in the image.

Figure 4 shows two typical HDR images generated with Radiance from the exported model. For the purposes of generating HDR images for glare analysis conducted in the study, six camera locations were chosen, three each on east and west wall, at a height of 2.4 meters from the floor level. The location of the cameras is highlighted in Figure 3 and Figure 5 shows HDR images generated for these camera locations at a single point-in-time. A total of 426 such images were generated for 71 sky conditions the purposes of the pilot study.

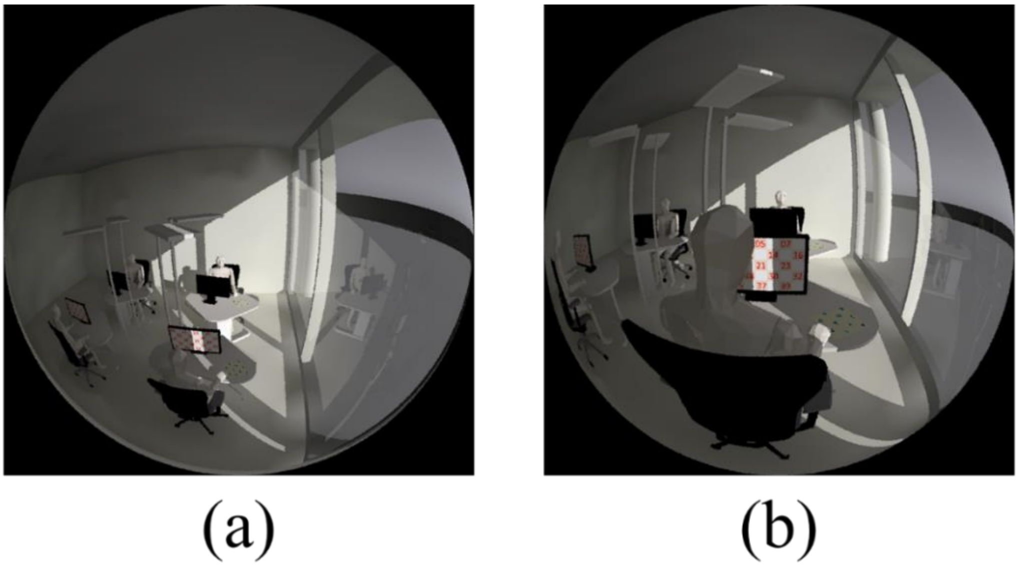

Figure 4. Fish-eye HDR images generated with Radiance for the same daylighting condition at two camera settings.

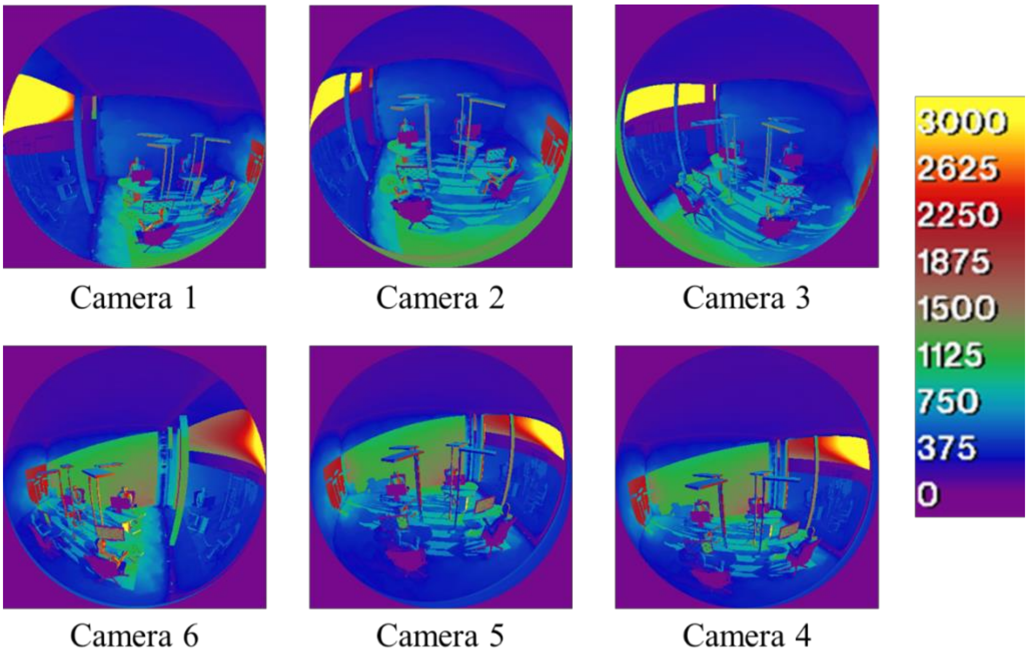

Figure 5. Falsecolour mappings of HDR images generated for the same daylighting condition at the six virtual camera positions. As is apparent from the images, the cameras are placed on either side of the room and at variable distances from the glazing. The value mapped through falsecolor is candela/m^2, the unit of luminance.

The sky conditions considered for the simulations were created using the Perez Sky Model implemented in a Radiance tool called Gendaylit [32, 33]. The location details and hourly radiation values required for the Perez Sky Model were obtained from Typical Meteorological Year (TMY) data for Berlin, Germany. The rationale for choosing the 71 conditions is explained further through Table 1.

Table 1. Timesteps considered for generating the HDR images considered in the study.

Detail	Quantity	Comment
Total timesteps considered	120	Hourly, from 9AM to 4PM (inclusive), between 1st November to 15th November
Timesteps with direct sun	71	The 49 hours that were filtered out consisted of overcast conditions.
HDR images generated	426	1 image/hour for 71 hours, captured by 6 cameras

An example of HDR images generated for different sky conditions is shown in Figure 6. The entire set of HDR images generated for the specified daylighting conditions and camera settings were then obfuscated to various levels by using procedural software filters. The authors initially tested image interpolation algorithms involving linear, bicubic and Lanczos filters. Since the interpolation algorithms usually reduce the size of the resulting image, they were found to drastically underestimate the luminance of glare sources in the HDR images. Subsequently, Gaussian blur filters were tested and were found to provide a reasonable balance between distortion and retention of useful luminance data. Figure 7 provides an example of the level of distortion achieved through progressively higher levels of blurring. As is evident from the general shape patterns and the magnitude of luminances mapped through false-colour, details relevant to the analysis of visual discomfort are retained to a certain extent even in distorted images. The next section provides a summary of the glare data obtained through the obfuscated images.

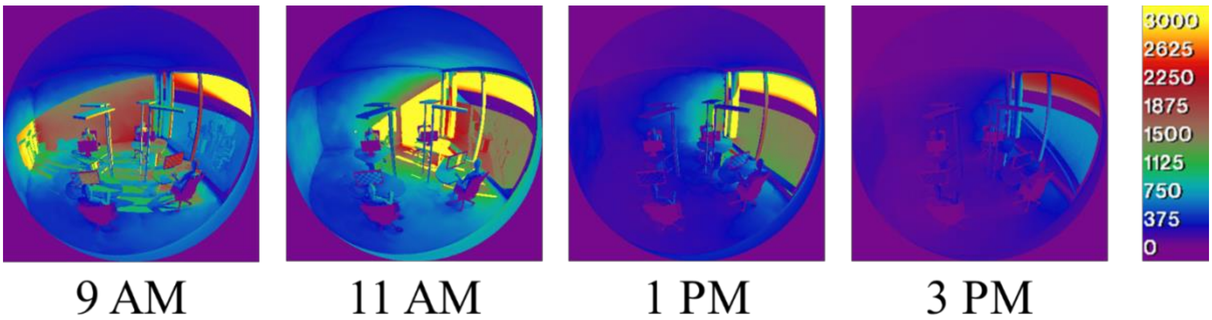

Figure 6. Falsecolour mappings of images generated for the same camera position for alternate hours on 3rd November. The value mapped through falsecolour is candela/m^2, the unit of luminance.

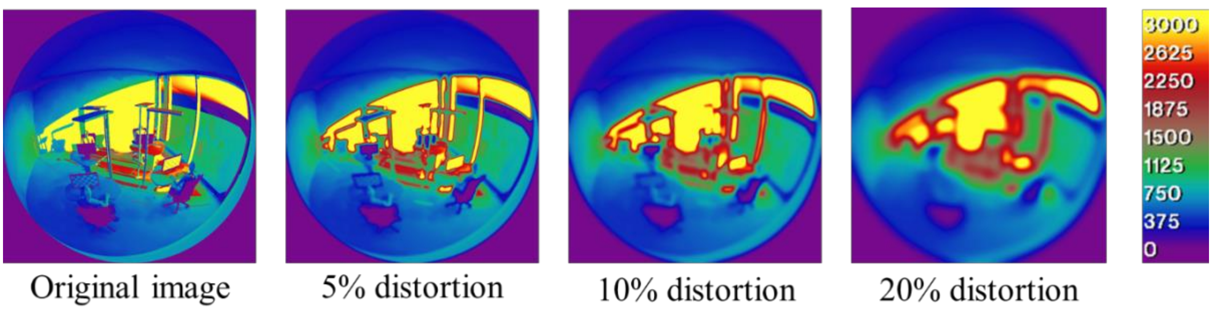

Figure 7. Progressive obfuscation of a single HDR image using a Gaussian blur filter. The value mapped through falsecolour is candela/m^2, the unit of luminance.

4. Results

Of the 426 HDR images generated for this study, 115 images contained daylight luminance and vertical illuminance levels lower than the threshold at which they could be effectively analysed. This threshold is based on the minimum vertical illuminance and minimum qualifiable DGP level assigned in Evalglare. 34 images yielded DGP values higher than 0.59, a value above which glare is characterized as intolerable. The remaining 277 images yielded DGP levels where the glare could be characterized as either imperceptible or perceptible. The obfuscated derivatives of these 277 images were also analysed with Evalglare to determine the DGP levels obtained after obfuscation.

Table 2. Categorical summary of the DGP values calculated for the 426 original HDR images generated for the study.

Scenario	Instances	Comment
DGP<0.2	115 (27%)	DGP is not defined for low lighting conditions
0.2<=DGP<=0.35	190 (45%)	Imperceptible glare
0.35<DGP<=0.59	87 (20%)	Perceptible to intolerable glare
DGP>0.59	34 (8%)	Beyond intolerable glare

Figure 8 summarizes the relative error in DGP calculation as a function of obfuscation level. Relative error for an individual image was calculated as:

Error%= Abs((DGP from Original Image – DGP from obfuscated Image)/(DGP from Original Image))

As indicated by the Figure 8, for all the distortion levels considered in this study, the mean error in the calculation of DGP was less than 5%. The box-plots in the figure also show that the error increased

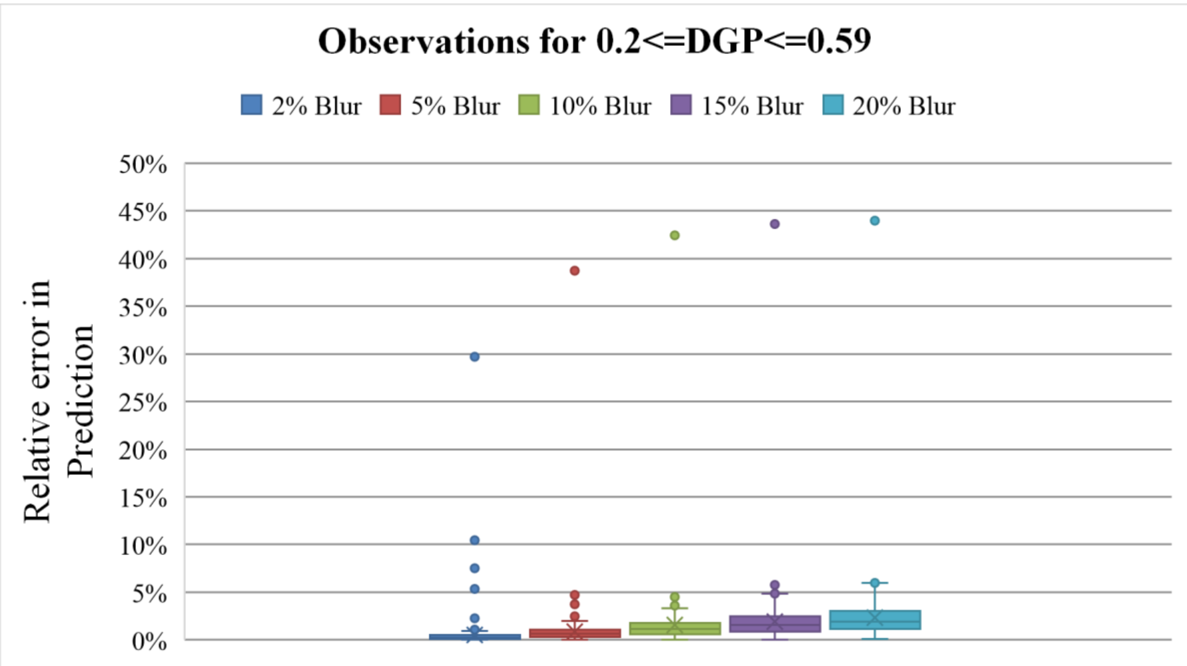

Figure 8. Box-plots of relative-error in DGP values calculated with HDR images that were obfuscated using Gaussian blur filters.

slightly and progressively as the order of distortion was increased. The one major outlier in Figure 8 relates to an instance where the blurring resulted in the erasure of several potential glare sources from the blurred images. The HDR images, both original and blurred, for this instance are shown in Figure 9. As can be noticed by the coloured patches on the original and blurred HDR images, progressive blurring resulted in a reduction of the number of identified glare sources and caused the retained glare sources to shrink in size.

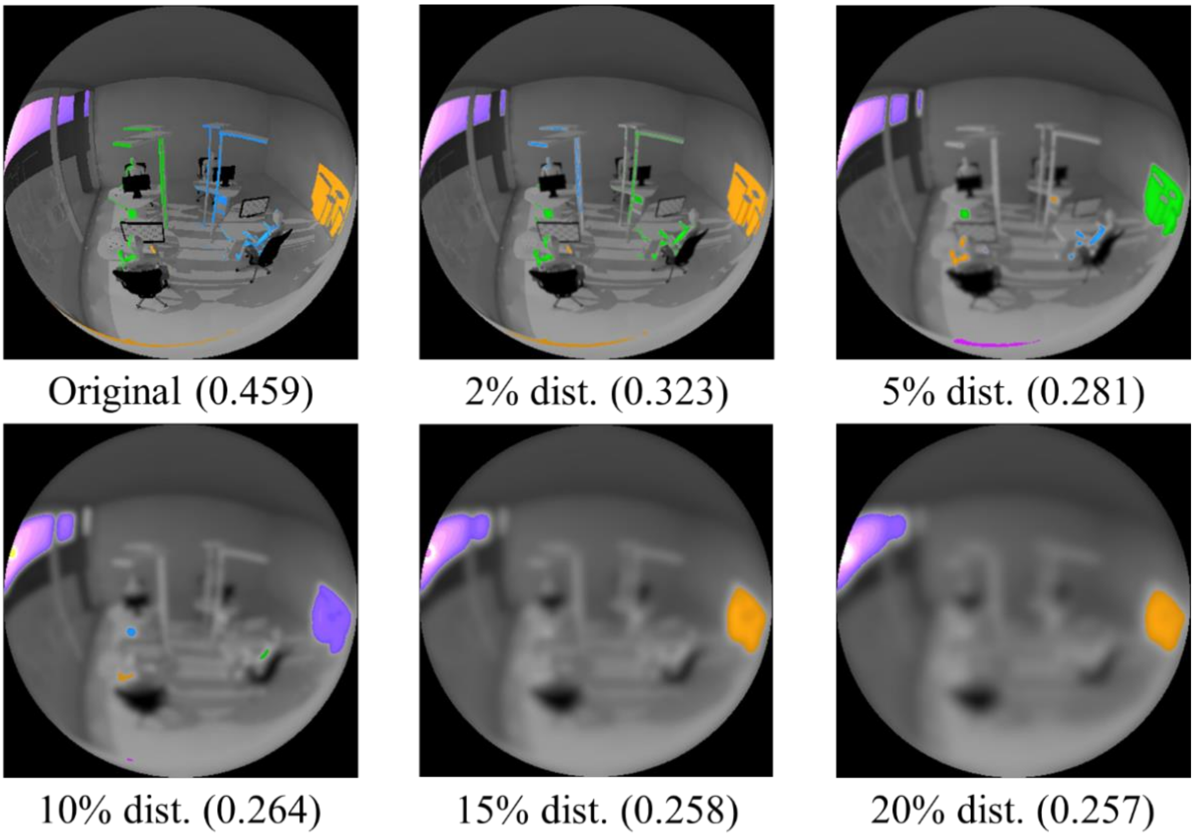

Figure 9. Glare sources identified in the outlier scenario in Figure 8. Distortion has been abbreviated to dist. The value of DGP calculated for each of the images is provided in parenthesis.

DGP values calculated within the range of 0.35 to 0.59 can be further categorized according to perceptible, disturbing or intolerable glare as shown in Table 3 [23]. A higher relative error in DGP calculation will lead to the glare being incorrectly categorized. Assuming that an automatic lighting control system will be actuated based on these glare categories, it is possible that larger values of relative errors in calculation of DGP will cause the control system to perform incorrectly. Figure 10 provides a relative comparison of the obfuscation levels as a function of the accuracy with which glare was categorized. For the 87 instances when the glare was categorized between perceptible to intolerable, images that were distorted using blur filters of up to 15%, led to incorrect categorization in 11 or less instances.

Table 3. Glare categorization within DGP range of 0.35 to 0.59.

Range	Category
0.2<=DGP<=0.35	Imperceptible
0.35 <=DGP<=0.40	Perceptible
0.40<DGP<=0.45	Disturbing
0.45<DGP<=0.59	Intolerable

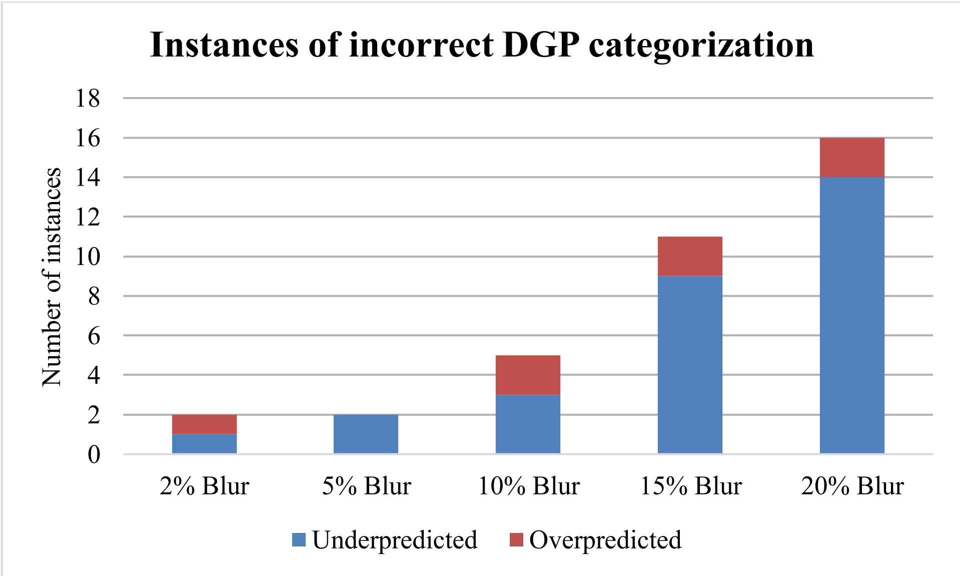

Figure 10. Number of instances, out of a total of 87, when the DGP values were incorrectly categorized.

5. Discussion and conclusion

The results summarized in the last section indicate that the error associated with the DGPs calculated through obfuscated images is usually within a relative error margin of 5%. In cases where the errors were encountered, the incorrect categorization of error was within a single category. Furthermore, the DGP values were more often underpredicted than overpredicted. For example, in Figure 10, for the 20% blur scenario, of the 16 (out of 87) instances when the glare rating was miscategorized, the glare rating was underpredicted in 14 (87.5%) instances. The underprediction of DGP values can be partially attributed to the fact that potential error sources with smaller solid angles are typically obscured during blurring.

In conclusion, the results from this pilot study indicate that obfuscated images can be employed for glare analysis, especially in cases where the results from such an analysis is intended to categorically actuate a lighting control system. As is logically expected, higher levels of obfuscation were associated with greater margins of error in DGP calculation. So, any real-world applications of obfuscated HDR images for glare analysis will require the selection of an obfuscation level that can strike a balance between privacy of occupants as well as accuracy of data acquisition.

Future initiatives planned for this research relate to a field study involving the use of miniature cameras mounted on a single-board computers for the purposes of HDRI acquisition.

The Three Sisters, klimaaktiv object of the month 12/2018

Kranzl M

Dr. Pfeiler ZT GmbH, Wielandgasse 36, 8010 Graz, Austria

M.Kranzl@zt-pfeiler.at

Abstract. In the lakeside city of Aspern in the 22nd district of Vienna, the homebuilding association for private employees has established the residential complex “The Three Sisters” on the construction site D22, a plot of land measuring 5,200m². When planning the building envelope of the three buildings which range from four to six floors, the responsible persons consciously decided to use the Wienerberger “Porotherm 50 W.i. Plan” brick. Thus, the first multi-storey residential building project has been constructed using the latest brick generation. The use of a mineral and monocoque construction method makes a significant contribution to eliminating the need for petroleum-based full heat insulation. Therefore, the building complex can throughout be categorized as a low-energy building. Further notable advantages of the applied construction method and building design include the use of an exterior wall system without additional insulation (upgraded insulation on the outside) to obtain a U-value of 0.12 W/m²K which corresponds the passive house standards. The high demands of the construction design in terms of ecological, economical and socio-cultural quality of the three building components are reflected in the ecological selection of construction materials, the persistence of the building complex and the stability of value, as well as apartment sizes, assisted living, smart-start-apartments, integrated green space concepts, roof terraces, urban gardening, etc. The TQB certification with 769 out of 1000 points has been obtained and the project has been awarded with klimaaktiv GOLD to prove the quality of the project and ensure quality assurance and management.

1. Goal to establish more sustainable buildings for the future of the urban development district lakeside city of Aspern

The substantial requirement for a sustainable building is to consider the holistic contemplation of a building (construction, operation and demolition) in the first planning-phases (ideally already included in the preliminary design/design). In the lakeside city of Aspern this is an aim resp. a prerequisite for every building to be constructed. The coordination of planning and implementation, execution of legal requirements, energy efficiency, sound insulation, ecological material-selection, user comfort, quality management of the building envelope by the means of BlowerDoor-tests, quality management of the room air by the means of internal space hygiene measurements can be observed throughout the project at hand. The achieved TQB-certification (with 769 out of 1000 points) and the klimaaktiv-certification with the highest possible rank “gold” and being the klimaaktiv object 2018-12 speaks for itself.

2. Implementation of sustainability-topics

In the course of the implementation of a sustainable building the responsible party purposely decided on the use of the Wienerberger “Porotherm 50 W. i. Plan” brick. It is the first multi-story residential building project to use the new generation of bricks during its construction. Due to the continuously in mineral and single layer type constructed structure in nearly zero energy building quality, an essential contribution was being made in order to relinquish from using crude oil-based heat insulation. Further benefits of the construction material brick lie in the easy separability of the material (mineral wool as cuttings in the tubular body) [1] at the end-of-life of a building and the recycling-ability of the brick fragments [2].

2.1. Heat insulation

With this exterior wall-system, a u-value of 0.12W/m2K (passive house standard) can be reached without the use of additional insulation (upgraded insulation on the exterior). The values of the energy performance certification are respectively positive:

- Heating demand: 21.31 kWh/m^2 gross floor area and year
- Primary energy demand: 48.04 kWh/m^2 gross floor area and year
- CO_2: 5.7 kgCO_2/m^2 gross floor area and year

The monolithically wall with integrated heat insulation (cuttings made of water-repellent mineral wool located in the tubular body) distinguishes itself due to optimal structural-physical and biological performance and therefore presents itself as a timely and sustainable exterior wall solution.

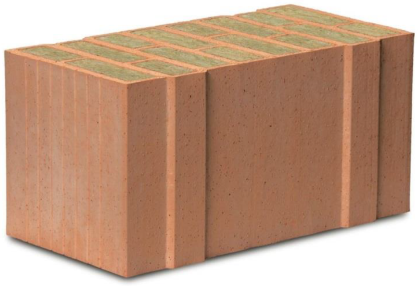

Figure 1. Wienerberger "Porotherm 50 W. i. Plan" (W. i. Wärmedämmung inklusive) [3].

a. Heating system

Building A and building B

Radiator: Individual room control with thermostatic valves, individual heat consumption calculation, radiator (60 ° C / 35 ° C)

Building C

Radiator: room thermostat zone control with time control, individual
Heat consumption calculation, radiator (60 ° C / 35 ° C)

b. Sources

Central space heating is provided by District Heating Vienna – "Fernwärme Wien" and is combined with a water tank in order to provide also hot water.

2.2. Requirements for the airborne noise insulation of the exterior components

According to the executed airborne noise measurements (for the W. i. series – 42,5, 38, etc.) at the acoustic testing facility of the TGM Vienna, a sound reduction index RW of 48dB can be reached with the Porotherm 50 W. i. Plan, bilaterally plastered. This corresponds approximately with a conventional Porotherm brick with a VWS-system, hence it accomplishes the legal minimum requirement for airborne noise insulation of exterior components until the category R'res w = 43dB. Therefore, generally the requirements for the airborne noise insulation are being met by the W. i. brick.

2.3. Requirements for the airborne noise insulation in the interior of the building (divider walls)
Indoor units resp. apartment divider walls at residential constructions are to be measured in a way that provides that between both neighbouring utilization units/apartments (conditioned by the sound transmission through the separating component and the acoustic vertical transmission of the flanking constructions) a minimum requirement for the airborne noise insulation according to legal basis resp. OIB directive 5 and ÖN B 8115-2 is being adhered to (minimum requirement for the residential divider walls -> evaluated standard sound level difference DnT.w > 55dB).

Considering the acoustic vertical transmission topic, the flank of the exterior wall brick W. i. presents a certain sonically weak spot due to the hole pattern and the meagre mass. Regarding this, a detailed design by the means of a sonically separation at the divider wall connection has been acquired by the cooperation with the company Wienerberger, to improve resp. solve this topic.

3. Result of sustainable planning and-topics

The optimized planning resp. implementation concerning power demand, selected construction material, construction, comfort and room air quality can be observed through the achieved awards:

Point statement of the main categories for KlimaAktiv GOLD:

PLANUNG UND AUSFÜHRUNG	137
ENERGIE UND VERSORGUNG	500
BAUSTOFFE UND KONSTRUKTION	150
KOMFORT UND RAUMLUFTQUALITÄT	115

Figure 2. Point statement for the KlimaAktiv-certification [4].

Point statement of the main categories for TQB:

Figure 3. Point statement for the TQB-certification [5].

4. "The Three Sisters"

Building A(NNA) / assembly house: This component with a total of 33 flats is designed as an assembly house for the group "Que[e]rbau". Que[e]rbau stands for self-chosen identity, self-chosen form of life and thinking outside the box, independent of propagated norms. In the assembly house, a five-storey central atrium assumes the function of opening up as a meeting place.

Building B(ELLA): There is something for everyone here: from the SMART start apartment with two rooms right up to five-room apartments. Two thirds of the apartments are oriented to the east and west. This component is comprised of 40 flats, and designed as a 6-storey building with recessed open-space zones and is accessible through two staircases. On the upper floors, the development is partly via an open access balcony.

Building C(LARA) / assisted living: This component is designed as a whole for assisted living with several operators and different care concepts.

On the ground floor, Diakoniewerk rented three apartments for the accommodation and care of migrants. On the 1st and 2nd floor, HABIT - Haus der Barmherzigkeit - runs a dormitory for children and adolescents with multiple disabilities. Furthermore, on the 3rd floor the association Integration Vienna operates a living community "Lebe bunt", for disabled and non-disabled young people.

An integrated green space concept connects the adjacent building plots into a coherent whole. Roof terraces, a communal sauna, a club café and an "urban gardening" field in the middle of the area complete the offer for the community.

4.1. Contributions to user satisfaction

Each of the 78 subsidized housing units has been supplemented by its own open space (terrace, balcony, loggia) and an additional storage room. In addition, all apartments have above-average room heights of about 2.63 m to 4.00 m and are therefore higher than required by the Vienna Building Code. Wherever possible, "French windows" have been installed that extend from floor to ceiling, visually increasing the space and allowing in more light and sun. The larger units are oriented and illuminated at least on two sides and therefore easy to ventilate, which provides great added value, especially in summer. Furthermore, each apartment is equipped with a controlled fresh air supply.

5. Conclusion

The requirements for the regionality of the materials (<200km linear distance to the construction site) for the primary structure resp. insulation could be met, as could be the application of low-pollution and low-emission construction products, which were implemented by the means of product management (separated approval before the installation of the materials).

Supplementary equipment like a playground, a roof terrace, a sauna, club- resp. common rooms and a community garden are available for the occupants of “the three sisters”.

The correct choice of ecological materials, validation-measurements of the airtightness (which prove the quality of the building envelope) during the construction progress resp. measurements of the room air quality (which ensure the innocuousness of the superficially installed materials) guarantee for the appropriate quality of this project.

Consequently, it can be guaranteed that “the three sisters”, due to the excellent cooperation of the architecture- and the sector planning team, the building owner; executing companies and urban development, was not only developed as an outstanding project but also put into action as such.

Reducing water footprint of building sector: concrete with seawater and marine aggregates

Arosio V[1], Arrigoni A[2], Dotelli G[1]

Abstract. Freshwater resources are currently under great pressure all over the world due to many factors, such as climate change and growing urbanization. Industrial products like concrete pauperize a significant share of available freshwater during their life cycle. Therefore, cutting down the amount of freshwater consumed by these products might be a solution to reduce the stress in regions affected by water scarcity. In this study, the potential freshwater savings linked to the adoption of innovative concrete mixtures were investigated via the Life Cycle Assessment (LCA) method. In particular, the use of marine aggregates instead of land-based ones and seawater rather than freshwater in the mixing process of concrete were examined. To improve the validity of the analysis, the applicability to the Italian context using geo-referenced data for the distance to the coastline and the availability of freshwater was explored. Results confirmed the positive effect that the use of seawater and marine aggregates might have in reducing the water footprint of the Italian construction sector, leaving freshwater available for human consumption. Mixing concrete with seawater would lead to a reduction of its water footprint up to 12%. Moreover, if land-won aggregates were replaced with marine ones, an 84% reduction of the water footprint could be achieved. In both cases, possible burden shifting (e.g. increase of greenhouse gases emissions) should be investigated.

1. Introduction

Freshwater resources are currently under great pressure all over the world due to many factors: climate change, population growth, higher standards of living, increased industrialization and widespread urbanization [1]. Water consumption grew twice as fast as population in the last century [2], and nearly half of the global population already live in areas that are potentially scarce in water at least one month per year [3]. The industrial sector accounts for approximately 19% of the total water withdrawals [4], and the construction industry is among the main users. Urbanization boosted, indeed, the demand for construction materials [5], with concrete reaching an annual production of more than 32 Gt in 2017 [6]. Besides the large demand for natural aggregates, concrete production also requires a lot of water. For instance, a standard concrete batching plant withdraws on average 100 m^3 of water each day just for the mixing process [7]. However, concrete demand for water goes well beyond this process. Water is required to process all the raw materials and to produce the energy and the fuels used along the concrete production chain [8]. However, inventory data for water demand throughout the life cycle of concrete are limited and inconsistent [9]. Miller et al. tried to estimate the global amount of water consumed to produce concrete at a global scale and concluded that, on a cradle to gate analysis, concrete production was responsible for a global water consumption of 16.6 Gm^3 in 2012, equivalent to the annual domestic use of 145 million US residents [10].

To avoid the corrosion of the steel rebars used in reinforced concrete structures, mixing water must be free of chlorides and therefore, the use of seawater is forbidden and freshwater is currently used [11]. However, the use of reinforcement elements resistant to corrosion (e.g. stainless steel, glass fibre reinforced polymers) has been investigated over the past few years, opening up the opportunity to the use of alternative types of water. For instance, results of the SEACON project showed that the properties of concrete could be preserved and even improved when seawater was used in the mixing process if reinforcing elements resistant to corrosion were used [12]. Moreover, using rebar that would extend the durability of the structure could also reduce the life cycle environmental impacts [13] and the life cycle costs of the structure [14]. Nevertheless, the actual implications of using seawater and, possibly, chloride contaminated aggregates on the Water Footprint (WF) of concrete produced in a specific geographic context were not investigated.

The goals of the study were: (1) to assess the life cycle water consumption and the WF of a generic concrete mix produced in Italy, identifying the most impacting stages of the life cycle, and (2) to assess the variation in the WF if seawater was used instead of freshwater in the mixing process and marine aggregates were included in the mix in place of land-won aggregates. To reach this goal, the WF of the different concrete mixes was evaluated with a GIS-based approach considering both the direct and indirect water consumption in the different life cycle stages of the production of concrete.

2. Materials and methods

The WF of the different concrete mixes was assessed following the ISO 14046 guidelines, which provide a metric to assess the potential impacts associated to the life cycle use of water for an activity [15]. The methodological steps, in line with the standardized life cycle assessment procedure, are presented in the following sections.

2.1. Goal and scope definition

The goal of the analysis was to assess the water footprint of a generic concrete produced in Italy and to investigate whether the use of seawater and marine aggregates could reduce it. Hence, three different mix designs were compared: 1) concrete with Land-won Aggregates (LA) mixed with Fresh-Water (FW), representing the base case scenario and referred to as "LAFW" in the analysis; 2) concrete with Land-won Aggregates mixed with Sea-Water (SW), referred to as "LASW"; and 3) concrete with Marine Aggregates (MA) mixed with Sea-Water, referred to as "MASW".

2.1.1. Declared unit. The declared unit was one cubic metre of unreinforced fresh generic concrete delivered to the construction site. Except for the type of aggregates (land-won or marine) and mixing water (freshwater or seawater), the same concrete mix was used for all the scenarios. Recipe for the mix (i.e. 200 kg of Portland cement, 1280 kg of gravel, 720 kg of sand and 170 litres of water) was taken from the Ecoinvent database [16] and represents a general unreinforced concrete. All mixes were assumed to have the same mechanical properties and service life.

2.1.2. System boundaries. The approach of the study was from cradle-to-gate, where the gate of the study was the construction site. Transportation to the construction site (i.e. stage A4 according to ISO 14046*)* was included in the analysis. The different unit processes considered for the analysis and their relative inputs of direct water are illustrated in 'figure 1'. Direct water refers to the water consumed in a specific process (e.g. water for mixing concrete). Although the component was not shown in the figure, indirect water (i.e. water consumed in preceding processes such as the one consumed in the generation of energy used to mix concrete) was also included in the assessment.

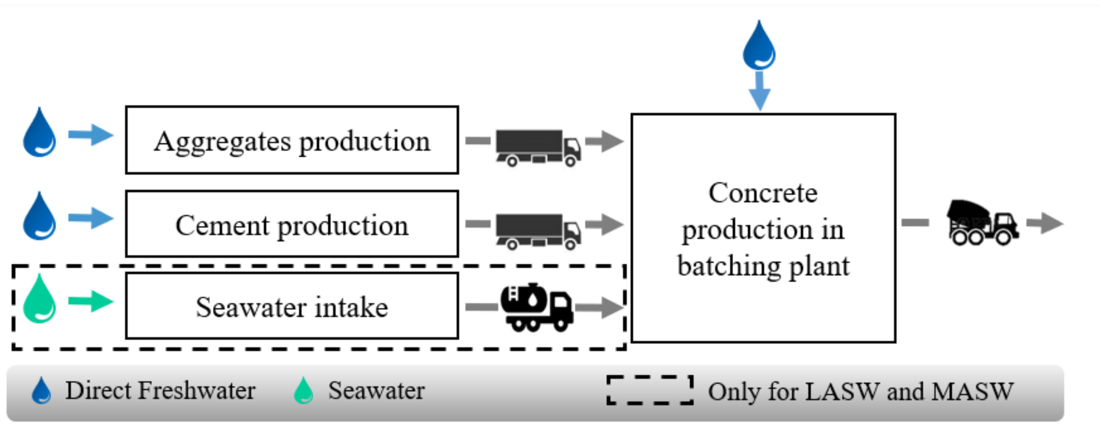

Figure 1. Unit processes considered in the study and their relative direct inputs of water.

2.1.3. Geography. Three different Italian regions (i.e. Abruzzo, Eastern Sicily and Lombardy) were considered for the analysis to investigate the influence of the geographical context on the WF. In fact, the three regions (in the central, southern and northern part of the country respectively) differ in terms of climate, freshwater availability, distance from the sea and type of quarries.

2.2. Life Cycle Inventory (LCI)
Different studies, databases and tools were used for the LCI: studies available in the scientific literature and the Ecoinvent database [16] were used as sources of secondary data; ArcGIS was used for the geolocation of quarries, cement factories, batching plants and seawater intake facilities; finally, the Distance Matrix API of Google was used to calculate the road distances between different points. The electricity consumed in quarries, cement factories and batching plants was modelled using the Italian electricity mix. A focus on the inventory for aggregates and water considered in the different scenarios is presented in the next sections. As for the quality of the data, primary data were collected for energy consumption and water withdrawals in a land quarry and a in a concrete batching plant, while secondary data were used for the other unit processes.

2.2.1. Aggregates. Aggregates, in Italy, are sourced from three different types of land quarries: wet, dry, and rock quarries. Wet quarries are open-pit mines characterized by the presence of a lake, formed when the excavations of sand and gravel penetrates the aquifer's water table. Conversely, in dry quarries the excavation process never reaches the water table. Finally, aggregates from rock quarries are produced from blasting and crushing rocks in mountainous areas. A hypothetical scenario where marine aggregates were used instead of land-won aggregates was also considered in the present study. Although the extraction of aggregates from the seabed is not currently practiced in Italy, this activity is common in other European countries such as the UK and the Netherlands [17]. For this scenario, aggregates were assumed to be dredged from the seabed off the Italian coast and transported by ship to the shore.

In wet quarries, water is used to wash the aggregates and the machinery on site. Aggregates are washed to separate the different sizes, while machineries are washed for productivity reasons. Although not directly used, freshwater is consumed in quarries due to evaporation. Water evaporates not only during the washing process, but also from the extracted aggregates (before and after washing) and from the quarry lake. If aggregates were not quarried, the evaporating water would remain in the aquifer and it would be available for other purposes. For this reason, evaporating water was included in the assessment. On the other hand, not all the water used to wash the aggregates and the machineries is consumed: most of it, in fact, either leaches back to the aquifer or it is conveyed to settling tanks, where silt deposits and decanted water is re-used for washing. For this reason, the only water that is actually consumed in the washing process is that which is adsorbed by the aggregates or that evaporates. Based on a previous study, the amount of evaporating water was assumed to be 10% of the withdrawn water [18]. As for the water evaporating from the quarry lake, it was calculated using the Visentini formulas, which correlate the evaporation rate from small water surface to the average temperature and the elevation [19]. A wet quarry located in Northern Italy was used as reference case study, and the annual evaporation from the quarry lake was then multiplied by the surface of the lake and the rate was divided by the annual production of the quarry in order to allocate the amount of evaporated water to the produced aggregates.

Water is used to wash aggregates and machineries in dry quarries too. However, since no lake is present in this case and water used for washing is collected and reused for the same purpose, the only water consumed is the one adsorbed by the aggregates or the one evaporating during the activity. Primary data collected by Rigamonti et al. were considered in this case [20].

In rock quarries, aggregates are not washed since there are not fine particles (i.e. silt) to be removed. Nevertheless, water is consumed to control dust and to wash machinery. Data were collected from another Italian study investigating this type of quarry [21]. Decanted harvested rainwater and new freshwater withdrawn from the well were used in the quarry; however, since not enough information was available on the amount of harvested rainwater, only the withdrawn component was considered.

Finally, in case of off-shore extractions, it was assumed that marine aggregates were washed with seawater to remove the fine particles and that no additional washing was required to remove the chlorides contamination. Therefore, direct consumption of freshwater was considered null in this case.

2.2.2. Batching plant. Primary data were collected for water consumed at the batching plant: total direct consumption was equal to 0.50 m^3 per cubic meter of fresh concrete, split between the water for mixing (equal to 0.17 m^3 based on the Ecoinvent recipe) and the one for washing the truck mixers and the area. For the base case scenario, water for mixing was assumed to be withdrawn from a well located at the concrete mixing plant. On the other hand, seawater was assumed to be collected from an open intake facility on the coast and then transported by truck to the concrete mixing plants.

2.2.3. Cement plant. Primary data from one of the main Italian cement manufacturers were used for the study and 0.24 m^3 of FW resulted to be used on average per metric ton of cement, mainly for gas conditioning and cooling activities.

2.2.4. Geolocation, distances and transports. Location of the active quarries in the different regions was retrieved from the official regional websites while location of batching plants and cement factories were provided, respectively, by the Italian Technical Economic Association for Ready-Mixed Concrete [22] and the Italian Association of Cement manufactures [23]. Coordinates of each plant and quarry were then imported to ArcGIS and, for each batching plant, it was assumed that cement was supplied from the closest producer and that aggregates were sourced in equal amounts from the closest four quarries. Finally, fresh concrete was assumed to be transported for 10 km with a truck mixer to reach the construction site [24].

Seawater intake facilities and marine aggregates extraction site were assumed to be located along the coastline, at a minimal linear distance to each batching plant. SW was considered to be transported by tankers from the intake facility to the concrete batching plant.

2.3. Life Cycle Impact Assessment

The AWARE method, developed by WULCA, was used for the impact assessment [25]. The AWARE characterization factors account for the Available WAter Remaining in a watershed after the demand of humans and aquatic ecosystems is met. The metric provides characterization factors both at the river basin scale and aggregated at national level. In the present study, basin scale factors were used for direct water consumptions, while aggregated national factors were considered for the indirect uses.

Characterization factors were then imported to ArcGIS and applied to the different plants based on their location.

3. Results and discussion

The actual amount of freshwater consumed to produce 1 m^3 of concrete in Italy and the water footprint for the different mixes assessed with the AWARE method are both presented in this section.

3.1. *Water consumption*

Direct and indirect freshwater consumption for each process unit are listed in 'table 1', where all the numbers are referred to the declared unit in the base case scenario (i.e. 1 m^3 of fresh concrete delivered to the construction site). An average distance was considered for transportation from the quarry and the cement plants to the concrete mixing facility. Water consumption to produce 1 m^3 of fresh concrete ranged between 1.7 and 5.5 m^3, according to the type of aggregate used in the mix. The minimum value corresponds to concrete containing aggregates from a rock quarry, while the maximum is referred to the case with aggregates from a wet quarry. The high value of direct consumption for the wet quarry was due to a large extent (i.e. 94%) to the water evaporated from the quarry lake.

Table 1. Direct, indirect and total freshwater consumption for the base case scenario.

Process unit	Indirect water consumption ($m^3_{water}/m^3_{concrete}$)	Direct water consumption ($m^3_{water}/m^3_{concrete}$)	Total Water consumption ($m^3_{water}/m^3_{concrete}$)
Aggregates production – dry quarry	0.03	1.68	1.71
Aggregates production – wet quarry	0.06	4.49	4.55
Aggregates production – rock quarry	0.04	0.71	0.75
Cement plant	0.30	0.05	0.35
Batching plant	0.05	0.50	0.55
Transport	0.03	0.00	0.03
Declared unit	0.41 - 0.44	1.26 - 5.04	1.65 - 5.48

3.2. *Water footprint*

3.2.1. Base case scenario. WF results for the Italian base case scenario (i.e. LAFW) are summarized in 'table 2'. In the table, the WF (expressed in world-equivalents m^3 of water) of each unit process is reported for the three regions investigated. The *mean* represents the calculated average WF for the concrete produced in the region, while the *range* represents the potential minimum and maximum for each region. Cases where all the aggregates were sourced from only one of the four closest quarries was also included in the analysis. The larger WF in Sicily (up to 300 m^3-eq. per m^3 produced) was due to the limited remaining available freshwater in the region; conversely, the larger availability of freshwater in Lombardy resulted in lower impacts. The ranges for cement production, batching plant and mixing water are related to the different characterization factors of the river basins where the plants are located. The range for aggregates production depends not only on the characterization factors, but also on the type of quarry. Finally, the range for transportation is related to the transport distance and does not depend on local water availability, since there was no direct water consumption involved in the process. For indirect water, national aggregated characterization factors of the producing countries based on the information available on Ecoinvent datasets were used.

Table 2. Water footprint of each unit process for the base case scenario in the regions investigated.

	Abruzzo			Eastern Sicily			Lombardy		
	Mean (m^3-eq.)	Range (m^3-eq.)	Share (%)	Mean (m^3-eq.)	Range (m^3-eq.)	Share (%)	Mean (m^3-eq.)	Range (m^3-eq.)	Share (%)
Aggregates prod	46	13-98	61	126	49-256	74	10	4-15	46
Cement prod	10	9-11	13	12	12	7	8	8	37
Batching plant	13	7-21	17	16	15-17	9	3	3	12
Mixing water	6	3-10	8	15	14-16	9	< 1	< 1	2
Transport	< 1	< 1	1	1	1	1	< 1	< 1 - 1	3
Declared unit	65	32-141	100	171	91-303	100	21	15-27	100

3.2.2. Alternative scenarios. A comparison of the WF for the different scenarios considered (i.e. LAFW, LASW and MASW) is presented in 'figure 2'. Error bars indicate the minimum and the maximum WF in the different batching plants. Differently from 'table 2', the minimum and maximum considered here do not consider the cases where all the aggregates were sourced from a single supplier. Since the AWARE characterization factor for seawater is null, the WF of the water used for mixing in the LASW and MASW scenarios was only due to its transportation from the coast to the batching plants.

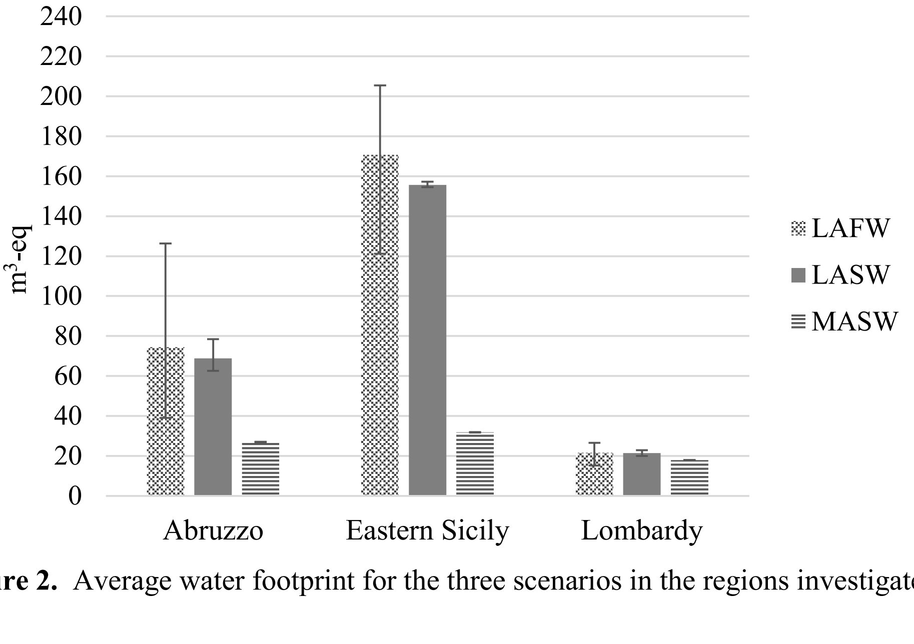

Figure 2. Average water footprint for the three scenarios in the regions investigated.

Replacing FW with SW resulted in a reduction of the WF of concrete from less than 2% in Lombardy to 9% in Eastern Sicily. Using MA instead of LA resulted in a further reduction of the WF in almost all the batching plants analyzed. In Abruzzo and Eastern Sicily, the reduction would be extremely significant (i.e. always larger than 45%) thanks to the avoided direct freshwater consumption in areas affected by high water stress. In Lombardy, on the other hand, the WF implications depend on the type of aggregates that would be substituted. Given the long distance from the coast, the benefits of using MA in terms of WF were clear (up to a 36% reduction) only when aggregates from wet quarries were replaced.

4. Conclusions

In the present study, the amount of freshwater consumed to produce 1 m^3 of fresh concrete and its WF were assessed for three Italian regions differently affected by water stress. Moreover, the implications on the final WF of substituting land-won aggregates with marine ones and using seawater instead of freshwater for mixing the concrete were investigated. The following conclusions could be drawn:

- Aggregates production proved to be the determining parameter on the final overall freshwater consumption, while water used to mix the concrete resulted to be only a fraction of all the freshwater consumed along the production chain (i.e. from a minimum of less than 2% to a maximum of 12%). Freshwater evaporating from quarry lakes could considerably increase the amount of water consumed in case aggregates from wet quarries were used, with a contribution that could reach 4.2 m^3 per m^3 of concrete (i.e. up to 77% of the total consumption). Moreover, cement production and water consumed in batching plants in addition to that used for mixing, contribute significantly to the overall consumption. On the other hand, the indirect water consumed to transport the different materials resulted to be trivial.
- Similarly, water physically incorporated in the fresh concrete was only partially responsible for its WF (i.e. 8 to 9% of the total WF in areas affected by high water stress and 2% in Lombardy, where the direct water consumptions are less impacting). Accordingly, using seawater could reduce the WF of concrete up to 12% in Eastern Sicily and would negligibly affect the WF in Lombardy.
- On the other hand, replacing land-won aggregates with the marine counterpart could reduce to a great extent the pressure of concrete on freshwater availability in areas affected by water stress, leaving freshwater available for human consumption. In Eastern Sicily, for instance, using marine aggregates and seawater could reduce the WF up to 80%. However, if aggregates need to be transported for a long distance and the area has a large availability of freshwater, using marine aggregates might be detrimental for the WF.

5. Further investigations

The present study was a first attempt to assess the implications of using alternative sources of water and aggregates on the WF of concrete. Even though the study showed positive outcomes, before promoting their use further research is necessary to investigate a possible burden shifting (e.g. implications on greenhouse gas emissions and aquatic ecosystems, which fell outside the scope of the present work). Moreover, the durability of the concrete designs and the water consumption in the manufacturing of the reinforcing elements should be included in the analysis to extend the present results to the whole life cycle of the building material. Furthermore, some assumptions made for the present analysis should be further revised to improve the robustness of the study. For instance, water evaporating from the quarry lake resulted to be a decisive parameter in the WF of concrete in regions with wet quarries. However, the dimension of the lake, the temperature in the region, the productivity and the service life of the quarry would greatly affect the amount of evaporating freshwater that should be allocated to the aggregates. Finally, an additional sensitivity analysis considering different strengths and water-to-binder ratios for concrete should be performed to investigate variations in the role that water for mixing and mixture components might play in the overall WF of the material.

Abstract. The search of sustainability is a need for human activities in general. Particularly, cement sector as a significant contributor to climate change has to implement strategies to reduce its environmental impacts. But, effective strategies have to be complemented by adequate methodological techniques to assess, guide and certificate sustainability. Amongst all the techniques developed by the scientific community in recent years, life cycle techniques highlight as one of the most used one due to its integrated and holistic philosophy. In Cuba, a new cement based on a combination of calcined clay and limestone to reduce clinker to 50% (Low Carbon Cement, LC^3) is been developed as part of an international collaboration project. The main goal of this research is to assess sustainability of cement sector in Cuba using life cycle techniques such as: Life cycle assessment (environmental-LCA), Social Life Cycle Assessment (S-LCA), Life Cycle Costing (LCC), Economic Life Cycle Assessment (EcLCA). As part of the assessment LC^3 is compared with traditional produced cements in Cuba OPC and PPC. Results show that LC^3 introduction allows increasing sustainability in cement sector by reducing carbon emissions, energy consumption, costs and reporting positive effects on society.

1. Introduction

One of the most intensive industries in capital and energy is the cement industry [1]. This industry constitutes the base for the sector producing construction materials, as cement is the main ingredient of concrete, and have multiple interrelations with all sectors and economic activities that exist or must exist for the proper functioning of the economy. However, the high production volumes of this industry make it responsible for approximately 6-10% of global CO_2 emissions of anthropogenic origin and about 5% of energy consumption in the industrial sector [2].

The increase of the energetic efficiency, the use of alternative fuels, the decrease of the clinker ratio by using supplementary cementitious materials (SCM), besides the sequestration and capture of carbon, are the main strategies developed to reduce the emissions of CO_2 and energy costs associated with cement production [2].

Low Carbon Cement (LC^3) is a cement with high level of clinker substitution with addition of 30% calcined clay and 15% limestone [3]. Several articles have been published proving the technical viability of this new product [4]–[6]. Although the lower clinker content in LC^3 is supposed to reduce energy consumption, associated costs and emissions and extend existing productive capacities; these assumptions need to be proven.

The Life Cycle Sustainability Assessment (LCSA) is one of the most modern tools applicable for the evaluation of investment impacts and programs oriented towards sustainability [7], [8]; nevertheless, its methodological structure is in development and its application is still limited [9-11]. In the solution of these limitations the proposal, selection and guidance for the use of indicators play a fundamental role; the availability of data and experience for its application, among others, that allow achieving the organicity of the three methodologies that make up the LCSA: Life Cycle Assessment (LCA), Life Cycle Costing (LCC) and Social Analysis of the Life Cycle Assessment (S-LCA).

2. Method for sustainability assessment

According to UNEP/SETAC (2011) the Life Cycle Sustainability Assessment considers all stages of the product and service life cycle and the complete study of its production and value chain. First ideas that guided LCSA approach can be attributed, according to Finkbeiner (2010), to the German Oeko-Institut for its method called "Product Line Analysis" (*Produktlinienanalyse*) [12]. Later, UNEP published several documents that serve as a methodological guide for the discussion and implementation of this tool [13].

In formula 1, proposed by Kloepffer (2008) [14], the LCSA is conceptually defined:

$$LCSA = LCA + LCC + S\text{-}LCA \quad (1)$$

Where:

LCSA = Life Cycle Sustainability Assessment LCC = Life Cycle Costing

LCA = Life Cycle Assessment (environmental) S-LCA = Social Life Cycle Assessment

The environmental life cycle assessment (environmental LCA) looks at the potential impacts of products and services in the environment. ISO standards for LCA guide these studies in four phases: (i) definition of objectives and scope; (ii) inventory analysis; (iii) impact assessment; (iv) interpretation of results; with close interrelation between the phases.

Life Cycle Costing (LCC) and financial analysis are combined with the economic analysis of the life cycle from the methodological guide proposed by Neugebauer et al. (2016) [16], understanding that the economic analysis comprises a number of variables that allow holistic evaluation of the impacts of an activity or service beyond the cost category [15], [16].

Social Life Cycle Assessment (S-LCA) were published by UNEP/SETAC in 2009 [17], then in 2013, methodological sheets for impact categories and indicators by stakeholder groups were published [18]. In this investigation the subcategories and indicators are adjusted to Cuban conditions to be evaluated. From the UNEP proposal (2013) 14 indicators are identified and 2 proposed for evaluation.

According to [14] there are at least two options to include LCC and S-LCA as part of LCSA. Option 1 is based on performing three separated life cycle assessments with identical system boundaries. Its graphical representation matches with formula 1. Option 2 is based on "a new life cycle assessment" where costs and social assessment are included as additional impact categories to the LCA (environmental). This option includes a life cycle inventory with the *inputs* and *outputs* needed to assess the three areas simultaneously and possibly to get the same protection areas.

The advantage of this option is that greater integration is achieved by having a single LCI associated with a single analysis system. However, there are reservations as to the compatibility of this variant with the ISO 14040 standard, since the standard in its introduction states that the LCA "does not usually consider the economic or social aspects of a product [...] but should be used as part of a much more complete decision process". This clearly favours the application of option 1 in the short term, while the international standards ISO 14040-44 are revised and modified so that they comply with option 2.

For its part UNEP (2011) clarifies that although standardization, aggregation and weighting are optional steps in accordance with ISO 14040, any aggregation and weighting of the results of the three techniques used in the ASCV is not recommended because the research and implementation of this approach is at an early stage and the results of each applied life cycle technique are not yet comparable to each other.

In order with previous ideas, in this paper final results are shown throughout a methodological proposal of pared indicators following eco-efficiency philosophy. These indicators are presented in a radial chart that allows to perform a combined interpretation and decide among several alternatives.

2.1. Choice of functional unit and system boundaries

The main objective is to evaluate the environmental, economic and social impacts of the introduction of low carbon cement in Cuba comparing LC3 with cements currently produced OPC and PPC. Table 1 shows material composition of the cements compared. The analysis is performed from cradle to gate, mainly focused on the production and transport of the cement constituents, as shown in [19]. According to the system boundaries, the functional unit selected in the study is 1 ton of cement. This functional unit is commonly used for cradle to gate LCA but one if its limitations is not being directly related with cement quality, this aspect remains as an extra task for evaluators in order to get an integral assessment of this construction product. When assessing concrete performance other units suit better to explain its performance like m^2 of wall, m^2 of built surface, m2 of usable floor area, etc. [20].

Table 1. Composition of the assessed cements.

Cement	Constituents (%)				
	Clinker	Limestone	Gypsum	Calcined Clay	Zeolite
OPC	0,88	0,05	0,07	-	-
PPC	0,75	-	0,05	-	0,20
LC^3	0,48	0,15	0,07	0,30	-

2.2. Data collection

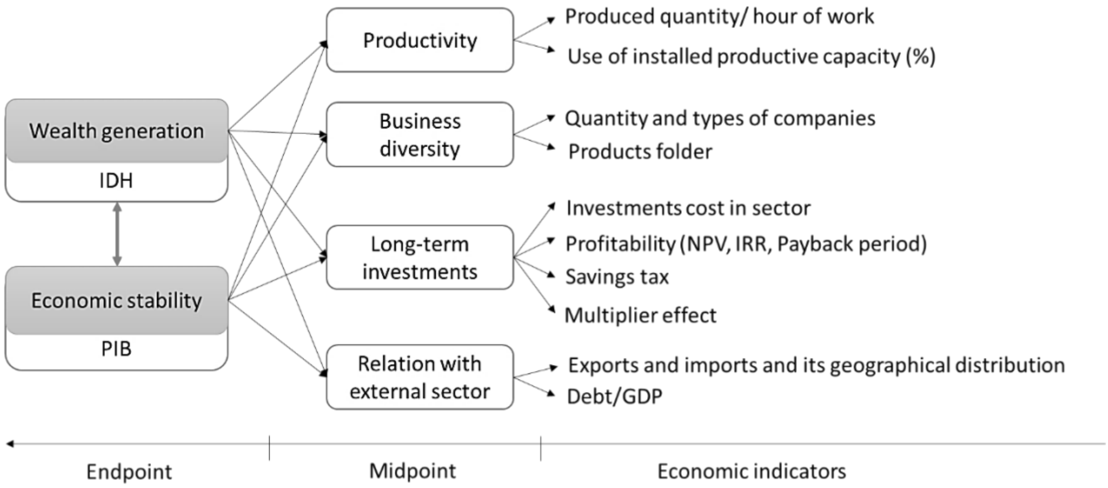
Data collection for the performed LCA has been published in [21]. The economic assessment used data collected from Siguaney cement factory relative to salary, consumption indexes, cost of energy, raw materials distances, depreciation, amongst other. Data from social area was obtained from several sources like official documents like statistical year book, production reports, accounting books of industry, interviews with workers and directives of different companies. To warranty liability of data, the triangulation of obtained information in interviews was performed by reviewing official documents related to the topic.

2.3. Impact assessment

In this study environmental assessment is performed applying ReCiPe impact assessment method. Specifically, for Cuban cement sector 11 midpoint categories are selected: Climate change, Ozone depletion, Chemical oxidants formation, Human toxicity, Particulate matter formation, Terrestrial acidification, Fresh water eutrophication, Marine eutrophication, Fresh water ecotoxicity, Marine ecotoxicity and Fossil fuel depletion. Three endpoint categories are analysed: Human health, Ecosystems and Resources.

Costs assessment is performed following life cycle of the product and its productive chain. Production process is divided into 5 stages: raw materials extraction, fuels extraction, transport, clinkerization and grinding plus other processes. Assessment of economic impacts (E-LCA) complements costs analysis with financial analysis of different investment scenarios, productivity and macro-economic variables analysis. Midpoint, endpoint and indicators proposed to Cuban cement sector and its interconnections are shown in Figure 1.

Figure 1. Proposal of categories and indicators to perform E-LCA in Cuban cement industry.



Source: Proposed following [16].

Social impact assessment is performed as Social Life Cycle Assessment following UNEP/SETAC methodological proposal [17], [18]. From the proposal of UNEP/SETAC 14 indicators, 9 midpoint and 3 endpoint categories were selected to assess cement industry in Cuba as shown in Table 2.

Table 2. Sub-categories and indicators selected to social assessment in Cuban cement sector.

Categories	Sub-categories	Indicators
1. Workers	1.4 Hours of work	No. hours of work/t cement
	1.7 Health and security	*Incidence of diseases related to cement production/ worker*
3. Local Community	3.3 Cultural patrimony	No. of buildings with patrimonial value restorable/year
	3.5 Local employment	Percentage of labour work employed in locality
		No. employees
	3.7 Access to material resources	No. of infrastructure projects developed with access and benefit of community
	3.8 Living conditions healthy and secure	*Incidence of diseases related to cement production/ community inhabitant*
5. Society	5.1 Public commitment to sustainability aspects	Presence of documents available publicly such as agreements in sustainability topics
		Implementation/firm of principles or conduct codes internationally conciliated
	5.3 Contribution to economic development	% GDP relative to construction sector
		Number of houses built/year
		Changes in acquisitive power of population
	5.5 Technological development	Sectorial efforts for technological development
		Relation with programs or projects of technological transfer

2.4. Integration of results

To be able of develop the final process of integrating economic, social and environmental results, a set of paired indicators is proposed allowing to combine the three dimensions of sustainability taking into account the main findings in the evaluations carried out separately and the efficiency of them characterizing each evaluated dimension. This facilitates the integration of the results without complicating the evaluation process. It was decided to calculate the indicators for those categories of considerable magnitude and that show greater impact for cement sector. Table 3 shows the proposed indicators, the unit of measurement in which they are expressed and their classification.

Table 3. Proposed indicators and its classification.

Indicator	Unit	Type
Production cost/ MPa*	Pesos / MPa	Technic-Economical
Investment cost/ MPa*	Pesos / MPa	Technic-Economical
Energy consumption/ MPa*	MJ/ MPa	Technic-Economical
Reduced emissions/ investment	tCO_{2eq}/ Peso (MT)	Economic-Environmental
Dust emissions/ hour of work	kg MP10/ h	Social-environmental

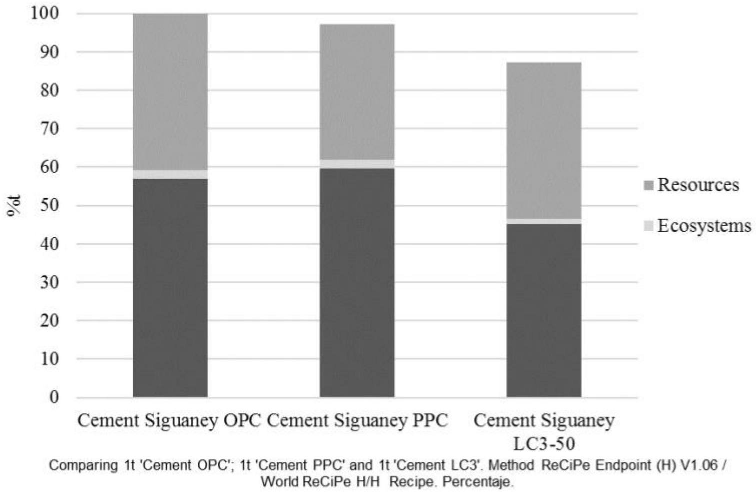
*MPa of compressive strength at 28 days

3. Results

3.1. Life Cycle Assessment

The comparative life cycle analysis of the OPC, PPC and LC^3 cements is performed to evaluate 11 intermediate categories and 3 final categories of the ReCiPe methodology. The calculations are performed using the professional software Simapro vs- 8.0.3.14. LC3 presents lower impact in 8 of the midpoint categories reporting higher impact in eutrophication and ecotoxity indicators. From the endpoint categories, the most affected category is human health, due to the damage caused by the gases emitted in the production process related to CO2 and particulate matter. The P-35 causes greater damage to human health and the ecosystem, as shown in Figure 2. The production of LC3 is the one that most affects resources by the calcination of kaolinitic clay with Cuban crude oil which is more polluting that pet-coke assumed to clinker production.

Figure 2. Results of endpoint categories of damage OPC vs. PPC vs. LC3.



The analysis of the energy consumption shows that with the introduction of LC3 can reduce in approximately 900 MJ the energy consumption per ton of cement produced. The main savings are obtained in the processes of clinkering, extraction of fuels and grinding.

3.2. Life Cycle Costing and Economic Life Cycle Assessment

Through the LCC, the cost composition of each cement is analyzed. The main costs are reported by the extraction and transportation of energy resources, raw materials and equipment depreciation. LC3 production reports a considerable decrease in production costs mainly related with reduction of clinker factor. Costs saving of 10-15 % are reported in Cuban conditions if LC3 is compared with PPC and OPC respectively [21].

To evaluate the profitability of the technological alternatives, 2 alternatives are compared with Business as Usual using a capital cost of 12%, discount rate of 35% and time horizon of 15 years. The results are shown in table 4.

Alternative 1: proposes the strategy of introducing the LC3 in the Cuban cement industry as the partial substitution of traditional cements from the conversion of kilns to calciners. Four calciners with capacity of 300 000 tons / year of calcined clay are estimated.

Alternative 2: Under this alternative, calcination of the clay should be done through flash calciners. Flash technology must be imported. The same amount of calciners is estimated as in alternative 1.

Table 4. Financial results for each of the investment alternatives.

Alternatives	**Indicators**		
	NPV (MPesos)	**IRR (%)**	**Payback period (Years)**
LC^3_Retrofitted calciners	$227.34	58%	3 years, $8^{1/3}$ months
LC^3_ Flash calciners	$123.53	33%	5 years

The internal rate of return and the payback period show that the conversion of kilns to calciners is the best alternative in the short-term. The cost of this conversion is taken from [22], where is establish a maximum retrofitting cost to produce calcined pozzolana of 12M€. Same results should be obtained if an industrial calciner is installed since recent investment costs are quite similar to this scenario [23].

Analyzing productivity aspects is expected that the introduction of Low Carbon Cement increases the productivity since a better use can be done with the same amount of clinker. In other words, decreasing clinker ratio Cuban cement industry will be able to offer a higher amount of cement to market with minor changes in its technology. This could have a positive impact on the business diversity and could stimulate exports to countries of the Caribbean and Latin American areas but this fact depends on several factors besides the level of cement production. Moreover, the reanimation of this sector would lead to a reanimation of Cuban economy due to the multiplier effect of construction as key sector for and investments and development.

3.3. Social Life Cycle Assessment

The assessment of social impacts is carried out mainly by assessing the potential for change in the selected indicators. When possible, quantitative analysis is performed. The following levels are proposed to evaluate the potential for change: a: Negligible, B. Minor, C. Moderate and D. Significant. The results of the evaluation show that 79% of the impacts present moderate or significant change potential [21].

Table 5. Potential of change (PC) of proposed social indicators

Sub-categories	PC	Indicators	PC
1.4 Hours of Work	A	No. of hours worked / t cement	A
1.7 Health and Safety	D	Incidence of diseases attributable to cement production/ worker	D
3.3 Cultural Heritage	C	No. of buildings with patrimonial value restore / year	C
3.5 Local Employment	B	Percentage of labor force contracted in the locality	A
		No. Of jobs	B
3.7 Access to Material Resources	C	No. of infrastructure projects developed with access and benefit to the community	C
3.8 Safe and Healthy Living Conditions	C	Incidence of diseases attributable to cement production / community residents	C
5.1 Public Commitment to Sustainability Issues	C	Presence of publicly available documents as agreements on sustainability issues	C
		Implementation / signature of principles or other internationally reconciled codes of conduct	D

5.3 Contribution to Economic Development	C	% GDP relative to the construction sector	C
		Number of houses / year	D
		Changes in the purchasing power of the population	C
5.5 Technological Development	C	Sectoral efforts for technological development	D
		Relationship with technology transfer programs or projects	C

3.4. Integration of results

For the integrated evaluation of the results in the economic, social and environmental dimensions, the combined analysis is proposed through scatter plots of the most significant variables of each sphere. The significance of the chosen variables is determined taking into account results of the assessment, literature review and expert's opinion (detailed information available in [21]). In this way, decision-makers can be offered a brief and simple analysis of the most sustainable investment variant. The indicators for the case study in the cement industry are shown in Table 6.

Table 6. Indicators selected to integrate and interpret the results

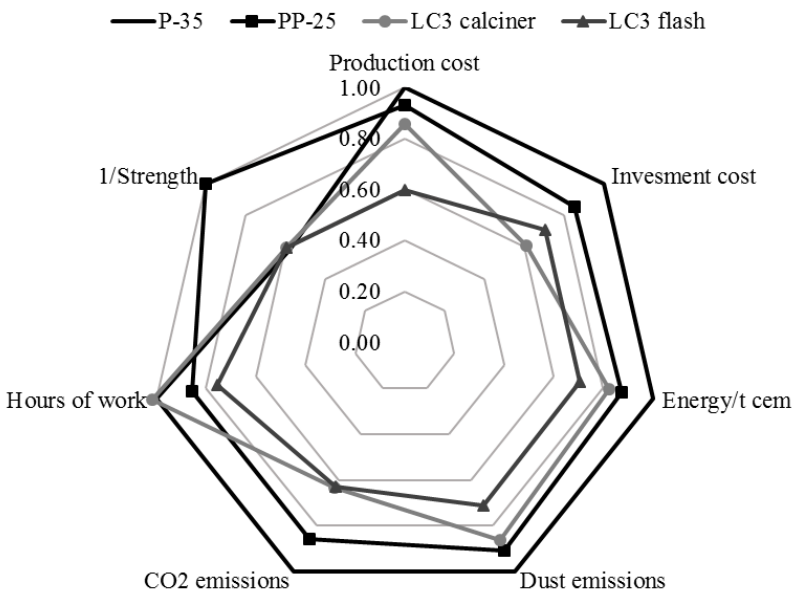
Indicators	UM	OPC	PPC	LC3_Calciner	LC3_Flash
Production cost	Pesos	187,70	174,55	160,86	112,12
Investment cost	USD	159,57	135,99	97,39	112,54
Compressive strength 28 days	MPa	43,07	25,00	42,08	42,08*
Energy consumption	MJ	5292,38	4626,33	4367,53	3254,22
Dust emissions	kg PM10eq	15,10	13,69	13,00	9,75
Carbon emissions	kg CO2eq	890,63	764,92	564,39	559,73
CO2 emissions reduced	kg CO2eq	-	125,71	326,24	330,90
Time of labor	Hour	0,035	0,030	0,036	0,027

* to LC^3_Flash is assumed equal compressive strength than obtained in the industrial trial with the calciner.

Source: [21]

To analyze results in an integrated way figure 4 is proposed, showing all indicators together.

Figure 3. Integrated assessment of impacts. Case study: introduction of LC^3 in Cuba.



The results of the economic, social and environmental evaluations show the positive impacts (see figure 3) of introducing low carbon cement in Cuba. The main impacts are associated with the reduction of emissions of greenhouse gases and dust, which could influence in the reduction of diseases associated with the production of cement; the saving of energy that influence in the reduction of the cost of production and the consequent impact on the purchasing power of the population. A revitalization of the cement production in Siguaney and consequently in Cuba, that would allow to satisfy the internal demand and increase the exports of this good, and the increase of the productive capacities through small investments with high profitability and short period of recovery.

4. Conclusions

The results of the Life Cycle Sustainability Assessment carried out show that the main impacts are associated with the reduction of greenhouse gas emissions and dust, which in turn influences the reduction of diseases associated with this type of production; the energy saving that is translated in the reduction of the cost of production and the consequent impact on the purchasing power of the population; the revitalization of the cement production in Cuba and in particular in Siguaney, which would allow to satisfy the domestic demand and to increase the exports of this good; in addition to the increase of productive capacities through small investments with high profitability and short recovery period.

Acknowledgments

The authors would like to acknowledge Siguaney cement factory for the technical and material support. The authors would like to thank to the whole team of the "Low Carbon Cement" Project for all the advisory and technical help during this paper creation.

yudieskycd@uclv.edu.cu

Abstract. This paper aims at assessing the sustainability of replacing conventional OPC/PPC by Limestone Calcined Clay Cement (LC3) in Cuba. Authors conducted an eco-efficiency (E-E) analysis supported by E-E ratios, which in turn are rooted on the environmental assessment (Life Cycle Assessment, LCA) and the economic analysis (Economic Value Added, EVA). Taking case studies in Villa Clara province capital district, three construction methods were compared and further conclusions emerged with regard to economic and ecological criteria. A square meter of built area was employed as functional unit. According to main results, Grand panel technique appears to be the benchmarking method, followed by Forsa system and, finally, concrete block technique. LC3 blend outperforms OPC/PPC from both economic and environmental perspective. Furthermore, productive efficiency potentials were found on the field of material selection and raw material procurement. Authors provided decision-makers with some policy recommendations in order to contribute enhancing the sustainable use of LC3 in Cuban construction sector.

1. Introduction

The building materials sector is the third-largest CO2 emitting industrial sector worldwide [1]. This sector represents 10% of the total anthropogenic CO2 emissions, most of which are related to concrete manufacture: about 85% of these CO2 emissions come from the provision of cement [2]. Due to the responsibility of construction activities on climate change, the global concern has been focused on the production of concrete structures. Modern civilisation construction is mainly built of concrete, the most consumed material in the world, after water. For emerging economies —where the building stock is still under construction and the potentials for renewable energy transition are not already proven— the need for alternative materials is increasingly recommended.

LC3 —Limestone Calcined Clay Cement— is a blended cement innovation proposed by an international team led by the Swiss Federal Institute of Technology, EPFL-Lausanne. LC3 is a combination of clinker (50%), calcined clay (30%), gypsum (5%) and limestone (15%). The calcined clay of this newly developed technology is metakaolin. Metakaolin has been gaining attention among cement producers as a supplementary cementitious material [3]. Abundant information is readily available on the literature, i.e., [4],[5],[6]. LC3 advantages not only lie on the energy reduction field and emission savings; moreover, it leads to approximately 15% cost- cutting.

This paper aims at assessing the sustainability of replacing conventional OPC/PPC by LC3 in Cuba. Three construction methods has been taken into consideration: (i) concrete block technology, (ii) Grand panel system (mainly prefabricated concrete elements) and (iii) Forsa system (mainly RMC-intensive). The aforementioned building systems were analysed along the following three scenarios: (i) Business As Usual (BAU scenario), which means producing/using conventional OPC/PPC cements, (ii) the country only replaces PPC by LC3, (iii) LC3 substitutes both existing cements. All the alternative choices are scrutinised by taken into account the eco-efficiency index early proposed by [7],[8],[9]. The ratios were built upon the results of Life Cycle Assessment (LCA) and Economic Value Added (EVA) as two so-called and so-accepted ways of looking at sustainability pillars.

Authors looked at the economies of scale coming from different building sizes, as well as the transportation distance breakeven point for building materials costing. Finally, some policy recommendations arisen from the results of four case-studies, were reached.

2. Methodology and data

The eco-efficiency index was calculated by means of the Equation 1, as proposed in the sustainability literature. Data sources for calculating LCA are twofold: background data took impact factors from previous researches [10],[11],[12] and foreground data is reported in table 1. Figure 1 shows the breakdown of material consumption according to the four case-studies under assessment in this paper.

$$Eco-efficiency\ index = \frac{EVA\ (Economic\ Value\ Added)}{CO_2\ (Carbon\ Dioxide\ Emissions)} \qquad (Eq. 1)$$

Table 1

Foreground data for the case studies under assessment

		Blocks	Grand Panel		Forsa
Building materials/Building system	Unit	Two-storey	Two-storey	Five-storey	Five-storey
Ready-Mix Concrete	m^3	30,6	10,9	40,1	397,0
Prefabricated concrete	m^3	9,5	52,0	277,8	14,3
Blocks 15 cm	u	7560,0	770,0	2381,0	2140
Cement	t	29,3	8,6	40,2	27,7
Sand	m^3	42,9	30,1	79,3	55,0
Gravel	m^3		0,37	0,9	
Calcium hydrate	t	4,92	2,25	9,9	6,8
Steel	t	2,83	0,86	2,6	31,5
Usable floor area	m^2	168,74	161,42	863,6	806,9

Data on table 1 stands for the data inventory needed to conduct LCA as well as the economic assessment. The amount of cement reported in row 4 is the cement used for mortar in masonry applications. The cement consumption per unit of building materials listed on the above table, behave as follows: 450 kg per cubic meter of ready mix concrete, 360 kg per cubic meter of precast concrete and 1,62 kg per block. Figure 1 reports the breakdown of construction materials consumption by construction technology type, expressed in percentage. It shows that Grand panel system is prefab. intensive while Forsa method is quite RMC consuming. Concrete block technique is mainly based on masonry applications, which require a great amount of cement in the construction site. The later system is labour-intensive and needs to mobilize the transportation of a huge amount of building materials.

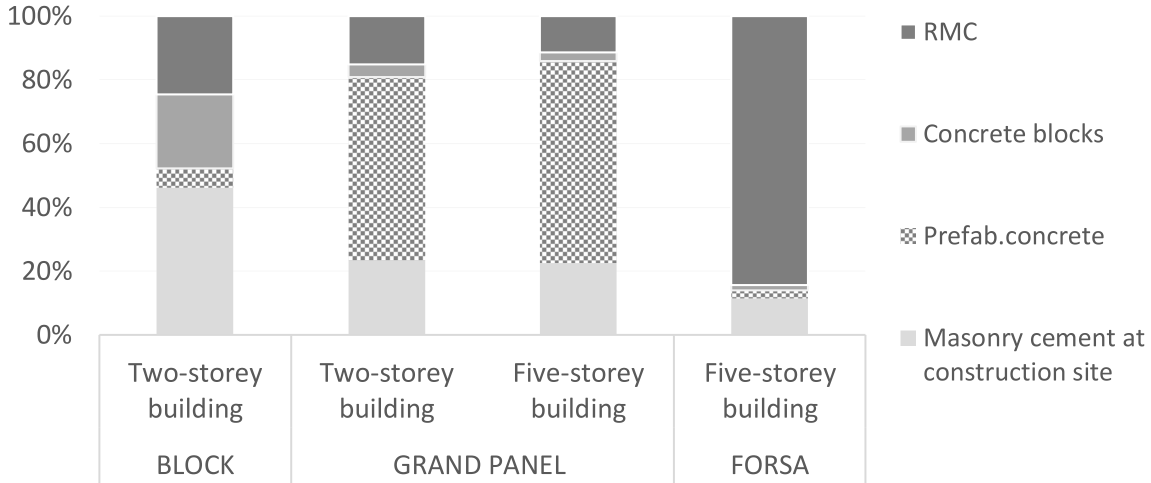

Fig. 1. Material consumption breakdown, by construction technology type (percentage).

3. Results

Figure 2 summarizes the eco-efficiency outputs of this study. Some concluding insights would be drawn from the results:

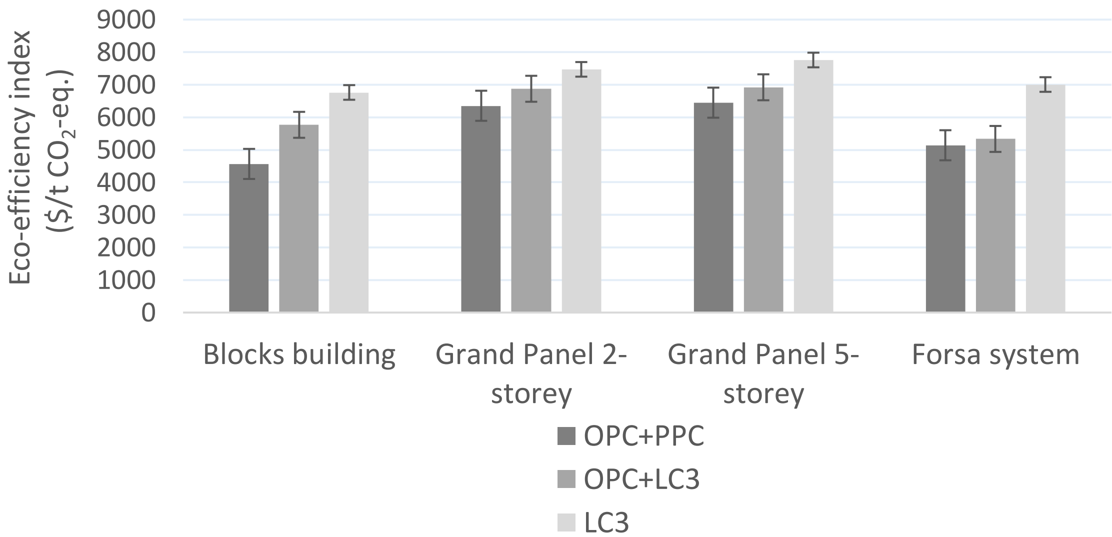

Fig. 2. Eco-efficiency index comparison for the case studies being assessed

- Grand panel seems to be the most eco-efficient construction technology within the case studies under examination, which represents an intermediate level of industrialisation in between the concrete block system and Forsa technology.
- By inspecting the two building sizes within Grand panel technique, some potentials for economies of scale are achieved: up to 15% cost reduction would be possible to attain, strictly coming from the building size. It also contributes reducing the land use, therefore, the ecological footprint of mankind construction activities.
- LC^3 would be more effectively used in RMC-intensive choices from a sustainability viewpoint, but it always must be seen in light of raw materials transport distances.

Ceteris paribus the cement type used for construction, the cost of transporting raw materials needs for attention, particularly for those economies like Cuba where the productive efficiency depends upon the transportation parameters. Material selection in construction sector is crucial because of the enormous volume and mass needed to be transported. That is why the nearness of raw materials deposits constitutes a core piece of the cost analysis.

The figure 3 describes an estimated transport cost function for raw materials, according to those case-studies under assessment. Detailed calculations can be found in [4].

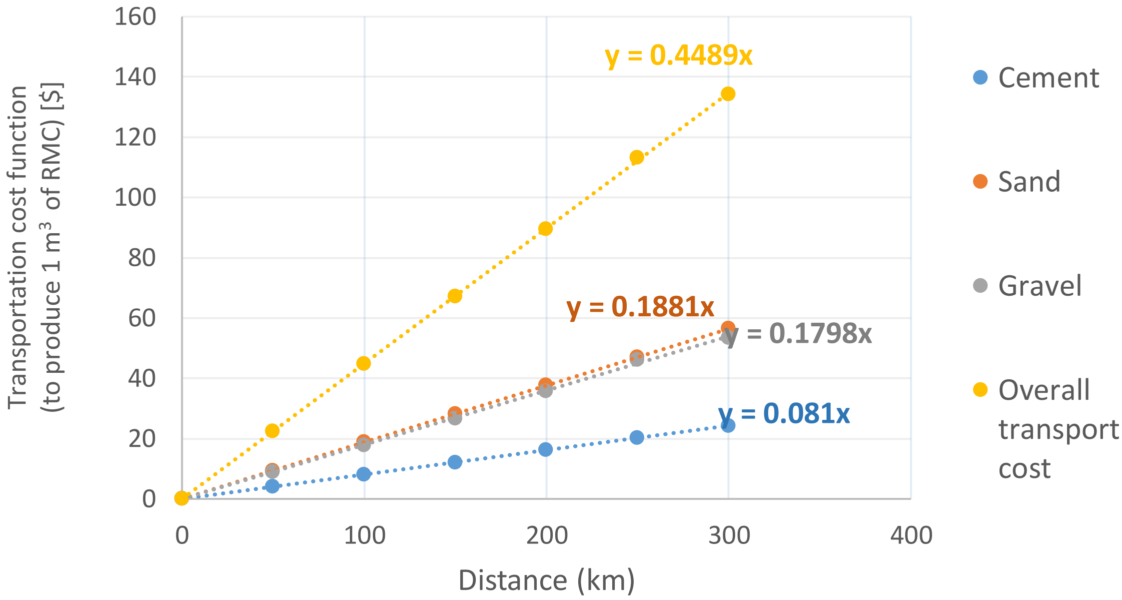

Fig. 3. Transportation cost function at the level of raw material

In a second step, using (i) functional data from formulas shown on Fig. 3, (ii) quantities from data inventory reported in table 1, and (iii) transport distances between source of materials and construction sites, authors developed the Overall Transport Cost Function at the level of buildings (Fig. 4). Afterwards, the distance breakeven point was calculated for each case study, taking as a relevant input, a maximum cost limit determined by the cost savings between LC3 and conventional cements. The economic distance threshold was anticipated around 50 km in the Forsa system, 141 km in the blocks building and 345 km for Grand panel. It means that beyond such a threshold the construction activities would become economically unfeasible, if transport parameters are taken into consideration.

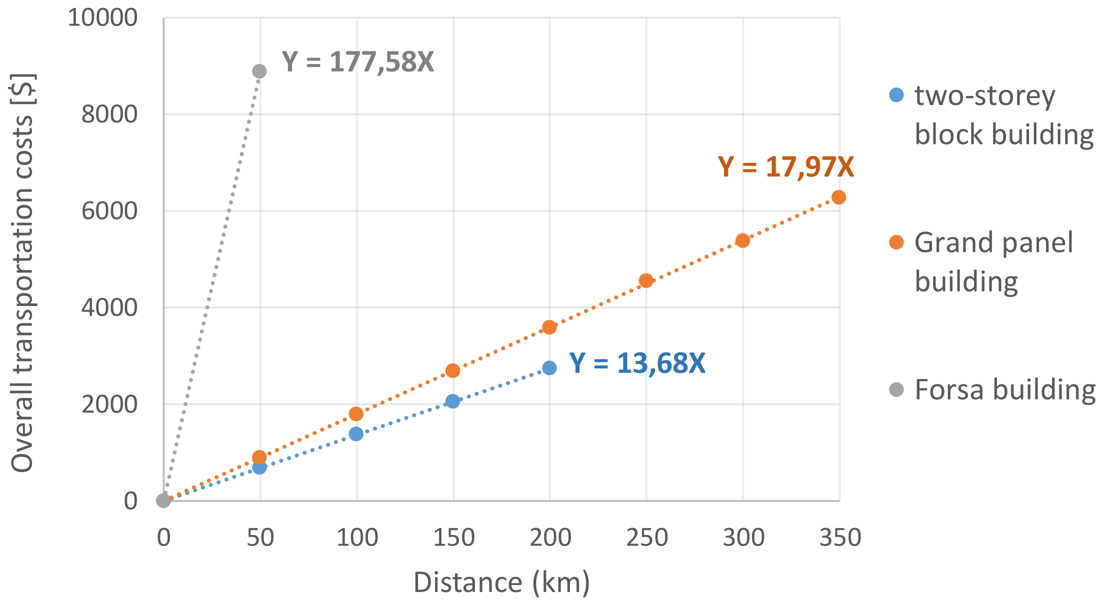

Fig. 4. Transportation cost function at the level of building

However, it appears to be clear that both material selection and the construction technology choice have to be thought in the light of case-to-case building design/location, because depending on the distance from construction site to quarries —particularly the deposits of aggregates due to the enormous amount per concrete volume— the construction method might be subject to adaptations and rethinking.

4. Conclusions

According to the case studies taken from Villa Clara province (Cuba), the future implementation of LC3 within the construction sector would attain better eco-efficiency parameters if those building methods characterised by medium-to-high level of industrialisation are prioritised. Least industrial intensive choices —such as concrete blocks— seems to be highly correlated to cement consumption, in turn, meaning high energy consumption, carbon emissions and production costs. Transportation parameters also would strongly influence the material selection and eventually the construction technology choice. None of the construction techniques is, in principle, superior per se; a proper combination of them based on a multiple-criteria approach, let decision makers better stick to the suitable benchmark combination of techniques through the lens of sustainability.

Optimizing the economic, environmental and technical performance of concrete mixes with fly ash and recycled concrete aggregates

Kurda R, Silvestre J D, Brito J

CERIS, Department of Civil Engineering, Architecture and Georesources, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais 1, 1049-001, Lisboa, Portugal

rawaz.kurda@tecnico.ulisboa.pt

Abstract. This study answers an important question that may arise when selecting a sustainable concrete, namely "concrete mixes containing low cement and recycled aggregates are a sustainable solution?" To answer this question, this study shows how to optimize concrete mixes in terms of technical performance, and economic and environmental life cycle. Firstly, the weight to be considered for each of these dimensions of performance depends on the concrete application (e.g. residential house and high-rise building) and on the consumer's requirements (e.g. business as usual, green, strength, service life and cost scenarios). In this study, concrete mixes containing recycled concrete aggregates (RCA) and/or fly ash (FA) are optimized to be used in sustainable residential houses. For that purpose, the CONCRE***Top*** methodology (developed by the same authors of this study) was applied to these concrete mixes by considering a "green scenario". The results show that, for sustainable residential houses, the concrete mixes made with high incorporation ratios of FA and RCA are considered the best option.

1. Introduction

Concrete has a serious influence on environmental impacts (EI) due to the fact that it is the most consumed product by Man after water. Thus, many alternative ways were suggested to decrease its influence on EI, specifically by using cementitious [1-7] and recycled materials [8-20]. For that purpose, there were many attempts to study the effect of non-conventional materials on the cost, quality (e.g. durability and mechanical characteristics) and EI (energy consumption and greenhouse gas emissions) of concrete. Since most of the studies focused on only one of the mentioned dimensions of performance (quality, cost and EI), and there is no direct relationship between them, a critical gap occurs concerning the assessment of sustainable concrete. Even though, there are many alternative materials which use in concrete is a sustainable solution because their EI are lower than that of the conventional materials. However, the advantage of these non-traditional materials may not be obvious when the service life of the concrete mixes made with them compares with that of conventional concrete.

To analyse these issues, this study optimized concrete mixes containing various incorporation ratios of fly ash (FA) and recycled aggregates (RA), with and without superplasticizer (SP). But it is not easy to compare the performance of concrete mixes considering simultaneously several dimensions of performance. Thus, the authors of this study had already proposed a novel method (CONCRE***Top*** - A multi-criteria decision method for concrete optimization - [21]) to optimize conventional and nonconventional concrete mixes in the mentioned dimensions. For that purpose, the CONCRE***Top*** methodology was applied to these concrete mixes by considering a "green scenario". This study is an example of CONCRE***Top***'s application and also contributes to its validation.

2. Materials and methods

This study followed the steps that are described in the CONCRE***Top*** method [21] to optimize concrete mixes. As mentioned before, the concrete mixes can be optimized only when their quality, EI and cost are known. It is known that the environmental and cost life cycle assessment data of different concrete mixes cannot be directly compared. Accordingly, the CONCRE***Top*** method used a non-parametric linear technique to optimize the concrete mixes. In addition, the aim of the *CONCRE**Top*** method is to simply compare the options without any complex analyses (e.g. Holomorphic function, disk algebra and power series) in order to be used by any Engineer in the construction industry. According to the CONCRE***Top*** method, seven actions are required to reach a final decision (Figure 1).

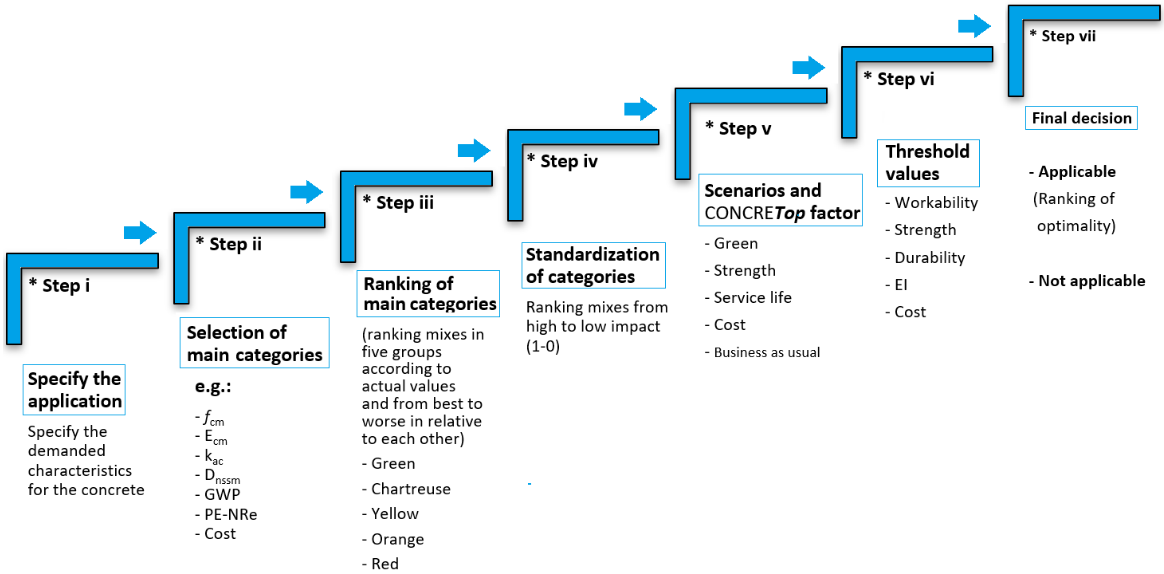

Figure 1 - Profile of the CONCRE***Top***. Each step is described in study [21]

Cement and FA used as binders were type "CEM I 42.5 R" and "F", respectively. The fine and coarse RA are made from the same source concrete without any contamination (100% concrete). The fine and coarse natural aggregates (NA) are "natural silica sand" and "crushed limestone", respectively. In this study, 20 concrete mixes (Table 1) are considered to be optimized. They were made with various incorporation ratio of FA (0%, 30% and 60%), fine RA (0%, 50 and 100%), coarse RA (0% and 100%) and SP (0% and 1%). All the information related to the characteristics of the materials (e.g. size of aggregates, density, and water absorption) and mix composition (e.g. mixing procedure, quantity of materials) is described in another study by the same authors [22].

To consider the requirements needed to optimize concrete mixes, the following standards were considered to determine the compressive strength [23], modulus of elasticity [24], carbonation [25], chloride ion penetration [26, 27], cost, and global warming potential and non-renewable primary energy consumption (based on Life Cycle Assessment (LCA) methodology [28, 29]) of the concrete mixes. Regarding LCA, the EI of the concrete mixes were found by considering the most probable case scenario in the centre of Portugal (Lisbon region). Further details regarding the mentioned characteristics (e.g. curing procedure, size of samples, number of samples and case scenario) are described in previous studies of the same authors [5, 7, 30, 31].

3. Application of CONCRE*Top* to the concrete mixes

3.1 Specification of the application (step i)

As detailed in the CONCRE***Top*** methodology, the optimization process of concrete mainly depends on its application. In this study, the concrete mixes are optimized to be used in a "sustainable residential houses". According to this methodology, "sustainable residential houses" will be categorized according to a "green" scenario. Thus, the threshold values that are specified for the green scenario were applied to the concrete mixes.

Table 1 - Mixes composition

Mixes [a]	Fine RA (%)	Coarse RA (%)	FA (%)
M1; M1-SP	0	0	0
M2; M2-SP	100	0	0
M3; M3-SP	50	0	30
M4; M4-SP	0	0	60
M5; M5-SP	100	0	60
M6; M6-SP	0	100	0
M7; M7-SP	100	100	0
M8; M8-SP	50	100	30
M9; M9-SP	0	100	60
M10; M10-SP	100	100	60

[a] M and M-SP are concrete mixes without and with SP (1% of binder's weight)

3.2 Selection of the main categories (step ii)

There are many characteristics that can be considered to optimize concrete. The CONCRE***Top*** method specifies the most relevant ones for this purpose, but unlimited characteristics can be considered using this method. According to this method, the following characteristics are relevant for the green scenario: workability, compressive strength (f_{cm}), modulus of elasticity (E_{cm}), carbonation resistance, chloride ion penetration resistance (D_{nssm}), global warming potential (GWP) and non-renewable energy consumption (PE-NRe).

3.3 Ranking of the main categories (step iii)

Before optimizing the concrete mixes based on the next steps (§3.4-§3.5), namely by considering the weight of each category, mathematical rules and threshold values, the characteristics of the concrete mixes were compared to each other in order to provide a general idea about their performance. However, the aim of the CONCRE***Top*** method is to find an optimal mixes instead of the best one in each category. According to this methodology, the results of the concrete mixes were compared (Table 2), namely by two main colours (green for the best performance and red for the worst performance). According to this step, mixes M3, M3-SP, M4-SP, M6-SP and M8-SP were identified as optimal for "sustainable residential houses", because most of their characteristics are not in the red category.

3.4 Standardization of categories (step iv)

The characteristic values of concrete mixes are standardized based on step iv from Kurda *et al.* [21]. It is known that the results of different properties cannot be compared if their measuring unit are not the same. Therefore, the actual values of all characteristic were standardized (normalised or homogenised) from 0 to 1. Then, the mixes were ranked according to the standardized values from the best to the worst performance (Table 3).

*3.5 Scenarios and CONCRE**Top** factor (step v)*

This step is one of the most important of the optimization process because the mixes were ranked based on the CONCRE***Top*** factor. This factor can be determined by the equation proposed in this method [21]. In addition, for the selected scenario (green), the weight of each category (characteristic of concrete) for the CONCRE***Top*** factor is defined in the same method according with their order of importance. For the selected application and scenario, the weight of the strength, durability, LCA and cost are 10%, 20%, 50% and 20%, respectively (based on 20 years of experience of one of the authors of this manuscript as a structural designer.). According to the CONCRE***Top*** method, the weights can be changed, depending on the client's perspective. However, this method was prepared for engineers with basic knowledge regarding the construction sector in order to choose the weights. But this method also include threshold values to overcome this issue. Even if the weights are not always considered properly, the threshold values will not permit inadequate choices. Figure 2 presents the result of the process of optimization of the concrete mixes based on green scenario ranked by their CONCRE***Top*** factor (1-0) without considering threshold values.

Table 2 - Ranking of concrete mixes according to their performance

Concrete mixes	Slump (cm)	$f_{cm,cube}$ (MPa)		E_{cm} (GPa)		D_{nssm} ($\times10^{-12}$ m²/s)		Carbonation "k_{ac}" (mm year$^{0.5}$)	GWP (kg CO_2 eq)	PE-NRe (MJ)	Cost (€/m³)

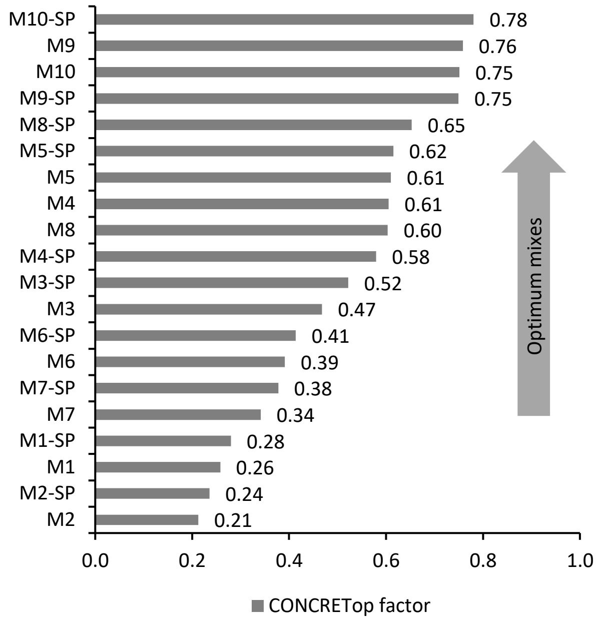

Figure 2 -Optimization of the concrete mixes according to green scenarios without considering threshold values

3.6 Threshold values (step vi)

As mentioned before, the considered weight may not be reliable or correct. Therefore, this step works as another sort of screen to optimize the concrete mixes. The boundaries (threshold values) for all the selected parameters (f_{cm}, E_{cm}, carbonation, D_{nssm}, GWP and PE-NRe) for this step are identified in the study of Kurda *et al.* [21]. According to this method, the threshold value depends on the case study. Thus, in this step, green scenario and its threshold value were chosen out of all scenarios (business as usual, strength, cost and service life) due to the fact that the concrete mixes are optimized for sustainable residential houses. Thus, the concrete mixes were ordered based on the values shown in Figure 2, and then the results were compared with the threshold values set by the mentioned study (Table 4). The concrete mixes that comply with the threshold values are not presented in Table 4. The results show that, along with the fact that the values of the CONCRE***Top*** factor of the traditional concrete (M1 and M1-SP) and of mixes containing 100% of fine RA (M2 and M2-SP), with and without SP, are relatively low, their characteristics also do not comply with the boundaries given by CONCRE***Top*** method.

3.7 Final decision (step viii)

One of the advantages of the CONCRE***Top*** method is that the consumer can easily choose the optimal mix for the selected application. According to the optimization process, mix M10-SP is the optimal one (highest CONCRE***Top*** factor) and the worst one is mix M7 (lowest CONCRE***Top*** factor). Based on the mentioned factor, all the mixes made with 100% coarse RA and 60% FA (M10-SP, M9, M10 and M9-SP) can be considered as optimal choices for sustainable residential houses (their CONCRETop factor is relatively similar). Thus, it is advisable to use high volume of coarse RA and FA to build sustainable residential houses. Furthermore, the method shows that the EI of the fine RA concrete made with ordinary Portland cement (OPC; M7 and M7-SP) is lower than that of conventional concrete, but it is still considered one of the worst choices because it significantly affects the service life of concrete.

The above conclusions show that consumers need to consider other dimensions of performance (e.g. quality and cost of concrete) to select the optimal/sustainable concrete, even if they only demand EI's minimization. In addition, the optimal mixes cannot be easily anticipated by simply looking at the individual results in each dimension (§3.3). Furthermore, in some cases, the high-strength concrete mixes are not considered as an optimum [21] solution due to their cost (their cost are very high) or EI (due to high cement content which is the major contributor to the high EI values of concrete).

Table 4 - Optimizing concrete mixes for sustainable residential house in the "GREEN" scenario

Ranked mixes	CONCRE***Top*** factor	Threshold	Applicable [21]	Reasons
M6-SP F 0% C 100% FA 0% SP 1%	0.41	Strength = 45/55 - 36 Carbonation R. = Very good Chloride R. = Very high GWP = Low PE-NRe = Low Cost = Very high	NO	The cost is very high.
M1-SP	0.28	Strength = 55/67 - 38 Carbonation R. = Very good Chloride R. = Very high GWP = Medium PE-NRe = Low Cost = Very high	NO	The cost is very high. For the green scenario, the GWP is expected to be lower than medium.
M1	0.26	Strength = 40/50 - 35 Carbonation R. = Good Chloride R. = Very high GWP = Medium PE-NRe = Low Cost = High	NO	For the green scenario, the GWP is expected to be lower than medium.
M2-SP	0.24	Strength = 35/45 - 34 Carbonation R. = Very good Chloride R. = High GWP = medium PE-NRe = Low Cost = Very high	NO	The cost is very high. For the green scenario, the GWP is expected to be lower than medium.
M2	0.21	Strength = 30/37 - 33 Carbonation R. = Good Chloride R. = Moderate GWP = Medium PE-NRe = Low Cost = High	NO	For the green scenario, the GWP is expected to be lower than medium.

Table 5 - Applicable concrete mixes for the sustainable residential house according to the "Green" scenario

Mixes	M10-SP	M9	M10	M9-SP	M8-SP	M5-SP	M5	M4	M8	M4-SP	M3-SP	M3	M6	M7-SP	M7
Fine RA (%)	100	0	100	0	50	100	100	0	50	0	50	50	0	100	100
Coarse RA (%)	100	100	100	100	100	0	0	0	100	0	0	0	100	100	100
FA (%)	60	60	60	60	30	60	60	60	30	60	30	30	0	0	0
SP (%)	1	0	0	1	1	1	0	0	0	1	1	0	0	1	0
CONCRE***Top*** factor	0.78	0.76	0.75	0.75	0.65	0.62	0.61	0.61	0.6	0.58	0.52	0.47	0.39	0.38	0.34

4. Conclusions

The results of this study show that the optimum concrete mixes may not be easily chosen by comparing the performance of concrete in each dimension (e.g. quality, cost and EI). In practical terms, for each selected application, it relies on the CONCRE***Top*** factor and threshold values. In other words, the weight of each characteristic depends on the specific concrete application. For example, mixes produced with high incorporation ratios of FA and RCA (e.g. M9 and M10 with and without SP) are not anticipated to be an optimal choice according to their individual characteristics, but their characteristics comply with the threshold values and their CONCRE***Top*** factors are the highest. In addition, the optimal mix (e.g. for sustainable house) may not necessarily be the one with the highest result in the demanded characteristic (e.g. EI). In practical terms, it is chosen by the combined performance in all the characteristics. Broadly speaking, the mixes are judged based on their performance on all characteristics, not in just one characteristic (dimension).

Finally, this study is an example of CONCRE***Top*** application and shows that concrete cannot be optimized without knowing its application and the consumer's demand. Therefore, the outcome may be different for other approaches or assumed scenarios.

Abstract. The construction sector is known as an important consumer of natural resources. The use of by-products from different production chains in the sector is encouraged, promoting a reduction in the extraction of natural resources, reducing the need for residues disposal and enhancing circularity. Silica fume is a by-product from the smelting process in the silicon and ferrosilicon industry, commonly used as concrete supplementary cementitious material, which provides chemical and physical effects on concrete microstructure. When LCA evaluation is conducted, different impact distribution models may be applied to assess the potential impact of the by-productss. Although their benefits are recognized, some studies still report them as burden free, having no allocated impacts . Thereby, the aim of this paper is to evaluate the differences in silica fume life cycle impacts by analyzing three scenarios from cradle to gate, considering the modeling procedures described by ISO 14040, the Cut-off model from Ecoinvent version 3.3 and the impact assessment method CML v.4.4, according to the CEN EN 15804 recommended categories. Results enhance the understanding regarding model selection and demonstrate that the selection of the proper distribution model is key, considering that this may lead to important differences in the results.

1. Introduction

The construction sector is recognized by producing numerous environmental impacts due to the high consumption of natural resources, high energy consumption for extraction of the raw material and for the large production of waste. These characteristics set up unsustainable patterns of development and consumption that could potentially lead to resource depletion and the inability to manage the amount of waste produced. Different studies and initiatives make efforts to mitigate this problem by improving materials, constructive techniques and developing new products. In addition, the production chain of the construction industry has enormous potential to increase the volume of materials it recycles, due to the large amount of materials consumed [1]. The use of construction and demolition waste, as well as the waste from other industries in the substitution of natural raw materials, is a sustainable way of handling by-products that would be otherwise disposed of.

There are environmental benefits related to the use of by-products in the construction industry. However, it is essential to quantify such benefits to provide clear information on the advantages or disadvantages related to their use. In this way, Life Cycle Assessment (LCA) is a methodology which allows for the assessment of potential environmental impacts of the use of such materials by calculating and evaluating resource consumption and emissions [2]. It is a recognized methodology that provides a structure to develop an environmental assessment of products [3].

LCA models the life cycle of a product through a system product, which is composed of activities that transform inputs to outputs (called 'processes') [3]. Processes that have more than one product as output, are known as multifunctional process [4]. In LCA studies involving multifunctional process(es), ISO 14044:2006 standard recommends firstly, the elementary process division or system expansion. Secondly, it recommends allocation using physical relationships and, thirdly, when a physical relationship cannot be applied, entries should be allocated by functions in a way that reflects other relationships between them such as economic value [5].

Tillman (2000) discussed the relevance of these different methodological choices in an LCA paper of a multifunctional process and its relationship between their goals and applications [6]. This paper distinguished a retrospective LCA, which are commonly known as attributional LCA and a prospective LCA, known as consequential LCA. The paper differentiates between the attributional approach, applied to learn about existing impacts, used to identify improvement possibilities or to make market claims; with the consequential approach, used to investigate the consequences of the changes in product or process design [6]. The ILCD handbook (2010) defines attributional modelling as involving the current or forecasted specific or average supply-chain [4].

Both approaches can be found being applied in LCA of the multifunctional process. Considering the attributional one, Chen et al. (2010) state that the mass allocation procedure has the advantage of being constant with time since the mass proportion between the product and the by-product is not very variable unless there are changes in its production process [7]. Despite being a consolidated method, there are different ways to conduct it. Choices related to the Life Cycle Inventory (LCI) modeling process, such as the different sets of rules that can be applied in the studies, may lead to different results [8]. On the other hand, Saade, Silva and Gomes (2015) mentioned that the conceptual limitations of allocation methods are that they do not look beyond partitioning impacts, and awkward ratios between physical characteristics and market value may distort the results [9]. These authors cited the system expansion approach (which encompasses the whole-system level, redefining the system boundaries to include the function related to the by-product) as their preference due to its capacity to precisely model the studied processes, following a complete and conceptually consistent description which also allows for the consideration of potential improvements at whole-system level. However, they recognize that system expansion application requires alternative data, which can be hard for certain processes [9].

In this regard, different modeling approaches are considered in the Ecoinvent v.3.3 database, giving consistency to studies related to diverse human activities. This database provides the choice among three system models. Two of them are based on the attributional system model - Allocation and Cut-off by classification (Cut-off) and Allocation at the point of substitution (APOS) and the last one is based on the consequential system model and named as Consequential, long-term [10]. It is important to mention that, whenever different alternatives of allocation procedures seem applicable, a sensitivity analysis should be conducted to explain the consequences of replacing the selected approach [5].

The environmental evaluation of the by-products used in the construction sector has been much discussed recently. Some of these studies are related to concrete production, one of the most produced materials in the world and with great potential for incorporating wastes/by-products [11]. In the concrete mix, pozzolanic materials have been used to improve properties related to mechanical strength and durability. Silica fume (SF) is one of these by-products, commonly applied due to its pozzolanic characteristics, extreme fineness and high amorphous silicon dioxide content. It is recognized as a pozzolanic admixture that is effective in enhancing concrete mechanical properties [12].

In the environmental assessment context, some SF studies have been developed assessing its environmental impacts as a supplementary cementitious material (SCM). Van Den Heede et al. (2014) compared a cement based concrete slab with a concrete slab with high cement replacement level [13]. By evaluating the impacts adopting an attributional approach, using economic allocation, the authors found a reduction when the SF is applied as SCM. Habert et al. (2011) assessing a concrete environmental impact, also applied an attributional approach, finding substantial differences coming from the three SF allocation procedures chosen (no allocation, mass allocation and economic allocation), with mass allocation showing the highest impact [14].

Although, some studies have been developed, the literature still has a lack of studies demonstrating in a clear way the influence of choice of multifuncional modeling procedure on the environmental impacts results. Considering that, and the common use of SF in construction products, the objective of this research is to enhance the understanding of differences in silica fume life cycle impacts by analyzing three scenarios from cradle to gate, considering the multifunctional modeling procedures by ISO 14040, the three distribution Cut-off models from Ecoinvent version 3.3 and the impact assessment method CML v.4.4-2001, according to the CEN EN 15804 recommended categories.

2. Methodological approach

2.1. Goal, scope and inventory analysis

The objective of this LCA is to understand the impacts of choosing a modeling procedure to deal with multifunctionality, as described by ISO 14040, in the LCA of the by-product SF. SF is produced during the silicon metallurgical production process, being collected in very large filters in the baghouse and then made available for use in concrete without further treatment (Figure 1). SF is also produced by the ferrosilicon productive process, but the silicon metallurgical is selected to this evaluation, since it produces higher amounts of proper SF for concrete production [1].

The scope of this LCA considers the production system from cradle to gate. In this way, the impacts related to the material extraction, material production stage, and transportation to the silicon metallurgical factory are evaluated. The use, maintenance phase and end-of-life (recycling and disposal, including transport) are not considered. The functional unit is defined as 1 kg of Silica Fume, produced in Brazil.

The Ecoinvent database version 3.3 presents the inventory data in three modeling methods to distribute environmental loads [8]. The Cut-off and APOS models are based on attributional approaches and they differ in the approach towards the allocation of recycling and waste treatment products. In the Cut-off model, the product system does not have any previous flows of by-products, waste treatment or recyclable materials since they are burden-free [8]. The APOS model measures all the benefits and impacts of any by-products by means of performing an expansion of the system, and allocation at the point of substitution. It is broader than the Cut-off because it includes all necessary secondary processes, such as treatment, to allow the material to be used as a by-product. Finally, the Consequential model is the broadest system, including the market and the consequences (avoided burden) of the replacement of the raw material by the by-product. And it differs considerably from the attributional system models, depending on the difference of perspective and the modeling principles [8].

Since this paper focuses on the multifunctional modeling procedures, the inventory data used is silicon production, metallurgical grade, location Rest of World (RoW) [15]. Complete data inventory is available on Ecoinvent v.3.3 documentation [15]. The location selected is due to the economic data applied, which are from Brazil. Despite the Ecoinvent v.3.3 having a SF dataset available (in the three models), it is not connected to the silicon production chain and it is reported as material for treatment or recyclable product. Even without this connections, SF is considered as a by-product in this study, and a system expansion and allocation are developed.

The Cut-off system model is selected. The simple cut-off method is the easiest to apply but it does not reflect the full consequences of the outflows and inflows [16]. The cut-off system and APOS system are similar since both models differ mainly in the treatment of recycling materials and wastes [17]. The conflicting criteria are probably part of the explanation as to why it is difficult for the international LCA community to agree on what allocation procedure is the best [16]. Figure 2 shows a silicon production scheme considering the three system models in evaluation.

LCA methodology is complex and demands a considerable amount of data because it is based on the life cycle perspective and demands data collection of different flows of energy and materials (input and output). The primary data collection cannot usually be gathered within each specific LCA due to high costs and time limitations [18]. When the primary data is not available, background data may be used as a supplement. The background LCI databases can be considered the backbone of any LCA because they provide the process building structure and the disaggregated unit data [8].

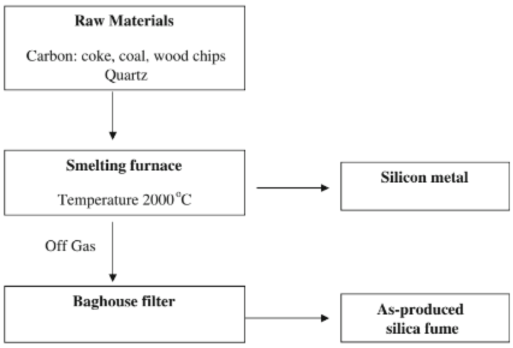

Figure 1. Schematic diagram of silica fume as produced [12].

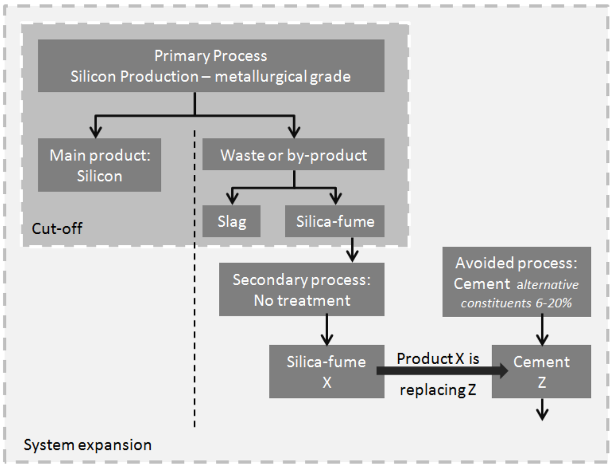

Figure 2. Silicon and silica fume production representation with the available multifunctional modeling procedures. No treatment needed to SF [1].

2.2. Scenarios description of sensitivity analysis

Three different scenarios are proposed resulting from the choice of the product system models: (i) Scenario 1- System expansion model; (ii) Scenario 2- System model Cut-off with allocation by physical relationship (mass); (iii) Scenario 3- System model Cut-off with allocation by economic value. The three scenarios are proposed in seeking to expand the discussion about by-product allocation in attributional LCA studies.

Scenario 1 is based on standard ISO 14044:2006 recommendation to divide the elementary process into two or more subprocesses or make a system expansion. In this scenario, a modelling adjustment is needed, because the silicon metallurgical production dataset does not have an output of SF, as a by-product or waste. In this study, the avoided burden of the SF as a cement replacer is considered [19]. The documents of Ecoinvent 3.3 of silica fume mention it as a replacer of different cement types [20]. The cement production, alternative constituents 6-20% - RoW (CEM II/A) is considered to calculate the avoided burden. This cement type is cited as the greater participation in the market [21].

Scenario 2 is calculated according to Chen et al., (2010) [7] and considers the percentage production as published by Fidjestol (2008) [22]. Scenario 3 is recommended in cases where the by-product represents more than 1% of the economic value of the product (SF accounts for 6.19% of the total economic value) and added to a share in relation to the total revenue considered low (less than 25%) [23]. The production percentages of SF (SiO_2 %) from silicon metallurgical production data were provided by a manufacturer [22], given as 40-50% (in mass) of SF. In this paper, a midpoint of 45% is used. Table 1 presents the values used in the allocation of SF.

2.3. Impact assessment

The support platform used for performing the LCA was OpenLCA 1.6.3, and the potential environmental impact evaluation is based only on the impact categories mentioned in CEN EN 15804 (2013): (i) Climate change – GWP-100 – kg de CO_2-Eq. (100a); (ii) Acidification potential – AP – kg

SO2-Eq. (average Europe); (iii) Eutrophication – generic EP – kg PO4-Eq. (generic); (iv) Photochemical oxidation -POCP – kg etileno-Eq. (high Nox); (v) Ozone layer depletion – ODP – kg CFC-11-Eq. (steady state); (vi) Depletion of abiotic resources – not fossil – ADPN – kg antimônio-Eq. (ultimate reserves); (vii) Depletion of abiotic resources – fossil – ADPF – MJ-Eq. (fossil fuels),; all from CML v. 4.4 baseline (2015) [24].

Table 1. Silica fume allocation percentages by mass and by economic value [7].

	Production (tons)	Market price (1 ton)	Allocation by mass	Allocation by economic value
Silicon	1,00 t	US$ 3145 [a,b]	-	-
Silica fume	0, 45 t	US$ 354 [a,b]	4,8%	31,0%

[a] Morales et al. (2016).
[b] Considering that US$ 1,00= R$ 3,82 (price of the currency in march/2019).

3. Results and discussion

Table 2 presents the impacts of the three available multifunctional modeling procedures by ISO 14040. Comparing the results, Scenario 2 (allocation by mass) shows higher numbers than the others followed by Scenario 3 (allocation by economic value).

Table 2. LCA impacts of 1kg of SF considering three available multifunctional modeling procedures by ISO 14040. Values (in %) represent the comparison between SF and the avoided product impacts.

	System model Cut-off 1kg de SF					**Avoided product[a]**	
Impacts	Scenario 1 - System expansion	Scenario 2 - Allocation by mass	%	Scenario 3 - Allocation by economic value	%	Cement CEM II/A	%
GWP-100	-8,56E-01	9,38E+00	1095%	1,46E+00	170%	8,56E-01	100
AP	-1,78E-03	4,81E-02	2697%	7,46E-03	419%	1,78E-03	100
EP	-4,32E-04	1,46E-02	3384%	2,27E-03	525%	4,32E-04	100
POCP	-6,98E-05	3,30E-03	4724%	5,12E-04	733%	6,98E-05	100
ODP	-2,13E-08	4,31E-07	2023%	6,69E-08	314%	2,13E-08	100
ADPN	-3,00E-07	2,40E-06	800%	3,73E-07	124%	3,00E-07	100
ADPF	-3,13E+00	8,07E+01	2577%	1,25E+01	400%	3,13E+00	100

[a] Silica fume is cement replacement.
GWP-100 - Climate change (kg de CO2-Eq. 100a); AP – Acidification potential (kg SO2-Eq.); EP - Eutrophication Potential (kg PO4-Eq.) ; POCP – Photochemical oxidation (kg etileno-Eq.); ODP – Ozone layer depletion (kg CFC-11-Eq.); ADPN - Depletion of abiotic resources – non fossil (kg antimônio-Eq.); ADPF - Depletion of abiotic resources – fossil (MJ-Eq.).

The Scenario 1 system expansion approach assume that 1 kg of SF could be applied in concrete production as an equivalent replacement of 1 kg cement CMII/A show negative results related to the avoided burden. This result is coherent since it is related to other markets. However, special attention should be given to issues regarding the availability of the by-product, because when we replace the main product (cement) with the by-product (SF), we assume "infinite" availability of the by-product, which does not occur because it belongs to a restricted production market. The worldwide generation of SF is estimated at 1.5 million tons, but today some of these materials are still not captured [22]. In an optimistic scenario assuming the capture of 70% of the generated SF (currently does not occur), the SF production would be 1.05 million tons [22]. This production represents approximately 0.13% of the world's cement production, which reached 818 million tons in 2016 [25]. This fact demonstrates that the market for SF production is restricted, and that it is therefore not appropriate to consider high cement replacement rates for this material because of its low availability in comparison to the large size of the cement market. Besides this, SF efficiency in concrete is not constant at all percentages of replacement [12].

The system boundaries of the LCA of multifunctional processes can be relevant in the results. In Scenario 2, allocation by mass value, the amount of by-product generated increases the percentage of impacts related to SF. These results prove the importance of the allocation method selection. In Scenario 3, allocation by economic value, the low sales value of SF in the generation point results in lower shareholdings (Table 1). The different allocation approaches can lead to significant result variability when economic parameters are applied. In contrast, mass relationships are controlled by the production process, which is tied to the main product's production process [7]. It is therefore quite straightforward and the mass ratios are mainly constant in time [9]. However, it is important to consider that allocation by mass induces large impacts on by-products that are used in the cement industry [7]. Hence, it could increase the impacts, influencing the interest to apply by-products as replacement. In this sense, the choice of system boundaries is closely related to the objective, including the activities relevant to the purpose of the study [26].

The use of pozzolanic material as SF in SCM has been consolidated. However, special attention should be given when the system expansion multifunctional modeling procedures are applied, because the avoided product functions can be equivalent to it but not equal. According to ASTM C 618 (1978) and NBR 12653 (ABNT, 1992), pozzolanic material is defined as a siliceous or silico-aluminous material which by itself has little or no cementitious property but when finely divided and in the presence of moisture, reacts with the calcium hydroxide at room temperature to form compounds with cementitious properties [1]. In this sense, SF may only partially substitute cement, in specific rates.

Despite the concern to reduce the environmental impact by replacing raw materials with by-products or residues, it is fundamental to guarantee the quality of the new product produced without causing losses in the durability and resistance [1]. In this way, the addition of SF to concrete protects the embedded steel from corrosion and improves the durability of concrete through reduction in the permeability and refined pore structure. This leads to a reduction in the diffusion of harmful ions and reduces calcium hydroxide content which results in a higher resistance to sulfate attack [12].

The lack of data affects the quality of the LCA application and emphasizes the importance of the quality of the available data of the unitary processes provided by the database, as well as its relation between the different productive chains.

4. Final remarks

The results enhance that the selection and understanding of the proper distribution model is key, due to their great influence on the results obtained. In addition, the evaluation of modeling choices and allocation systems is decisive, since they may influence the decision-making process. When the by-product allocation is not considered, an increase in fluxes in the main product is observed. In the system expansion, the avoided burden of by-product (in this case SF) replacing a virgin raw material, (in this case cement) with a by-product (in this case the SF) contains the assumption that the by-product is available for the entire world market. This inference may not be real, in this particular case, as the demand for clinker is considerably greater than the SF production, it seems like the system expansion is not suitable.

Finally, the importance of the modelling choice and its understanding must be highlighted, especially in product systems that deal with multifunctionality, to promote results that properly represent the evaluated products.

Abstract. Life Cycle Assessment is a powerful tool towards sustainable construction, but it often relies on average impact results, failing to identify the dispersion of environmental impact among construction product manufacturers. This work presents cradle-to-gate impact results for ready-mix concrete production, based on primary data provided by several plants in Brazil, and the associated variability among plants and in the upstream processes of cement and sand production. Four compressive strength classes are considered. Concrete, cement and aggregates inventories are modeled with Brazilian information and other upstream processes are based on ecoinvent. EN 15804 impact categories are assessed. The ranges between minimum and maximum impact values can be as large as 7.2 times the average impact result of the analyzed sample, which shows that the variability among manufacturers is high and decisions based on average impacts may be highly misleading. For some impact categories, the differences among concrete plants (mix design, cement type and operational conditions) represent the highest contribution for variability, while for others the dominant variation comes from upstream processes, especially clinker production. These results indicate a high potential for process improvement and that manufacturer selection based on environmental performance can be an effective strategy for sustainable construction.

1. Introduction

Concrete is the most consumed manufactured substance on the planet [1]. It is a vital construction material, but also a key driver of many environmental impacts in the construction sector, including global warming potential [1], fossil fuels depletion [2], mineral resources depletion [3], water consumption [4], among others. Since concrete cannot be substituted by other construction materials on a large scale, it is essential to improve its environmental performance, which requires assessment methods capable of measuring the environmental impacts of concrete production and tracking the results of these improvement initiatives [5].

Life Cycle Assessment (LCA) suits well this purpose, due to its quantitative and comprehensive approach [6]. Many LCA studies on concrete have been conducted [2,7], with Life Cycle Inventories (LCIs) and Environmental Product Declarations (EPDs) for concrete and concrete products published in databases [8–13]. Most studies only disclose average impact values and therefore do not consider the variability of impact results among concrete producers or among suppliers of its raw materials

[2,7] and “average EPDs” are even accepted by standards [14–16]. Moreover, these averages are not necessarily calculated based on a statistically representative sample of the population.

However, studies show that the variability among construction material producers should not be disregarded. For concrete, differences in CO_2 emissions for the same strength class can easily reach 100 kg CO_2/m^3 [17] and be as high as 400 kg CO_2/m^3 of concrete, which is larger than the magnitude of the average emissions [18]. Different cement types and binder intensity explain these variations [19]. Furthermore, LCA studies on cement production show high variability among manufacturers [20,21]. Sand and gravel production also vary considerably in energy consumption and corresponding environmental impacts [22]. By adding the variability of the concrete production and of its upstream processes, impact values can significantly deviate from the average. In this scenario, selecting the optimum concrete source bears significant mitigation potential.

The aim of this work is to present and discuss cradle-to-gate impact results for ready-mix concrete production in Brazil and the associated variability due to differences between concrete plants, as well as variations in upstream processes, based on primary industry data.

2. Method

This study covers four concrete strength classes (characteristic compressive strength of 25 MPa, 30 MPa, 35 MPa and 40 MPa), made with two Brazilian cement types according to ABNT NBR 11578 [23][1]: CP-II-E (with addition of 6% to 34% of ground granulated blast furnace slag and up to 10% limestone filler) and CP-II-F (with addition of 6% to 10% limestone filler), with a 100 mm slump value.

Data about the concrete production process were collected via questionnaires responded by the managers of 34 ready-mix concrete plants, located in 10 different states of Brazil (predominantly in the state of São Paulo), on a voluntary contribution, under a confidentiality agreement. Each plant provided information about concrete mix design; consumption of water for the mixing and other purposes (such as mixer truck cleaning), electricity and diesel for internal equipment (such as loaders; the fuel used for mixer trucks is not included); consumption of other process inputs (lubricating oil, steel parts and rubber parts for replacing worn industrial equipment parts) and total concrete production for the year of 2017. These flows were informed based on plant controls per month, in order to avoid mistakes in the calculation of unit flows, which were done by the authors of this study. Validation of data was carried out by comparing the resulting inventories to literature data and existing datasets, and clear outliers were excluded.

Except for mix design and diesel consumption, some flows have not been reported by all plants. Electricity consumption, for example, was informed by only 79% of the plants. In such cases, the average of the reported flows was adopted for the plants that did not provide data for it. Although required, origins of raw materials to assess their transportation distances to the concrete plant were not informed, so they were approximated by the average distance informed by Brazilian concrete block manufacturers from their respective aggregate suppliers [22]. Despite covering multiple plants and regions, the data that were collected correspond to less than 10% of the national ready-mix concrete production volume for these strength classes [24] and this sample probably represents an optimistic estimate of the environmental performance of ready-mix concrete in Brazil, since it is composed of plants that agreed to deliver their data.

This data collection was part of a broader initiative to develop life cycle inventories for construction products in Brazil. Therefore, it was also possible to model the production of some raw materials based on primary data from the Brazilian industry, namely cement, including the production of clinker and the granulation and grinding of blast furnace slag, sand and gravel. For cement, data were collected from six Brazilian manufacturers, which represent about 70% of the national production volume, with plants distributed over the Brazilian territory, which allowed to assess the dispersion of impact results among cement manufacturers and plants. For natural sand, extraction from

[1] Superseded version, valid at the time of the data collection.

open pit and from riverbed sources were inventoried; however, each process was modelled using data from only one quarry, located in the South and Southeastern regions of Brazil. It was not possible to obtain variability information for gravel, since it was modeled using data from only one Brazilian manufacturer and one quarry.

Other upstream processes, such as the production of admixtures, provision of water, production of diesel, electricity and auxiliary inputs (lubricating oil, steel and rubber parts), were modeled using the ecoinvent database version 3.4, with the allocation system “cut-off by classification” and the geographical scope “Rest of the World” – except for electricity, since the Brazilian electrical mix is available in this database. The use of this database to provide part of the inventories, due to the lack of local data, has the drawback of underestimating the actual variation between companies, as discussed later. The variability of upstream processes modeled with the ecoinvent database was not taken into account, because uncertainty information cannot be considered representative for Brazil.

Cradle-to-gate life cycle impact assessment (LCIA) was carried out using the “CML baseline” method, considering the impact categories requested by EN 15804 [15]: abiotic depletion potential of elements (ADP-e), abiotic depletion potential of fossil fuels (ADP-f), global warming potential (GWP), ozone layer depletion potential (ODP), photochemical oxidation potential (POCP), acidification potential (AP) and eutrophication potential (EP); using the Simapro software version 8.5, excluding infrastructure processes.

Impact results were calculated for each mix design to assess the variability among concrete producers within a specific strength class, irrespective of the cement type, since in Brazil ready-mix concrete is usually requested by the strength class specified in the structural design and the cement type is chosen by the concrete producer (e.g. based on local availability). In this first step, upstream processes were modeled considering only their average values. Average, minimum and maximum concrete impact results were calculated from the sample, for each strength class.

A second step was carried out, considering the minimum and the maximum values of the embodied impact of cement (dispersion among manufacturers) and sand (variation between two production routes), in order to assess the effect of upstream variability on the variability of concrete impact results. Overall minimum and maximum concrete impact results for each strength class were extracted from this second step of analysis. Variability propagation was done using a simplified approach, in which ranges were compiled by combining all minimum and all maximum values for the impact results [25]. This approach assumes that all cement and sand manufacturers may supply all concrete plants with equal probability, which is a rather conservative estimate.

3. Results

Table 1 shows an overview of the average impact results for 1 m³ of ready-mix concrete, by strength class. Figure 1 shows the ranges between minimum and maximum impact values, expressed as relative numbers to the average impact (which is considered equal to 1.0), including the range only among ready-mix concrete plants (hatched bars) and the range considering upstream variability (grey bars). Table 2 shows the variations in concrete mix, with the minimum and maximum content of each material considering the sample of concrete plants, by strength class; no distinction was made between cement types because the ranges of material contents of both cement types overlap.

Table 1. Sample average impact results for 1 m³ of ready-mix concrete, by strength class.

Impact category	25 MPa	30 MPa	35 MPa	40 MPa
GWP (kg CO_2 eq.)	196	220	248	295
ODP (10^{-6} kg CFC-11 eq.)	7.3	7.8	8.4	9.2
POCP (kg C_2H_4 eq.)	0.031	0.034	0.038	0.044
AP (kg SO_2 eq.)	0.74	0.80	0.87	0.98

Global warming (GWP) shows a considerable variation among ready-mix concrete plants, with minimum impact values up to 28% lower than the average and maximum impact values up to 41% higher than the average. The use of two different cement types, with different clinker content, along with variations in mix design (cement content) among producers (Table 2) explain the differences in the impact results. This variation corresponds to an impact range between 157 and 267 kg CO_2 eq./m³ for the 25 MPa strength class, i.e., a difference of 110 kg CO_2 eq./m³. This difference increases for higher strength classes, reaching 192 kg CO_2 eq./m³ for 40 MPa (between 213 and 405 kg CO_2 eq./m³).

For the impact categories ozone depletion (ODP), photochemical oxidation (POCP), acidification (AP), eutrophication (EP) and depletion of fossil resources (ADP-f), the ranges between minimum and maximum impact results are generally within the limits of ± 20% relative to the average impact. These variations can be attributed mainly to differences in the mix design, especially cement consumption (which varies between -10% and +26% relative to the average consumption) and gravel consumption (which varies between -21% and +27% relative to the average consumption), since these inputs significantly influence these impact categories in concrete production.

The impact category with the highest variability among concrete plants is abiotic depletion of elements (ADP-e), with ranges from 0.70 to 2.14 times the average impact result, because this category has a significant contribution from the steel parts' consumption for factory maintenance and this flow cannot be estimated with a good accuracy level by manufacturers.

By considering the variations in upstream processes, the total variability of concrete impact results increases, but in different proportions according to the impact category. For GWP, ODP and ADP-F, the increase in the coefficient of variation is rather small. For GWP for example, there is an increase of up to 71 kg CO_2 eq./m³ between those limits compared to the fluctuation among ready-mix plants (for the 40 MPa strength class). Direct CO_2 emission from the clinker production process is the major cause for GWP and this flow shows low variability among cement manufacturers (coefficient of variation of 3%). Fossil fuel consumption is also similar among cement producers, which explains the low upstream variability for ODP and ADP-F. For ADP-e, the increase in the impact range is not significant and the variability among concrete plants is still predominant.

For POCP, AP and EP, the contribution of upstream processes to total variability is much larger than the variation among concrete plants. For EP, the range increases from approximately 0.4 times the average to 1.3 times the average. This increase can be attributed to variations in NO_x emissions among clinker manufacturers (coefficient of variation of 65%), since NO_x emissions cause 85% of clinker EP impact and the clinker contributes for 91% (CP-II-E) and 94% (CP-II-F) of cement EP impact (on average). Variations in NO_x emissions during clinker production are also a major variability source for AP (NO_x corresponds on average to 46% of clinker impact), together with variations in SO_2 emissions in the same process (coefficient of variation of 128% among manufacturers, contribution of 44% for the clinker impact result, contribution of clinker of 94% for CP-II-E and of 97% for CP-II-F impact results). Maximum values for the AP impact category can be almost 3 times higher than the average. The extremely high maximum impact values considering upstream variability observed for POCP (up to 7.6 times the average) occur because some cement manufacturers use charcoal as fuel for clinker production and the charcoal production process has a high POCP impact; if those manufacturers were excluded from the sample, the variability level would be similar to the AP impact category.

Impact results per cubic meter of concrete increase with the increase in strength, due to the corresponding increase in cement consumption. However, if the reference unit is changed from 1 m³ to 1 m³ x 1 MPa, by dividing impact results by the declared characteristic compressive strength (which defines the strength class), impact results generally decrease for the higher strength classes, as presented in Table 3. It can also be observed that the level of variation of impact results is similar for the different concrete strength classes. This reference unit (1 m³ x 1 MPa) is closer to the functional unit concept of LCA, since it includes the strength provided by the concrete [18].

Table 3. Sample average impact results for 1m³ x 1 MPa of ready-mix concrete, by strength class.

Impact category	25 MPa	30 MPa	35 MPa	40 MPa
GWP (kg CO_2 eq.)	7.9	7.3	7.1	7.4
ODP (10^{-7} kg CFC-11 eq.)	2.9	2.6	2.4	2.3
POCP (10^{-3} kg C_2H_4 eq.)	1.2	1.1	1.1	1.1
AP (kg SO_2 eq.)	0.029	0.027	0.025	0.025
EP (10^{-3} kg PO_4^{3-} eq.)	5.4	4.9	4.5	4.4
ADP-e (10^{-7} kg Sb eq.)	5.1	4.4	4.0	3.7
ADP-f (MJ eq.)	28	25	24	23

4. Discussion

Absolute differences between best and worst producers are staggering. Even for impact categories with lower levels of variation, maximum impact values (worst environmental performance) can be up to 1.5 times higher than minimum impact values (best environmental performance), exclusively due to differences in mix design and operation variables of concrete plants. For GWP, the indicator that is recognized as a priority for cementitious products, the difference between minimum and maximum values can reach values from 110 to 192 kg CO_2 eq./m³, which correspond to approximately 60% of the average impact values. These ranges are comparable to the dispersion assessed by Damineli et al. [18] and by Park et al. [17] for cradle-to-gate CO_2 emissions for concrete. They are also of the same magnitude of the ranges assessed by Oliveira et al. [22] for cradle-to-gate CO_2 emissions among concrete block producers in Brazil.

The results demonstrate the large mitigation potential of selecting the best ready-mix concrete producers. Although the technology adopted by ready-mix concrete producers is quite similar (dry batching trucks), there is large room for process improvements aiming to minimize the environmental impact of ready-mix concrete, such as optimization of mix design. Even though it might not be possible for all manufacturers to reach minimum impact values (for instance, due to local aggregates' characteristics), it is likely that some reduction can be achieved with existing technology and management measures.

Another important aspect is the propagation of variability of upstream processes to final variability. This study considered only the variations for the production of cement and sand, for which primary data were available, although for sand variation reflects only the differences between two production routes. The contribution of the variability of cement impact to the variability of concrete impact is relevant, especially for those impact categories affected by NO_x and SO_2 emissions, for which high variation has also been reported in literature about cement production [7,20,26]. Because sand contributes with a maximum of 9% to the total impact of concrete, the variation between production routes did not have a significant effect on the variability of concrete impact results.

Gravel constitutes most of concrete's mass and contributes with up to 66% of concrete's impact results. If variability in gravel production had been considered [22], total upstream variability would be certainly higher, as well as the variations in transportation distances for the raw materials to the concrete plants. Despite the underestimation caused by lack of data for upstream processes, the contribution of upstream variability to the total variability detected is still significant. These findings regarding upstream processes offer an additional evidence of the potential of mitigation given by the selection of suppliers of construction products.

Furthermore, these results show that decisions based on "average" or "typical" impact values can be highly misleading. Nevertheless, assuming that these single values are representative of a technology is, unfortunately, a common practice in LCA [2]. In our case study, the minimum error of using average values can be of 10% (disregarding upstream variability) or 21% (considering upstream variability), while in the worst case, these deviations can reach values up to 114% (no upstream variability) and 658% (with upstream variability). For GWP, for instance, the difference in impact results considering upstream variability ranges from 158 to 263 kg CO_2 eq./m³ (the higher being 1.7 times the lower) which is a considerable level since it is almost of the same magnitude of the average impact. The variations observed are significantly above the level of variation recommended by ISO 21930 [14] for considering an “average EPD” valid, which is of ±10% of the environmental impact indicators, raising questions about the usability of those average assessments. By comparing technology options without considering variability between producers, one may select a product that looks better according to “average” values, but end up buying from a local producer that is actually much worse than its alternative.

Regarding uncertainty propagation, this work adopted a simplified approach of compiling ranges of extreme values, while there are more sophisticated techniques, e.g., Monte Carlo sampling. Although the probability of occurrence of extreme values is low (e.g., maximum cement content combined with maximum clinker content in cement and maximum emissions in clinker manufacturing), it is still possible since data were provided by existing suppliers. Therefore, the ranges presented here reflect the possible variations in ready-mix concrete impact results.

5. Conclusion

This works shows the high level of variation of life cycle impact results among some ready-mix concrete producers in Brazil, including both variations among concrete plants due to differences in mix design and among raw material suppliers. For GWP, the indicator most assessed for cement-based products, maximum impact values can be more than 2 times higher than minimum impact values. Depending on the impact category, total variability can be dominated by differences between concrete plants or by differences in the upstream processes.

It may be concluded that supplier selection based on environmental performance is a key strategy for reducing the overall environmental impacts in the construction sector, since bad performers will be forced by market conditions to improve their indicators, while good performers would be rewarded for their lower impact results. For decisions made when construction material suppliers are not yet defined, such as in early-design stages, the impact ranges must be considered when comparing technological alternatives and generic life cycle inventory databases must allow users to do so. This would allow LCA to effectively work as a sustainability promotion tool in the construction sector.

Acknowledgments

We would like to acknowledge the *Sustainable Recycling Industries* Program, the ecoinvent database and the Swiss Secretariat for Economic Affairs (SECO) for funding the data collection initiative for the development of life cycle inventories for construction products in Brazil, as well as the institutions involved in this project: IPT, USP, Unicamp, UFES, UFRGS and Quantis.

Ecological performance and recycling options of primary structures

Fadai A, Stephan D
Vienna University of Technology, Department of Structural Design and Timber Engineering, Karlsplatz 13 / 259-2, A-1040 Vienna, Austria

fadai@iti.tuwien.ac.at

Abstract. A sustainably and optimally building material is defined consequently in a well-balanced relation between ecological aspects and structural engineering requirements and should be selected depending on external conditions. By choosing environmentally friendly building materials and joining techniques, at least resource-efficient and sustainable construction can be achieved. As a contribution to the discussion about which building materials offer the most optimal and environmentally friendly properties for the construction industry, this paper gives an overview of sustainable construction. It illustrates the advantages and disadvantages of certain building materials and structural components by comparing their mechanical properties and ecological aspects using various types of life-cycle assessment (LCA). As far as construction materials are concerned, e.g. wood-based materials have the greatest potential in terms of renewable primary energy demand compared to all other constructions materials. Furthermore, due to the high recycling potential, wood has the lowest share of non-renewable primary energy demand, whereas the highest non-renewable primary energy demand is caused by mineral building materials. This paper illustrates how the natural resources can be used both optimally and sustainably. It presents a conceptual framework for scenario development of the LCA of primary structures, their effect on the design and decision-making process.

1 Introduction

2017 greenhouse gas (GHG) emissions in Austria have risen for the third time in succession (cf. **Figure 1-1**). With 51.7 million tons CO_2-equivalent (not including any emission allowances from the European Union Emissions Trading System) the national goal was initially exceeded. In total, emissions rose to 82.3 million tons, which equates to a 3.3 % increase compared to 2016. This is due to the increased usage of fossil fuels in the energy and industry sector (plus 5.4 %) as well as the increased demand for the transportation of goods. Also the emissions attributed to the transportation and building sector have noticeably risen. On the contrary, the waste management industry and agricultural sector recorded falling emissions compared to 2016 [1].

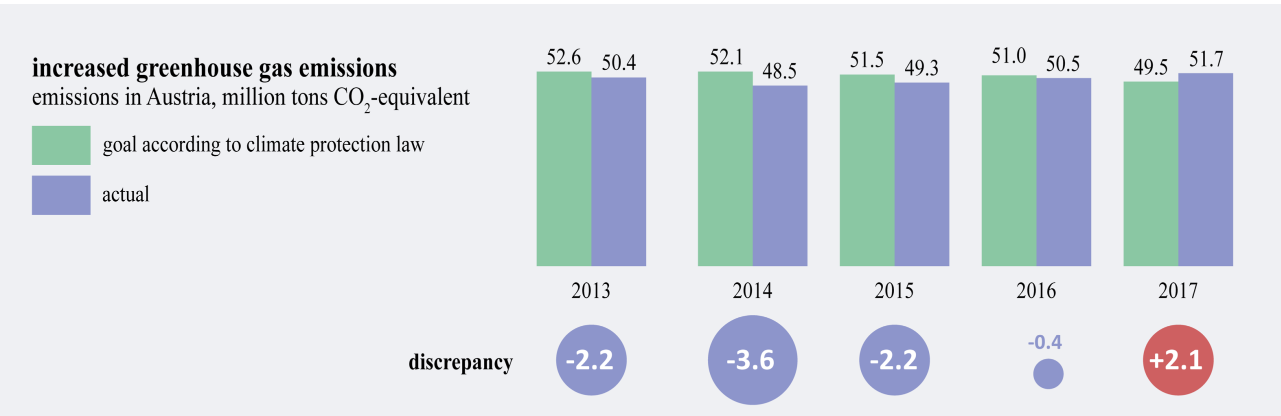

Figure 1-1 Greenhouse emissions in Austria from 2013 to 2017 [1]

1.1 State of the Art
An integral part of the European energy strategy is the increase of power efficiency. On one hand, the European council demands a 20% reduction of greenhouse emissions by the year 2020, compared to 1990 and a 20% share of renewable energy of the final energy consumption throughout the European Union. On the other hand, an increase of power efficiency is being demanded, so that the initial value for 2020 is undercut by 20% [2].

Particularly in the building sector, the focus lies on residential building. As a whole, residential buildings hold a high proportion of energy usage in this sector. But, thanks to the stricter requirements on new constructions in the past two decades and the reinforced funding conditions, the emissions induced by heating the buildings stayed relatively constant from 1990 to 2003 [2].

Nowadays the required energy standard of buildings according to building regulation is at the level of a low-energy house. By introducing the "Energy Performance of Buildings Directive", the European council established the basis for uniform valuation. These guidelines indicate that a building has to be sustainable, the used construction materials and components have to be recyclable and the use of environmentally friendly resources and secondary materials is welcome [2].

1.2 Deconstruction and recyclability
Recycling means employing the materials used for the construction and operation of a building after the initial use for a new purpose [3]. Waste products turn into secondary raw material. Easier dismantlability of an object into its components means that this object shows a better deconstruction [4]. Already in the planning stage of construction projects (cf. **Table 1-1**), recyclability of the materials has to be considered. Preferably, recyclable components or already recycled components should be used. In **Table 1-1** the life cycle phases of a building are classified.

Table 1-1 Life cycle phases of a building. [5]

Life cycle phases of a building																Additional information outside of the life cycle
A1-3 Product stage			A4-5 Construc-tion stage		B1-7 Use stage							C1-4 end of life cycle				*D* *advantages and liabilities outside of the system boundaries*
A1 Raw material supply	A2 Transport	A3 Manufacturing	A4 Transport to construction site	A5 Installation at construction site	B1 Use	B2 Maintenance	B3 Repair	B4 Replacement	B5 Refurbishment	B6 Operational energy use	B7 Operational water use	C1 De-construction and demolition	C2 Transport	C3 Waste processing	C4 Disposal	*Potential of reuse. Recycling and energy recovery*

The following factors concerning the recyclability should be considered [4]:

- Homogeneity
  Used building materials should be as homogenous as possible. The less different the materials are, the less differentiated the waste management is [3].
- Separability
  Material compounds which are easily separable, are ecologically valuable. Easily detachable materials increase the probability of a pure division and the recirculation into the substance flow [3].

- <u>Absence of pollutants</u>
  The use of building materials, that are harmful for the environment and the people, is being significantly reduced in sustainable construction. Moreover, the diligent use of unpolluted recyclable building materials optimizes the economic efficiency of the materials cycle and prolongs the material's lifespan [3].

The lifecycle of the construction alternatives is being analyzed according to EN 15978 "Sustainability of construction works - Assessment of environmental performance of buildings - Calculation method". [6]

2 Life cycle assessment indicators

For the life cycle assessment of building materials, the following indicators are being calculated based on the German Sustainable Building Council (DGNB) [7]:

- Primary energy content PEI_{ne}, PEI_e [MJ]
- Global warming potential GWP [kg CO_2 – eq] calculated over a time horizon of 100 years
- Acidification potential AP [kg SO_2 – eq]

3 Systematic analysis of the environmental impact of building materials

The ecological attributes of the compared building materials originate from "IBU-EPD" [8], a standardized database for ecological evaluations by the Federal Ministry of Interior, Building and Community in Germany. Most of the available data refers to the life cycle phase A1-3 "production phase" (cf. **Table 1-1**).

Figure 3-1 shows the environmental impact of wood (oriented strand board, solid structural timber, medium density fiberboard) compared to bricks (insulating and non-insulating) and concrete (different classes of compression strength). The data indicates the environmental impact per m³.

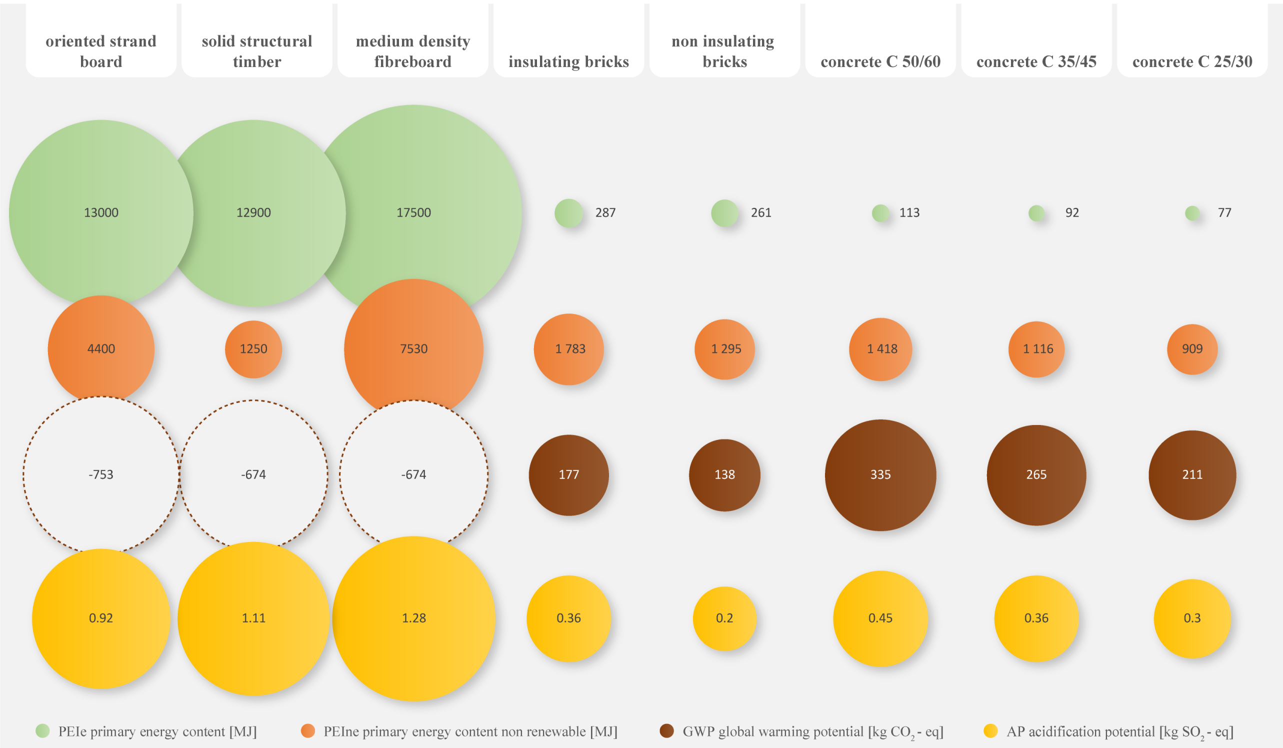

Figure 3-1 LCA indicators of building materials per m³ for the "production phase" A1-3.

Generally speaking, wood has relatively high primary energy content values in the production phases A1-3 (c.f. **Figure 3-1**). Nevertheless, compared to the other building materials most of the primary energy content is renewable. Bricks with a density of 740 kg/m³ have better environmental effects than those filled with pearlite (density 800 kg/m³). However, with the non-insulating bricks, an insulation layer with relatively high environmental impacts will most probably be needed later on. The environmental impacts of concrete increase with the compression strength. Concrete C25/30 therefore causes the least environmental effects whereas concrete C50/60 causes the most.

4 Structural elements

The ecological values of the compared structural elements also originate from "IBU-EPD" [8]. To ensure comparability all values are referenced to 1 m² of the component. The period of observation is 100 years and all life cycle phases, including phase D „*advantages and liabilities outside of the system boundaries*" are considered (c.f. **Table 1-1**). Furthermore, the structural elements were calculated referring to the location of Vienna.

4.1 Intermediate floors

Comparing the different versions of intermediate floor structures (c.f. **Figure 4-1**), it is noticeable that concrete structures have the lowest renewable primary energy consumption but nevertheless the highest non-renewable primary energy consumption. In contrast, timber floors have the highest potential in renewable primary energy consumption, while in most cases having negative non renewable primary energy consumption values, which counts as a credit for the rest of its life cycle.

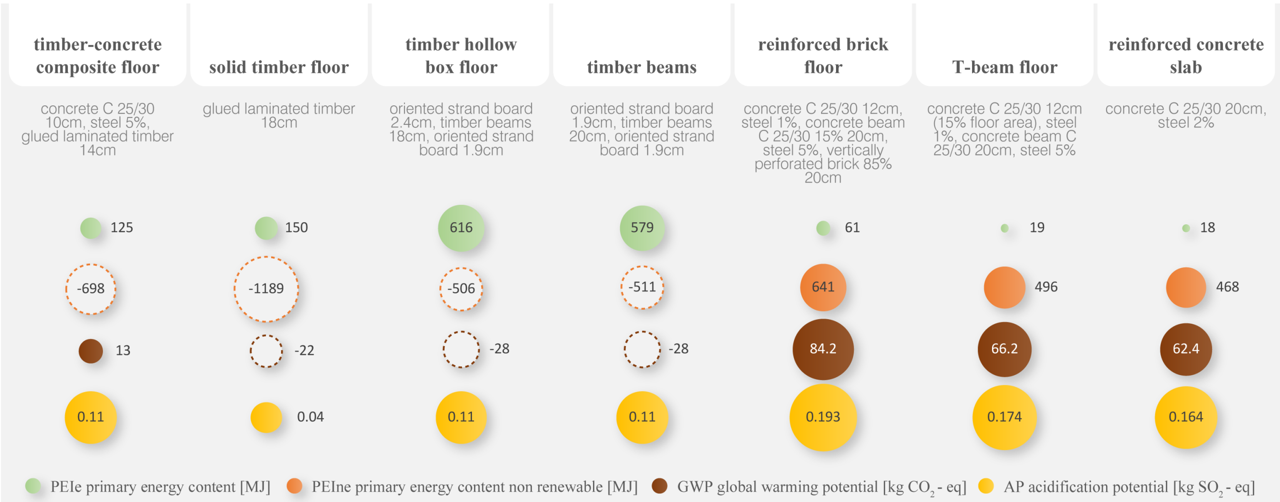

Figure 4-1 LCA indicators of intermediate floors (only constructions) per m² for the life cycle phases A-D.

4.2 Intermediate floors including floor assemblies

Concrete structures have a relatively low primary energy demand, but have the highest non-renewable primary energy demand (c.f. **Figure 4-2**). Especially, the T-Beam floor with cement screed and laminate hast outstandingly high values. By comparison, wooden floor structures have the highest potential for renewable primary energy demand and, in most cases, have negative values for non-renewable primary energy demand, which can be counted as a credit for the further life cycle. An example for this is the solid timber floor with cement screed and stoneware tiles.

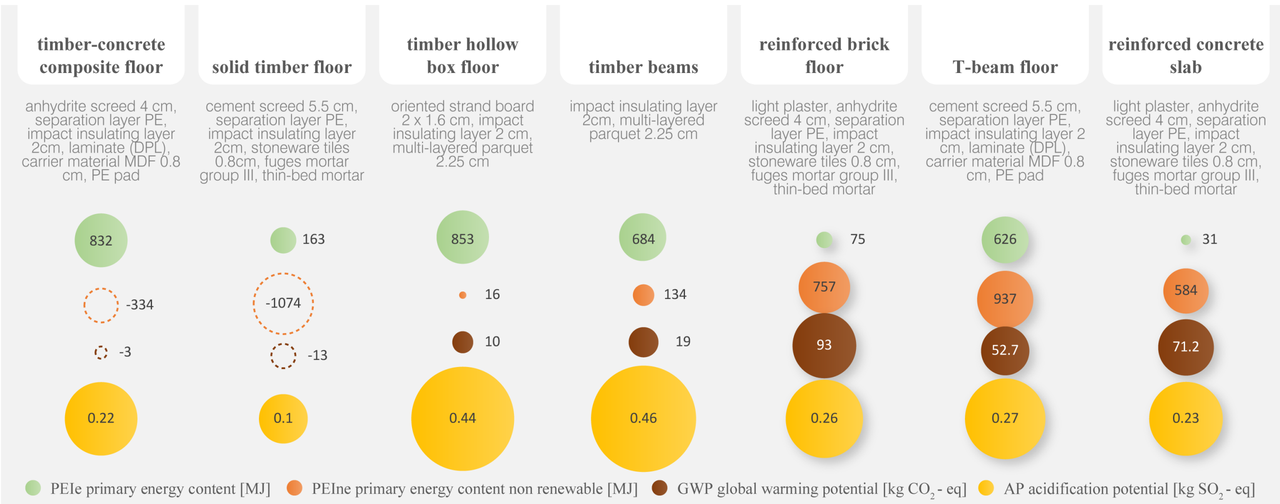

Figure 4-2 LCA indicators of intermediate floors incl. floor assembly per m² for the life cycle phases A-D.

4.3 Flat roof structures

Comparing the entire flat roof structures (c.f. **Figure 4-3**), it is noticeable, that the classic inverted roof has the highest ecological values in every aspect. The conventional warm roof performs the best. Merely the renewable primary energy consumption values are the same for all three roofs.

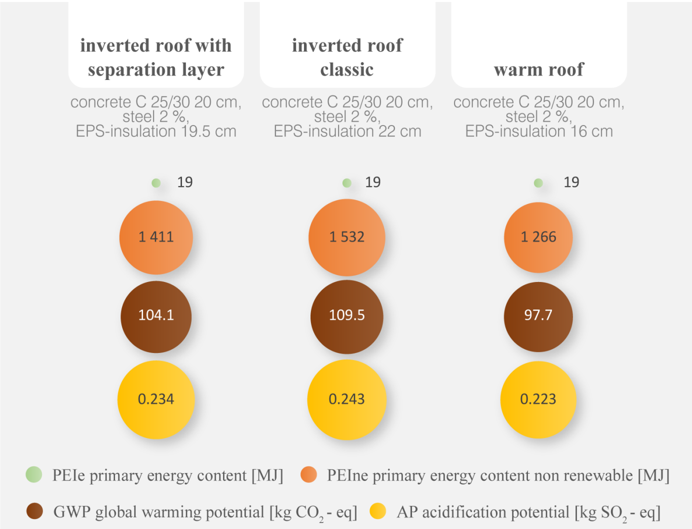

Figure 4-3 LCA indicators of flat roof structures (only construction) per m² for the life cycle phases A-D.

4.4 Flat roof structures including finished components

As shown in **Figure 4-4**, the classic inverted roof has the highest environmental impact in every aspect. A standard warm roof has the lowest values in all categories. Only in the case of the values for the renewable primary energy demand, the flat roof structures hardly differ. However, with regard to the roof construction it is noticeable, that the values of the individual roofs have become more similar.

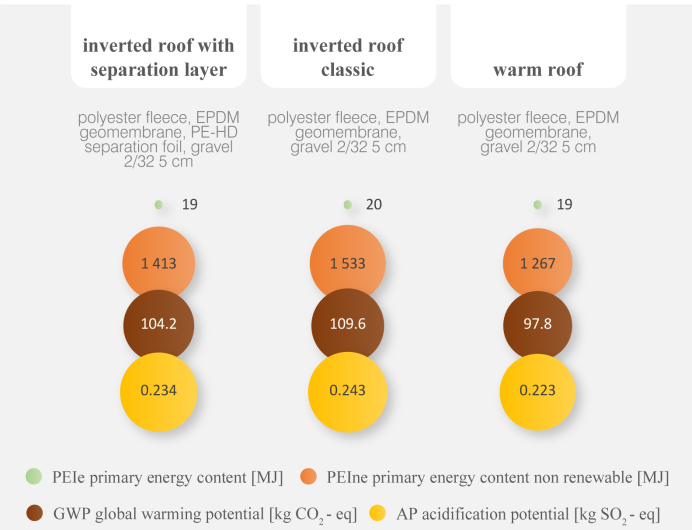

Figure 4-4 LCA indicators of flat roofs including finished components per m² for the life cycle phases A-D.

4.5 Opaque external walls

As shown in **Figure 4-5**, the renewable primary energy consumption values for brick and concrete walls in opaque external walls are the lowest, while their non-renewable primary energy consumption values are the highest. Timber constructions on the other hand perform better.

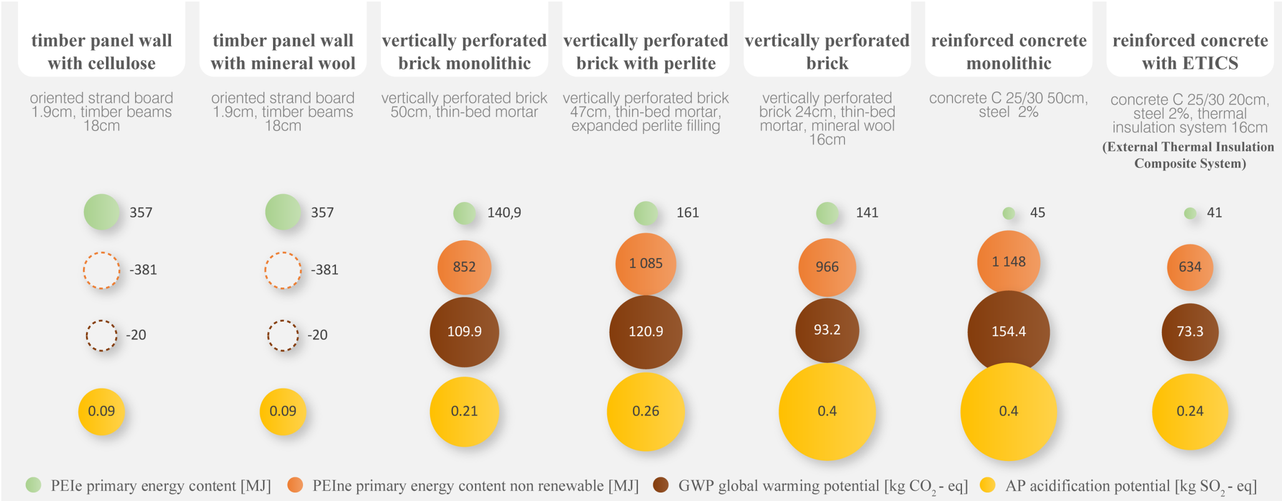

Figure 4-5 LCA indicators of opaque external walls (only construction) per m² for the life cycle phases A-D.

4.6 Opaque external walls including wall assemblies

Brick and concrete structures have the lowest values for the renewable primary energy demand, but the highest values for non-renewable primary energy demand. (c.f. **Figure 4-6**) Particularly, the reinforced concrete monolithic wall has a significantly higher primary energy demand than the other mineral wall structures. Timber constructions on the other hand perform better in this respect. Similar to intermediate floors, timber constructions consume a significantly lower amount of non-renewable primary energy.

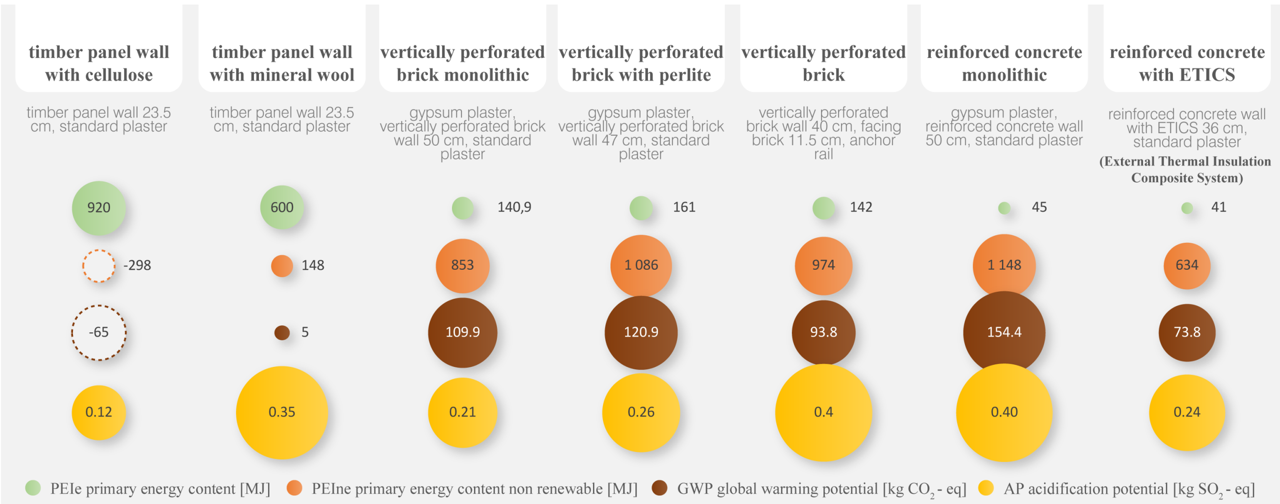

Figure 4-6 LCA indicators of opaque external walls including assemblies per m² for the life cycle phases A-D.

5 Case study

The case study consists of following components: the building site is in the yard of the main building of the Vienna University of Technology at the 4th municipal District of Vienna, Austria. The floor area of the building is 24 x 24m and is planned with two upper floors and a punctuated façade. The number of floors was chosen to give the investigation the best possible conditions. The total height of the building is 9.55 m, the floor height is 3.10 m and the clear room height is 2.70 m. The room has a floor area of 9 x 5.5m, is strained on one side and has a span width of 5.5m. The exterior design of the building (**Figure 5-1**) is a punctuated façade, which is plastered depending on the building type (bricks, ETICS = external thermal insulation composite systems) or on sight (exposed concrete).

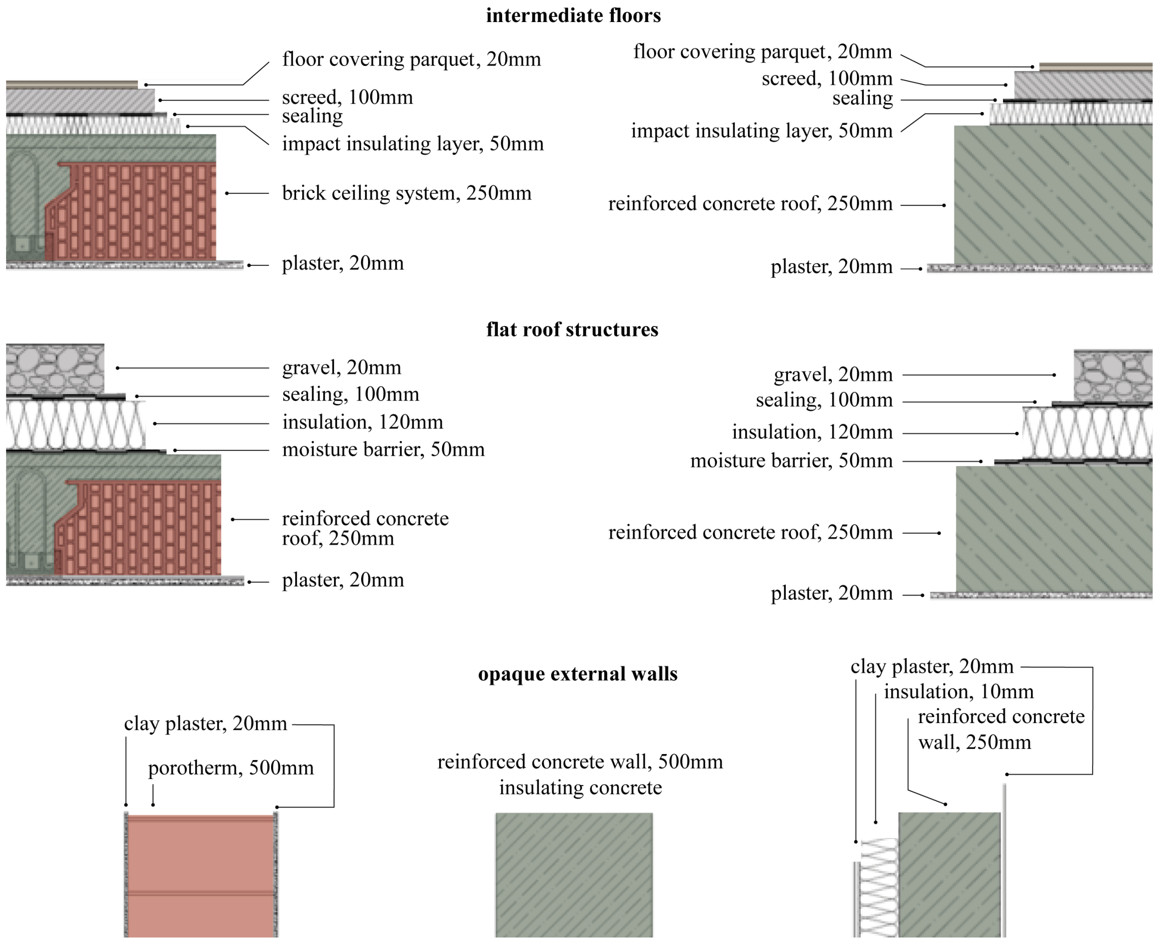

Figure 5-1 Detailed view of the chosen components

5.1 Optimization of material usage in the construction process

Both sustainability and ecological ideas should be understood as a process. To give an overview of the optimization measures in this process, individual planning strategies and processes are assigned to the generally valid planning phases: preliminary study, competition / preliminary planning, conceptual design / approval planning, tendering and contracting / implementation planning, execution / completion, handover / operation [9].

In the life cycle of materials, attention is paid to the use of resource-saving and environmental friendly building materials, whereas the focus in the building life cycle is on the adaptation of the intended use. In the material life cycle this means: use of permanently available resources, use of building materials with low primary energy consumption, use of pollutant-free and low-emission products, exchange of primary raw materials through recycling material, design optimization of the used components, preparation for reuse [9].

When optimizing use in the building life cycle, the following principles must be observed: adaptation to intended use, adaptation to durability and integration of efficiency enhancing designs, use of recoverable constructions, integration for possible conversion [9].

5.2 Component optimization of the construction model

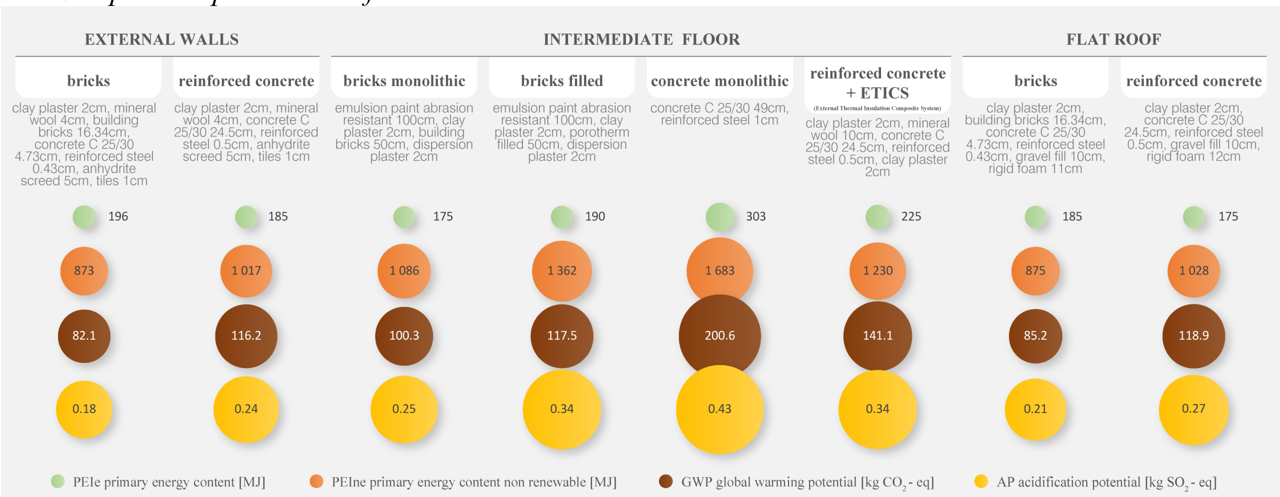

Figure 5-2 Life cycle assessment indicators of the construction model per m² for the life cycle phases A-D.

Based on necessary component optimization, the monolithic construction, both in concrete and in bricks, need more measures to achieve the summer suitability according to ÖNORM B 8110-3 [10] than constructions with a thermal insulation composite system. The concrete performs better within the particular construction. However, the best protection against summer overheating, regardless of building material, is nocturnal ventilation to get the indoor heat out of the room. It can be observed, that with an optimized design, the orientation of the room has little effect on the course of the operative room temperature.

The LCA in **Figure 5-2** shows that, among the selected parameters, the non-renewable primary energy consumption has the largest environmental impact. Within the chosen system boundaries concrete constructions tend to produce more environmental effects than brick constructions. For concrete, the monolithic variant has significantly higher environmental impacts than the insulated component, whereas for brick components the insulated brick components cause more environmental effects than the monolithic counterpart.

Overall, the calculations for the external wall reveal significantly greater differences in the component variants than would be the case with intermediate floors or flat roofs.

6 Conclusion

A sustainably and optimally building material is defined consequently in a well-balanced relation between ecological aspects and structural engineering requirements and should be selected depending on external conditions. By choosing environmentally friendly building materials and joining techniques, at least resource-efficient and sustainable construction can be achieved.

In the context of the building there are many aspects to be considered. Building materials are in a functional relationship with each other and with the construction structure. When assessing the overall situation, aspects such as location, climatic conditions, availability of renewable energy sources, user behavior or special need of the client play such an important role that they have to be taken into account when choosing the building materials.

The ecological performance and recycling options of the components are influenced to a great extent by both the choice of construction material and the insulating material, details and the type of construction in general as well as the methods of reusing and recycling them.

By selecting environmentally friendly building materials and joining techniques, at least resource-saving and sustainable construction can be achieved. Legal requirements and minimum standards will make the need to incorporate sustainable criteria into the planning process more relevant in the future. Nevertheless, it can be seen that today the results vary greatly due to different data bases. Each database and rating system is based on different criteria and objectives. Therefore it is advisable to deal with this early in the planning process and to adapt the objectives of the construction planning. Sustainable building planning requires holistic and flexible planning. Long-term thinking and matching the lifespan of building materials with utilization flexibility is essential for ecological construction.

Abstract. Along with the urbanization process, large amount of construction and demolition (C&D) waste during the construction, reconstruction, expansion or demolition of buildings is generated. Meanwhile, the impact on environment due to natural aggregate mining has become increasingly significant. These factors have driven the building industry to look for environmentally friendly materials and focusing on sustainable construction. Through nearly a decade of research, recycled concrete (RC) made with recycled aggregates manufactured from construction and demolition (C&D) waste has shown a competitive performance compared to natural materials and has already achieved industrial application. Researches on sustainably recycled concrete have become an essential part of sustainable development and continue to play a vital role for future research.
This paper engages in the discussion and the overview of research done by the Research Group for Recycled Concrete Structures and Construction at Tongji University, Shanghai. The first part discusses the necessary mechanical and durability properties of recycled concrete with recycled aggregate as well as recycled powder focusing on workability, strength, Poisson's ratio, stress-strain behaviour along with carbonation, chloride penetration shrinkage and creep. The second part throws light on the elements and structures made with recycled aggregate concrete (RAC), discussing the behaviours of RAC components and structures.

1. Introduction

In recent years, large upscale of the construction sector and increasing requirement of advance and new habitats, caused by population growth and migration from rural to urban, have exploited a large number of construction materials. Environmental regulations and depletion of high-quality aggregates along with urgent need make natural aggregate the last option for the construction industry. Moreover, increase the cost of haulage from one place to another adds up to the increased cost of final construction materials along with explosive urbanization and increase modernization for alternate materials for construction. To reduce the impact on the environment and reduce the landfill space, it is of the dire need of finding an alternative for the construction materials in a friendlier and economical way. Moreover, to have a sustainable concrete industry, the attention should be paid to the conserve energy, resources, and environment protection.

In last decade, China has witnessed the significant degradation of natural resources. There has been a massive generation of C&D waste, which accounts for the 500 million tons of waste generated annually [1,2] as shown in Figure 1. Recycled aggregate concrete (RAC) being a sustainable material on one side, also helpful in saving the ecology by reducing the use of natural aggregates (NA). Literature suggests that the mechanical properties of recycled aggregate (RA) may be lower than those of normal concrete (NC) generally, but can be utilized in practical application for the structural purpose [3–5]. Studies prove that there are differences between the properties of recycled coarse aggregate (RCA) and natural coarse aggregate (NCA), due to some physical properties like rough and porous surface, reduced bulk and apparent density, increased porosity and adhered mortar on aggregates. These properties impact on the crushing value, soundness, and water absorption of aggregates, which are bases for the strength indexes of any concrete [5–9]. At present, implementing RAC is still at a demonstration phase, but our group has focused the research from 2004 onwards on RAC studies, thru micro-, meso- and full-scale structure.

2. RAC materials

2.1. Strength indexes

The compressive strength is one of the most essential mechanical property, which is the basis for the differentiation of RAC as compared to natural aggregate concrete (NAC). Due to difference in the physical properties between RCA and NCA compressive strength is the most important mechanical property. Based on the overall analysis of the results at early stage the compressive strength of RAC follows a similar pattern with NAC when undergoing curing.

For the evaluation of factors influencing the strength indexes and research has been carried out a test on more and 635 cube specimens in the concrete materials research laboratory, Tongji University, China. During the research phase of concrete with RA, various mixes were made using the different replacement ratio. This paper represents the review of the work done by the research team in Tongji University. Mixes with the different water-cement ratio (w/c) and the obtained results are shown in Figure 2, which shows the relative cube compressive strength at 28 days concrete strength of RAC which was cured in fog room (20±2 °C, 95% relative humidity). Figure 2 shows that the development of compressive strength coefficient before 28 days curing of RAC is higher than that of NAC. Whereas, the strength development coefficient after 28 days of curing of RAC is less than that of NAC. The reason being that additional water absorption of RA tends to provide additional internal curing in RAC than NAC. Another factor influencing the compressive strength is the weak bonding between the recycled concrete aggregate (RCA) and the new and old mortar. At the same time, higher w/c ratio leads to excess water in the pores of RCA [1,10].

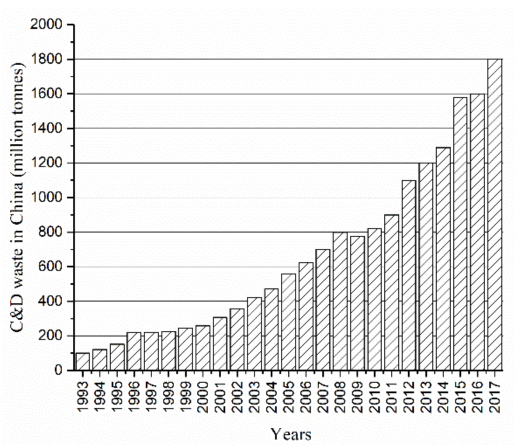

Figure 1: C&D waste generation in China [1,2]

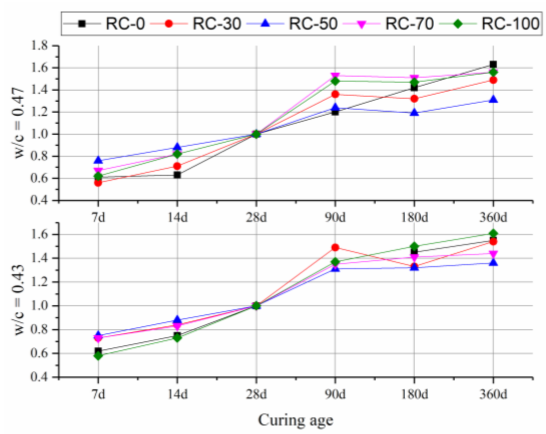

Figure 2: Relative cube compressive strength at 28 days

The results were analysed using a statistical approach to compare the outcome of RAC with NAC, which followed a normal distribution. The analysis showed that the coefficient of variance (COV) of compressive strength is not very large as compared to NAC, proving that the RCA replacement does not influence the RAC's compressive strength variation coefficient. Furthermore, to check the feasibility of a normal distribution model, Monte Carlo simulation was used for evaluation of strength distribution of RAC and probability density function (π(σ)) for concrete compressive strength of RAC was obtained:

$$\pi(\sigma) = \frac{1}{\sqrt{2\pi}\sigma_\sigma} e^{-\frac{(\sigma-\mu_\sigma)^2}{2\sigma_\sigma^2}} \qquad \text{Eq. 1}$$

Where, the average value of the standard deviation of compressive strength μ_σ =4.31 MPa, and the standard deviation σ_σ =1.1141 MPa. Furthermore, the Bayes estimation was used to get the SD for the various strength grade as shown in Table 1, but considering the situation the mixing plants, SD of RAC30 was kept at 5.0 MPa, which is closely identical to that of NAC but only applicable to the RCA from a single source which can control the quality of RCA.

Table 1: The Bayes estimation results of the standard deviation for RAC C30 compressive strength

***r* (%)**	0	30	50	100
σ (MPa)	4.31	4.5	3.95	3.2

On further analysis, after the comparison between the experimental and simulation data, the following relationships between the splitting tensile strength and the compressive strength, flexural strength and the compressive strength of the RAC are shown in Eq. 2 and Eq. 3 respectively [11].

$$f_{sp} = 0.24 f_{cu}^{0.65} \qquad \text{Eq. 2}$$

$$f_f = 0.75\sqrt{f_{cu}} \qquad \text{Eq. 3}$$

Where, f_{cu} is the compressive strength in MPa, f_{sp} is splitting tensile strength in MPa and f_f is the flexural strength in MPa.

2.2 Constitutive relationship

For the constitutive relationship between various parameters of concrete, with an investigation on a stress-strain curve with/without confinements [12], axial loading [13], shear loading [14] and impact loading [15] along with shear transfer behavior and compressive behavior of RAC under high strain rate. During testing, strain rate of the test specimens was kept constant to 44×10^{-6}/s and Eq. 4 [16] was used to represent the axial loading constitutive model for the linear analysis of the RAC structure and members:

$$y = \begin{cases} ax + (3-2a)x^2 + (a-2)x^3 & 0 \le x < 1 \\ \dfrac{x}{b(x-1)^2 + x} & x \ge 1 \end{cases} \qquad \text{Eq. 4}$$

The values attained a and b using the statistical data are:

$$a = 2.2(0.748r^2 - 1.231r + 0.975)$$

$$b = 0.8(7.6483r + 1.142)$$

1.

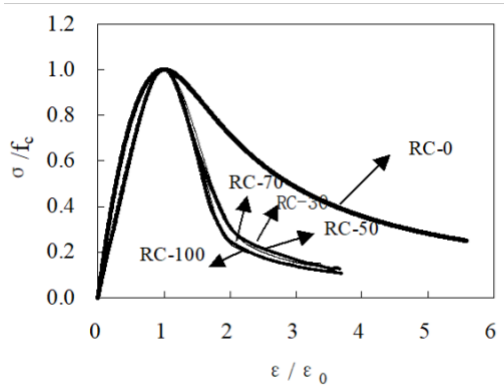

Figure 3: Normalized stress-strain curve for recycled aggregate

Where, $x = \varepsilon / \varepsilon_0, y = \sigma / f_c$ from a normalized recycled concrete stress-strain curves as shown in Figure 3, a is the initial gradient line non-dimensional curve, it reflects RAC's initial modulus of elasticity, b the value is related to the non-dimensional dropping stage of the curve area, representing the ductility of concrete and r is the replacement ratio of RCA.

2.3 Long term properties

In real conditions, the materials are usually exposed to prolong loading or cyclic loading during the design life of a structure. The first and far most important long-term property is shrinkage and creep. Test were carried out as per GB/T 50090-2002 [17]. The shrinkage and creep of RAC with four different replacements ratio of 33, 66 and 100% are 2.6, 15.4 and 26.9% and 28.7, 75 and 103% higher than that of NAC respectively, whereas environment has no drastic impact on the shrinkage and creep of RAC [18]. Mineral admixtures, water-reducing agents, bulking agents, etc. can reduce shrinkage deformation, whereas old adhering mortar cannot be ignored when calculating the creep of RAC because creep characteristics of RAC are influenced significantly by the content, elastic modulus, and creep behaviour of the old adhering mortar.

Evaluation of carbonation and chloride diffusivity are by Chinese codes GB/T50082-2009 [19] which are the second most long-term property. The porosity and attached mortar, which is higher in RCA than natural aggregate along with the same w/c ratio, can improve the carbonation resistance. Based on ghe esisting formula from *fib* carboantion model [20], Chinese code's model [21], Zhang and Jiang's model [22], Xiao and Lei [23] represented two modified carbonation models, namely Xiao and Lei Model 'a' (Eq. 5) and Xiao and Lei Model 'b' (Eq. 6). These models are based on the factor, replacement percentage, which is an important factor in prediciton of carbonation depth.

$$x_c(t) = K_{CO_2} \cdot K_{k1} \cdot K_{ks} \cdot T^{0.25} \cdot RH^{1.5} \cdot (1 - RH) \cdot \left(\frac{230}{f_{cu}^{RC}} + 2.5 \right) \cdot \sqrt{t} \quad \text{Eq. 5}$$

$$x_c(t) = 839 \cdot g_{RC} (1 - RH)^{1.1} \sqrt{\frac{W / \gamma_c C - 0.34}{\gamma_{HD} \gamma_c C} n_0} \cdot \sqrt{t} \quad \text{Eq. 6}$$

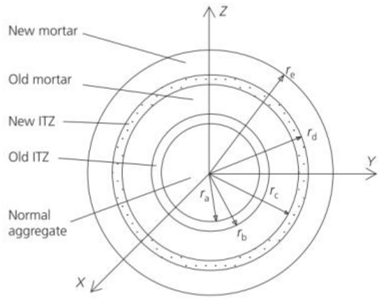

Figure 4: Five-phase composite model of RA

where $x_c(t)$ is the carbonation depth of concrete at time t, in mm; W is the water content (kg/m^3); C is the cement content (kg/m^3); γ_c is the coefficient for cement type (1.0 for Portland cement); γ_{HD} is the coefficient of the degree of hydration (0.85 for 28 days' curing, 1.0 for 90 days' curing); and n_0 is the CO_2 concentration by volume (%); K_{CO2} is the factor of CO_2 concentration, $K_{CO_2} = \sqrt{\frac{n_0}{0.02}}$; K_{k1} is the location factor, 1.4 for corner and 1.0 for another place; K_{ks} is the stress factor, 1.0 for compression and 1.1 for tension; T is the temperature (°C); RH is the relative humidity; f_{cu}^{RC} is mean value of RAC compressive strength; and g_{RC} equals to 1.0, while for RAC with a 100% replacement percentage of RCA, g_{RC} equals to 1.5. On the other hand, for chloride diffusivity, the experimental and theoretical data are generally in agreement with Fick's second law similar having a deviation from NAC. Moreover, Xiao et al. [24] proposed a model that considered RAC as a five-phase composite model (Figure 4) [25] in order to describe the chloride diffusion coefficient (D_{eff}) in RAC (Eq. 7 and Eq. 8). Based on the residual mortars, which is the critical factor, the RAC will become NAC when the attached mortar value is less than the threshold value of 0.5.

$$D_{eff} = \frac{x^2}{4\left[erfc^{-1}\left(\frac{C_{mean}}{C_s}\right)\right]^2 t} \quad \text{Eq. 7}$$

$$C_T = \int_{-5mm}^{+5mm} C(5,y)dy \quad \text{Eq. 8}$$

where C_s is the boundary conditions of chloride concentration (x10^{-1} mg/mm^3), and erfc^{-1}() is the inverse complementary error function, C_{mean} is the mean value of C_T at the position of x and the mean value of chloride amount along the boundary X = 5 mm is calculated by Cmean = CT ÷10 mm.

Theoretical equation, finite element method (FEM) and simulation on modeled RAC (MRAC) [26] showed that D_{eff} decreases with the rise in RCA volume fraction, but increases with the adhesive rate of the old mortar adhering and the thickness of the ITZ.

3 New types of RAC

3.1 Modification of conventional RAC

Compared to traditional concrete, it is hard to predict the properties of RAC on a direct basis. Investigators have found that a two-stage mixing approach (TSMA) have improved the mechanical properties and durability of RAC [27]. Nano-indentation was used to evaluate the microstructural and nanomechanical properties of ITZs in RAC prepared with different mixing approaches. The contour variation of indentation modulus histogram is seen in old ITZ and new ITZ with TSMA (Figure 5). The result proves that TSMA can effectively reduce the size and effect of water layers, reducing the amount of porosity enhancing hydration. TSMA also produce a stronger and denser ITZ due to the calcium carbonate crystals covering the RCA surface [28].
Moreover, it should be noted that modulus distribution with age of old and new ITZ is different. The properties of old ITZ in RAC do not change with the hydration age, while the indentation modulus of new ITZ and new paste matrix increases with the curing age

Nano-SiO_2 and nano-TiO_2 particles were also used to enhance the properties of RAC. Due to the large specific surface area and high activity [29], nano-particles helped in refining the pore structure of RAC. The pore structure increases and then decreases up to an extent with increasing content. Results proved that 2% addition of nano-TiO_2 is slightly better than nano-SiO_2 [30]. Moreover, hydrated cement in old ITZ between gravel and cement paste (OITZ), the calcium silicate hydrate (CSH) having a short rapid growth and decline rapidly, whereas in new ITZ between new and old cement paste (NITZ) the rapid growth is close to zero and begin with a relatively high generation of CSH gel.

3.2 Sea-water and Sea-sand RAC

Based on the previous studies and sustainability issues, the combination of seawater, sea-sand, and RCA was investigated. The focus is on the demolition of the structures from coastal and the marine regions, which suffer the corrosion from chemicals like chloride, and hard to separate the harmful chemicals from the waste. So, this kind of concrete can be used to deal with resource exhaustion and the disposal of waste concrete [31]. Two additional types of sea-sand with seawater is used for mixing of concrete. Various concrete mixes were cast and tested for the mechanical properties of properties were examined. The concrete produced with sea-sand, seawater, and RAC showed good cohesion, required workability, increased behavior of early strength is noted but delayed in the underlying strength. Moreover, an increase in 8%-16% of elastic modulus is observed in the concrete made with sea-sand, seawater, and RAC, following the models for strain and strain by previous researchers and specifications [10,32]. Figure 6 and Figure 7 represent the compressive strength, split tensile and variation between split tensile and axial compressive strength of concrete made with sea-sand, seawater, and RCA.

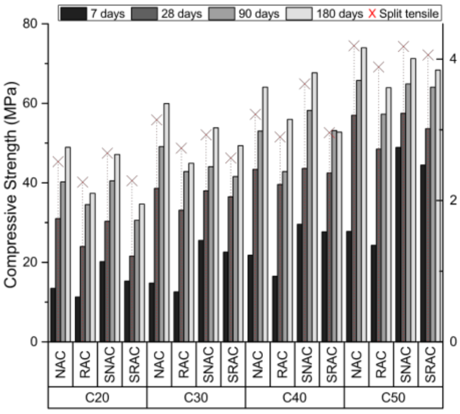

Figure 6: Variation between the strength of different strength grade

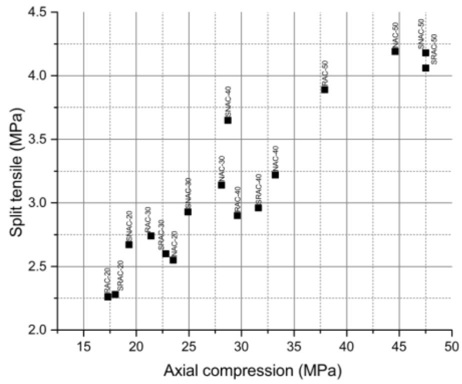

Figure 7: Variation between axial and split tensile strength

4 RAC structures

4.1 Flexural and shear properties

Properties may differ due to different mix proportions and different replacement percentage of RA. Based on these, semi-precast elements are better in quality as compared to precast hybrid-components. Flexural and shear specimens were cast with U-shape and C-shape precast beams, regular and eccentric columns and slabs for shear. Based on the assumptions of “plan cross-section” and the results, plane section assumptions remain valid in applications for semi-precast beams made of RAC and follows the Chinese code DG/TJ08-2018-2007 [33]. Based on the reliability analysis, beams showed that the reliability was lowest and highest when 100% permanent and 100% live load was applied respectively [34]. In bending behavior of RAC beam, diagonal cross-sectional area cracking load is smaller than NAC. Also, the cracking pattern, deflections, and bearing capacity of U-, C-shaped beams are similar to that of NAC beams with no adverse effects on flexural performance. Along with RAC columns under axial and eccentric compressions, the RAC column showed failure by axial compression, small eccentricity compression failure, limit failure, and large eccentric compression failure, and the increase in the RCA replacement percentage did not cause any change.

4.2 Seismic performance

Based on the test on the precast elements, under cyclic loading, the characteristics of the RAC elements are the same as that of NAC. The ductility coefficient of fully cast-in-situ is more than that of semi-cast columns, along with better ductility of external elements than internal. These results conclude on the full-scale test on the elements with a generation of hysteresis loops. In this study, understanding of structural behaviour of frames under low-frequency cyclic lateral load with constant vertical actions. Based on these the failure pattern, the hysteresis curves, the skeleton curves, the energy dissipation capacity, and the stiffness degradation laws of frame structures with RAC were examined. The failure of the frames is characterized in a manner of “strongest joints, stronger columns and weaker beams” because the ductility coefficient was about 4.0 implying the fine ductility of the structural frames [35]. Whereas, RCA has no remarkable effect on the energy dissipation capacity of frames and is good enough to resist earthquake according to Chinese standard GB 50011-2001 [36].

5 Life cycle assessment

Apart from the specifications, and technical objectives, the drive toward sustainable development leads to the methodological framework and the life cycle assessment (LCA). From the time of introduction from 1994, International Standard Organization (ISO) played an essential role in the area of multi-criteria optimization for NAC and RAC, based on their local life cycle inventory (LCI) [37–41]. The research was focused on the feasibility of aggregate delivery and production and is based on ISO 1404

(2016) and ISO 14044 (2006) [37,39]. In this study, the data for regional LCI for NAC and RAC collected and comparative study was made between both with 50% and 100% replacement ratio to have a rational understanding of LCA [42]. To be more precise the cradle-to-grave theory was adopted to change it to cradle-to-cradle (Figure 8) shows the methodologies. Another method for the LCA based on the CO_2 absorption model is evaluated. Effect of NAC replacement with RAC on the carbon footprint of a tall structure having 12 floors and area of 15000 m^2 were investigated. The system boundary used in this study, as shown in Figure 9. In this whole study, the pre-wetting RCA were used to provide the required additional water.

It should be noted that utilizing non-local LCI data for estimation of carbon emissions. The assumption was made on the choice of NAC or RAC as the new building material, which has been the determining factor which affects the choice of waste processing strategy, recycling vs. landfilling, for the container terminal. Based on these, the end-of-life phase of the demolished project was considered. The RAC and NAC structures emitted on average 2.152×10^6 (i.e., 143.47 kgC_e/m^2 or 366.64 kgC_e/m^3 of concrete) and 2.302 $\times10^6$ kgC_e (i.e., 153.47 kgC_e/m^2 or 392.20 kgC_e/m^3 of concrete), respectively. Furthermore, these two towers led, on average, to 8.345×10^6 MJ (i.e., 556.32 MJ/m^2 or 1421.71 MJ/m^3) and 8.907×10^6 MJ (i.e., 593.78MJ/m^2 or 1517.45MJ/m^3 of concrete) embodied energy, respectively. Based on the RAC's environmental benefits and reduced embodied carbon, energy consumption, need of natural resource and C&D wastes processing and its competitive structural performance, the result highlights RAC as a sustainable alternative to NAC. The carbon emission implications of RAC were found to be highly dependent on landfill and transportation phases.

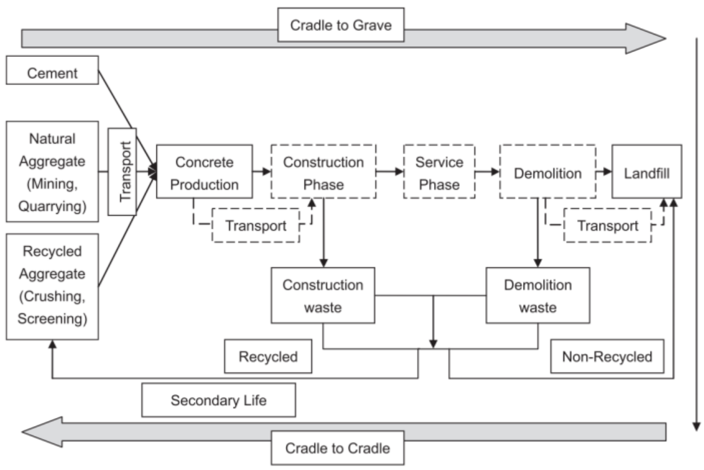

Figure 8: Methodologies from cradle-to-grave and cradle-to-cradle

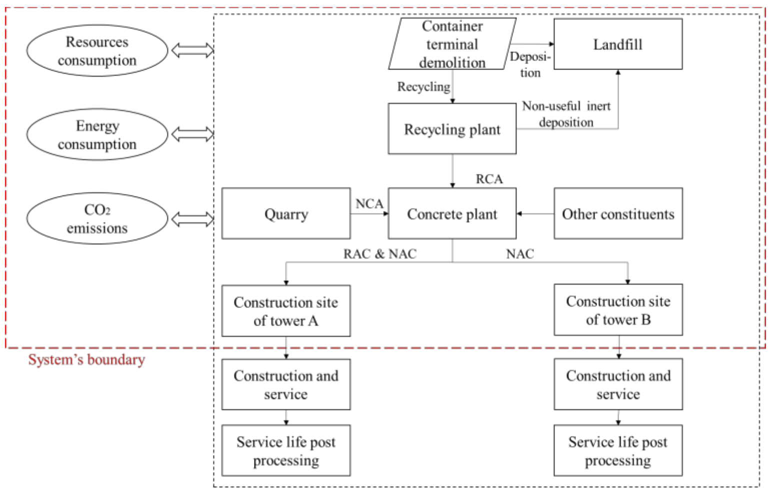

Figure 9: System's boundary and LCI analysis based procedures

6 Conclusions

Based on the experimental results and analysis, the main findings can be summarized as follows:

The structural behaviour of RAC elements/members has inferior properties as compared to members or structures made with NAC. Tensile and shear strengths of RAC are generally lower than those of conventional concrete, modulus of elasticity for RAC generally reduces as the RCA content increases; however, the strain at peak stress is larger than that of conventional concrete. Additional modification parameters such addition of nano-SiO_2 and nano-TiO_2 helps in enhancing the durability, chloride diffusion resistivity. Whereas, the modification with carbonation proves to be beneficial for enhancing the interfacial properties of RAC. Sea-sand and seawater minimum affect the workability and accelerate the strength development at an early age due to higher chloride content. Addition of three components (sea-sand, seawater, and RCA) is expected to enhance the sustainability of concrete structures at a greater level.

Further investigation on LCI and LCA showed that carbon emission implications of RAC were found to be highly dependent on the transportation phase. Also, with the continuing expansion of cities and the resulting increase in distance to remote quarries and landfills, the carbon reduction benefits of RAC, compared to NAC, is expected to increase.

However, taking in the account of the situation where we can use the recycled aggregates instead of natural aggregates to supplement the need the environment protection, would definitely leads to the solution to the sustainability of concrete structures. This concept can lead to a 'zero' waste encouraging researchers and construction industry to provide green solution for a sustainable future.

Abstract. It has been well accepted that applying recycled aggregate concrete (RAC) into structural engineering is a sustainable method to solve the problem of construction and building waste (CDW) accumulation meanwhile to save natural resources exploitation. Precast RAC members in factories is beneficial to improve their qualities and will extend the RAC application. This study presents nonlinear damping behaviors of precast and cast-in-situ RAC frames after simulated earthquakes, as a reference of quality control of precast RAC members, and of damage detection under ambient vibration. The nonlinear damping of precast RAC slabs with different damage degrees was studied to validate the feasibility of applying the quadratic damping coefficient as a sensitive damage factor without any requirement of undamaged baseline. Meanwhile a comparative study on nonlinear damping behaviors of a precast and a cast-in-situ RAC frames was conducted. Results highlight a change of nonlinear damping mechanism for both precast and cast-in-situ RAC frames from a viscous damping into a nonlinear damping. The precast RAC frame had a comparatively larger quadratic damping coefficient before and after earthquake hitting, indicating it had more severe initial damage and damage developed more significantly compared with the cast-in-situ frame. A unified damage classification was proposed for both precast and cast-in-situ RAC frames based on quadratic damping coefficient and observation.

1. Introduction

The use of construction and demolition (C&D) wastes as building materials has been gradually common in recent decades. Both the growing scarcity of raw materials and the gradual accumulated C&D wastes encourage the application of recycled materials in new built structures. Concrete recycling, crushing waste concrete into recycled concrete aggregates (RCAs), is considered as one of the most widely adopted strategies around the world, mostly due to its ease of implementation and the availability of market for the recycled products, such as recycled aggregate concrete (RAC). For extending the application of RAC to consume more C&D wastes, many reliable researches have been reported in terms of mechanical properties, durability, workability and seismicity of RAC structures [1-4]. It is generally accepted that the durability of RAC is inferior to that of natural aggregate concrete (NAC), which significantly limit the application of RAC in engineering, especially those exposed in corrosive environment [5]. Precast RAC members in factories might be a solution to this problem, considering its superior qualities of concrete members to the cast-in-situ ones [6].

Furthermore, prefabrication in factories has the benefits of higher opportunity for standardization of concrete structures, processing large waste concrete for on-site activities, and saving cost and construction time [7].

For proving the feasibility of precast RAC structures, the authors carried on the first shaking table test of a precast RAC frame model [6]. The result demonstrated that the precast RAC frame had a comparable seismic performance under minor earthquakes to the corresponding cast-in-site one; the displacement ductility of the precast RAC frame was adequate to resist moderate earthquakes; however, a more significant damage occurred in the joint area of the precast RAC frame lead to an inferior stiffness deterioration and energy dissipation performance under stronger earthquakes.

Though the advantages of combining the RAC and the prefabrication technique, there are still challenges faced by researchers and engineers. One of them is how to control their qualities of the prefabricated RAC members, and to detect the damage within the RAC structures after extreme events, for example, strong earthquakes. In this study, the nonlinear damping mechanism was identified of precast RAC slabs and frames based on their vibration responses, as a reference of quality control of precast RAC members, and of damage detection under ambient vibration as well.

2. Nonlinear damping and damage detection method

Normally, the linear damping mechanism was generally applied in dynamic calculation for the sake of simplification and adequate accuracy when the structural members were undamaged. However, it has been clearly expressed by Franchetti and Modena [8] that the damaged concrete members generally behaved nonlinearly, not only considering the stiffness softening behavior, but also a nonlinear damping behavior. Researchers have proposed manifolds of models to describe the nonlinearity of damping under damage [8-11]. Among these, the viscous-quadratic combined damping model firstly proposed by Franchetti and Modena [8] could properly estimate the nonlinearity of damping with comparatively small vibration amplitudes. This model assumed that the undamaged concrete behaved following a viscous damping mechanism, while the damaged part in concrete members behaved nonlinearly. The pure viscous damping was combined with a polynomial damping, as illustrated in Eq.(1) [8]:

$$F_D = c\dot{x} + d\dot{x}|\dot{x}| \# (1)$$

where F_D represents the damping force; $c\dot{x}$ represents the viscous damping force; and $d\dot{x}|\dot{x}|$ represents a quadratic damping force, in which d was a constant coefficient.

The equation of motion of a free oscillation with small vibration amplitudes for a quadratic and viscous combined system became:

$$m\ddot{x} + c\dot{x} + d\dot{x}|\dot{x}| + kx = 0 \# (2)$$

Through energy balance, the envelope curve of a free oscillation could be presented as Eq.(3):

$$a(t) = \frac{(a_0 c_1)e^{-c_1 t}}{c_1 + a_0 c_2 (1 - e^{-c_1 t})} \# (3)$$

where

$$c_1 = \xi\omega \# (4)$$

$$c_2 = \frac{4}{3\pi}\delta\omega \# (5)$$

$$\delta = \frac{d}{m} \# (6)$$

By fitting the envelope curve of the free decay vibration, the viscous damping factor ξ and the quadratic damping factor δ could be estimated and give information about the percentage of the total energy dissipated by each damping mechanism. δ=0 means that no nonlinear damping acted on the system, therefore no damage occurred. On the contrary, a positive value of δ means a nonlinear dissipation acted on the concrete member. Therefore, the quadratic damping factor δ could be directly correlated to the presence of damage in the considered concrete structure. This damage detection method has the benefit of baseline free, which is especially suitable for application in detection initial imperfections in precast members in factories, as well as structures survived after earthquakes. For RAC members and structures, this benefit was even more valuable due to the fact that the essential difference between RAC and NAC was the initial imperfections introduced by pores and weak interfacial transition zones (ITZs) and damage development during extreme events.

3. Nonlinear damping behaviors of the precast NAC and RAC slabs

Two precast slabs, one made with NAC and the other with RAC whose aggregates were 100% replaced by RCA, were damaged to different levels by static loads and subjected to impact loads by a hammer, to extract the damage information in the free delay vibration signal of acceleration through the aforementioned damage detection method. The NAC and the RAC slabs shared the same geomatic sizes and reinforcements, as shown in Figure 1.

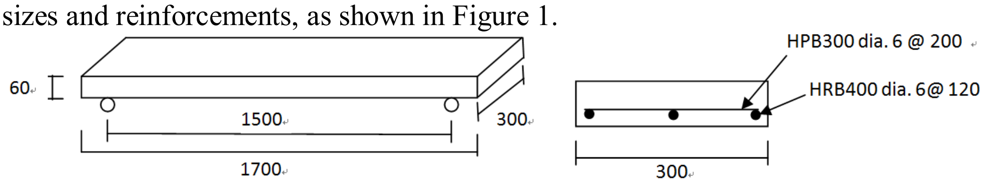

Figure 1. Geomatic sizes of precast NAC and RAC slabs.

5 damage phases were subjected by static loads on slabs, i.e. undamaged, cracked, yielding, peak bearing capacity and failure, judged by strains on the surface of concrete and reinforcement, and deflections of the slabs as well. Then, impact loads were subjected by a hammer after each phase and the free delay vibration responses were recorded by the acceleration gauges. A typical acceleration record is shown in Figure 2. And a comparison between fitting results by the combined damping model and the viscous damping model is shown in Figure 3. It is easily to find that the acceleration responses showed significant features of nonlinearity that the combined damping model achieved a better fitting result compared to the viscous damping model.

Development of damping coefficients, namely, viscous damping coefficient ξ and quadratic damping coefficient δ for the combined damping model, and the equivalent viscous damping ratio for the viscous damping model, correspondingly, are demonstrated in Figure 4. For the sake of convenient discussion, only relative values to the initial corresponding damping coefficient of the NAC slab was presented. A comparatively high value of equivalent viscous damping ratio of the RAC slab was observed at different damage stages in Figure 4, which agreed well with the other reliable experimental observations [12]. However, the viscous constituent of the dissipated energy somehow decreased with the increasing damage, for both NAC and RAC slabs. The viscous damping coefficient ξ decreased to 0.246 and 0.115 at failure stage correspondingly for the NAC slab and the RAC slab compared to the undamaged conditions. While the higher quadratic damping coefficient of the RAC slab than that of the NAC slab accounted for the higher equivalent damping ratio of the RAC member caused by the more energy dissipated by the nonlinear channel. The initial quadratic damping coefficient of the RAC slab was slightly higher than that of the NAC slab, demonstrating a severer initial damage within the RAC slab. The differences between the quadratic damping coefficients of the RAC slab and the NAC slab increased at first, then tend to decrease when the slabs suffered severe damages. However, the quadratic damping coefficient had an increasing trend along with the damage accumulation for both RAC and NAC, which increased to 6.885 and 7.087 times higher at failure stage than beginning for the NAC and RAC slabs correspondingly. The decrease of the viscous damping coefficient and the increase of the quadratic damping coefficient illustrate a shift of the energy dissipation mechanism. It is generally accepted that the nature of the viscous damping mechanism was molecular forces within materials, while the nonlinear damping mechanism might be caused by the friction between imperfections and cracks [13]. This phenomenon confirmed the fact that the undamaged precast RAC slab contained more imperfections, i.e. pores or weak ITZs compared to the NAC slab, besides a more significant damage development. Meanwhile, the increasing trend of the quadratic damping coefficient δ with cumulative damage highlighted the feasibility of using as a unified baseline free reference of damage detection for both precast RAC and NAC members and structures.

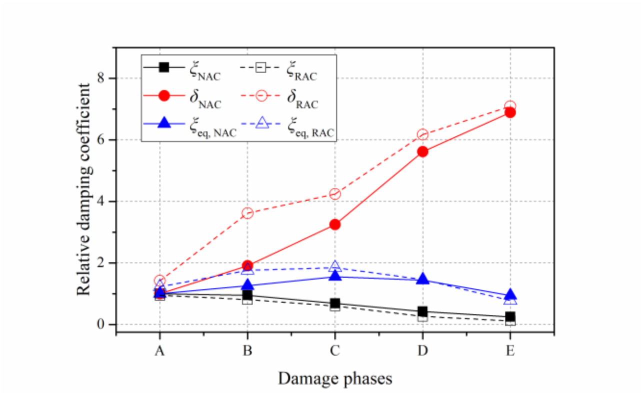

Figure 4. Development of relative damping coefficients with damage.

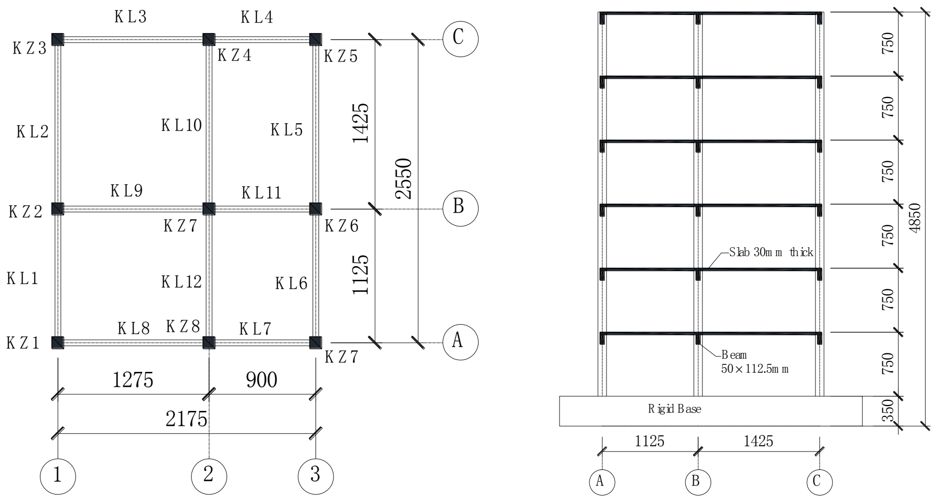
4. Nonlinear damping behavior of precast and cast-in-situ RAC frames

4.1. Description of the RAC frames

Two 6-floor, 2-span, 2-bay RAC frame structures, one was prefabricated and one was cast in-site, were constructed to conduct the shaking table test. These two frames had totally same configuration, as shown in Figure 5, as well as the reinforcement distributions. These two frames utilized the identical target strength RAC, whose replacement percentages of RCA were 100%. For the sake of convenient discussion, the precast RAC frame was represented as RAC-PRE, well the cast-in-site RAC frame was represented as RAC-CIS.



(a) Layout plan (b) Elevation

Figure 5. Configuration of the precast and cast-in-situ frames.

The process of constructing the precast RAC frame included three steps: (1) fabricated beams and columns in a factory, and (2) transported the members to the lab and (3) constructed the frame. 9 columns and 12 beams were erected on each floor level. The beams were seated on the head of columns. For assuring rigid beam-column connections between beams and columns, the longitudinal reinforcements were welded within the joint, as shown in Figure 6. Following that the molds were erected and RAC in joints and slabs was casted, as shown in Figure 7.

Figure 6. Erecting columns and beams.

Figure 7. Casting joints and slabs.

4.2. Shaking table tests

The Wenchuan wave (WCW), El Centro wave (ELW) and the artificial Shanghai wave (SHW) as a group with increasing peak ground accelerations (PGAs) of 0.066g, 0.130g, 0.185g, 0.264g, 0.370g, 0.415g, 0.550g and 0.750g were inputted into the frame from the rigid ground of the shaking table. Before and after each group of earthquakes, low-intensity white noise waves (WNW) were inputted to extract dynamic characteristics and to detect damage.

The displacement and acceleration responses were recorded by the displacement linear variable differential transducers (LVDTs) and acceleration gauges, respectively, on the rigid table and each floor of the frames. Meanwhile, strain gauges were fixed on the surface of concrete and reinforcement to analyze the failure procedures of these two RAC frames under earthquakes.

4.3. Nonlinear damping behaviors and damage detection

The aforementioned method of damage detection was proposed for the members or structures behaved harmonically without any load. However, in this study, the structures were excited by the earthquake waves and WNWs, and the nonlinear fitting method could not be applied directly. The random decrement technique (RDT) [14] was applied to extend the application of this damage detection method from free decay vibration into vibration excited by WNWs. WNW is the most accessible vibration that can be easily acquired from a real structure in the ambient environment, since the measurement requires neither the structure being taken out of service, nor expensive exogenous excitations. The RDT enables the resulting signature from the ensemble averaging of segments of the response to extract damping characteristics from free vibration signature.

The detailed comparison of failure pattern and seismic performances of these two models was elaborately discussed in reference [15]. It could be found in this comparative study that the precast RAC frame suffered a more significant damage under the same dynamic loads than the cast-in-situ one. The relatively severe damage level of a post-cast joint was the main reason for the overall inferior seismic performance of the precast structure, during an earthquake of high-level intensity. Compared to the cast-in-situ RAC frame, it was observed that the precast frame suffered more serious damage under the shear action of the earthquakes.

The quadratic damping coefficient δ and viscous damping coefficient ξ by nonlinear fitting with the combined damping model are shown in Figure 8. It is worth to mentioning that these coefficients were extracted from the acceleration responses recorded by the acceleration gauges fixed on the roofs of both precast and cast-in-situ RAC frames. In Figure 8, it could be observed that the viscous damping coefficients increased at first and then decreased, while the quadratic damping coefficient increased with the cumulative damage for both precast and cast-in-situ RAC frames. Based on the assumptions of the combined damping model that the undamaged part of structure behaved viscously, while the damaged part behaved nonlinearly, the energy dissipation mechanism changed from the viscous damping mechanism into a viscous-nonlinear damping mechanism, demonstrating a damage development process with the increasing PGA. It could be deduced that the friction and sliding between the two sides of cracks absorbed the inputted energy and accounted for the nonlinear damping mechanism.

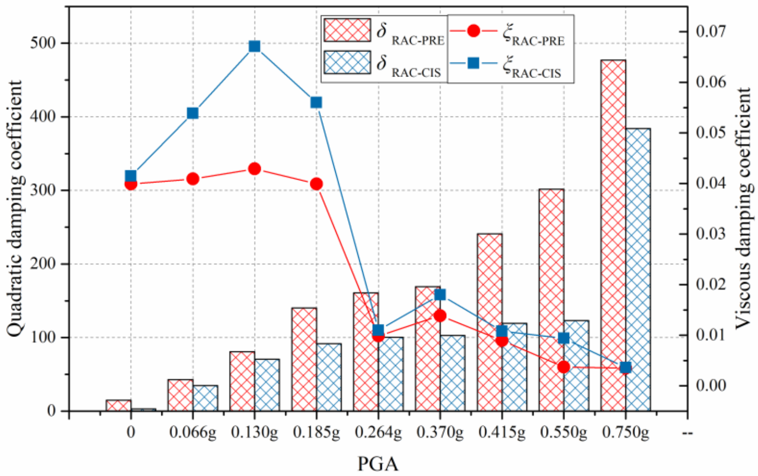


Figure 8. Variations of quadratic and viscous damping coefficient with the increasing PGA.

Furthermore, due to the advantage of baseline free feature, the initial damage within the precast and the cast-in-situ RAC frames were detected. Before excited by earthquakes, the precast RAC frame presented a much higher quadratic damping coefficient than that of the cast-in-situ one. This fact might be caused by the initial cracks between the precast members and the post-cast joints. This difference kept constant after suffered the earthquakes with 0.066g and 0.130g PGA, demonstrating that under low-intensity earthquakes, the precast RAC frame presented a similar seismic resistance compared to the cast-in-situ frame. However, the difference between the quadratic damping coefficients of these two frames became significant under 0.185g PGA earthquakes. It demonstrated the inferior seismic performance of the precast RAC frame to the cast-in-situ one.

Combining the description of the failure procedures and the quadratic damping coefficients for these two frames, it can be concluded that the precast RAC frame suffered a severe damage under 0.185g with a δ of 140.1, and was completely damaged under 0.550g with a δ of 307.7; while the cast-in-situ RAC frame suffered a severe damage under 0.415g with a δ of 123.3, and was completely damaged under 0.750g with a δ of 384.1. This result highlighted a better seismic performance of the cast-in-situ RAC frame under strong earthquakes. And the quadratic damping coefficient could be used as a reference to guide the retrofit of precast and cast-in-situ RAC structures after earthquakes.

5. Conclusions

In this study, nonlinear damping behaviors of precast and cast-in-situ RAC frames after simulated earthquakes were analyzed, aiming to provide a reference of quality control of precast RAC members, as well as of damage detection under ambient vibration. The nonlinear damping of both the precast NAC and RAC slabs with different damage degrees was studied to validate the feasibility of applying the quadratic damping coefficient as a sensitive damage factor without any requirement of undamaged baseline. By analyzing the experimental results, a shift of the damping mechanism was confirmed from a viscous damping mechanism into a viscous-quadratic combined damping mechanism. Meanwhile a comparative study on nonlinear damping behaviors of a precast and a cast-in-situ RAC frames was conducted. The precast RAC frame had a comparatively larger quadratic damping coefficient before and after earthquake hitting, indicating it had more severe initial damage and more significant damage developed compared to the cast-in-situ frame. The friction and sliding between cracks were deduced to explain the increase of quadratic damping coefficient. A unified damage classification was proposed for both precast and cast-in-situ RAC frames based on quadratic damping coefficient and experimental observation.

Abstract. Recycled aggregates produced from waste concrete are widely accepted as green building material. However, demolition processes will bring recycled aggregates with a lower apparent density, bulk density whereas a higher porosity, silt content, water absorption, crushing index value when compared with natural aggregates. So the strengthening and modification of recycled aggregates have become a prominent technological issue in the producing process.
This paper introduces current modification methods on the recycled aggregates, which mainly include: (1) physical technology, its basic idea is to remove the waste cement paste adhered to recycled aggregates, such processions as rubbing, heating, particle shaping, and micro-heating; (2) chemical technology, carried out by immersing recycled aggregates in different kinds of chemical grout, which can be mixed with additive Kim powder, silica fume, fly ash, and any other fine mineral powder or slag; (3) carbonation technology, when newly collected crushed aggregates are put into atmosphere with high CO2 concentration, the adhesive cement paste can react with CO2 and produce CaCO3 that will precipitate in the capillary pores or cracks, which will improve properties of recycled aggregates; (4) nano technology, the use of nanomaterials can promote the hydration reaction, react with cement based materials, fill pores and control the process of crystallization. Conclusions are put forward and several problems concerning modification need to be considered for further research and application are proposed and discussed. Compared with natural concrete, RAC is superior to environmental value in the reduction of CO2 emission in Life Cycle Assessment.

1. Introduction

The demolition of buildings will produce more than 200 million tons of solid wastes in China every year, and 80% are waste concrete, however, there are still no effective disposal measures. The building wastes need to be buried or piled up after demolition thus will occupy more arable lands or even bring about pollution to the lands. Therefore, it’s urgent to develop the recirculation and reutilization of building resources. Among them, recycled concrete aggregates are available impetus[1]. This improves efficiency of recycling of concrete and provides a topic linked to sustainability of cement based materials.

Researchers all over the world have conducted majority experiments on modification of recycled aggregates, these modifications can be summarized as physical technology, chemical technology, carbonation technology and nano technology.

2. Physical Technology

2.1. Abrasive Grinding Method

For grinding the preliminary crushed concrete blocks (diameter 5~40mm), the use of ball mill or rod mill to remove effectively the adhesive hardened cement pastes can produce high quality recycled aggregates, this idea can be described as abrasive grinding method[2]. The ball mill usually has dry treatment or wet treatment, while the rod mill is usually designed for wet treatment. Take the example of ball mill, its working principle is shown in Figure 1. This device is provided with several partitions, between the partitions there is a lot of steel balls. The interactive collisions between steel balls and recycled aggregates or interactive collisions simply between recycled aggregates will remove the adhesive cement paste and thus improve the properties of recycled aggregates. However, the abrasive grinding equipment will always lead to higher energy consumption and lower efficiency, besides, the device and grinding blocks will suffer a lot from serious wear and tear.

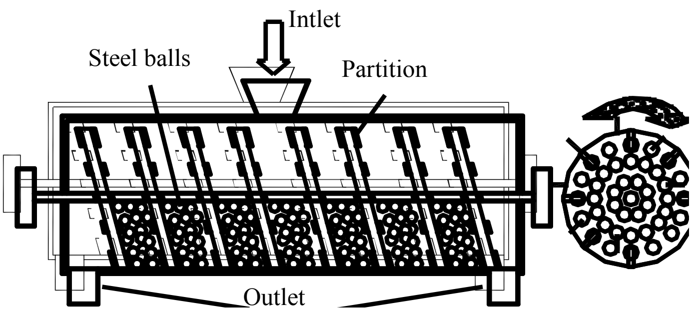

Figure 1. Ball milling equipment of abrasive grinding method

2.2. Particle Shaping Method

The configuration and structural principle of the particle shaping equipment are shown in Figure 2. This equipment consists of host system, dust removal system, electric control system, lubricating system and pressure sealing system. The host system is provided with a vertical totary impeller (the aggregates projection disk). Recycled aggregates that need to be modified are introduced into the machine from the upper inlet and then are divided into two streams; one part falls into the impeller cavity and is projected with high speed (the maximum can be 100m/s) due to the centrifugal effect; another falls along the aggregates distribution system of the host and its aggregates then collide with the ones projected from the impeller. After several times' collisions the recycled aggregates will be crushed and modified. In this process, the equipment consumes less energy and has a longer service life because the high-speed recycled aggregates rarely contact with the machine wall, it's also convenient to install, operate and repair the equipment. After the process, the recycled aggregates will have smooth surface, good particle shape, and the bulk density will be improved with higher purity[3].

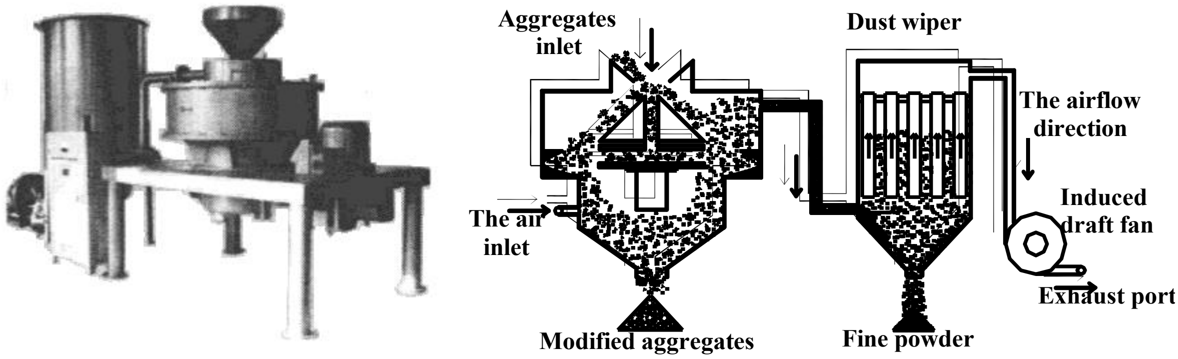

Figure 2. The configuration and structural diagram of the particle shaping equipment

2.3. Microwave-Assisted Method

A novel microwave-assisted method may be effectively used to partially remove the adhering cement paste by developing high temperature gradients and high thermal stresses within the mortar, especially at the interfacial zone with the gravels. Furthermore, recycled aggregates exposed to microwaves can significantly increase other properties. The Pilot microwave heating system is shown in Figure 3. Unlike conventional heating method, microwave-assisted method needs lower temperature, less energy and shorter duration which would eliminate degradation of recycled aggregates during processing as well as the potential durability concerns. According to experimental studies[4], concrete prepared with microwave-treated recycled aggregates can significantly enhance the mechanical properties such as the compressive and flexural strengths and modulus of elasticity.

Figure 3. Pilot microwave heating system used for experimental program

3. Chemical Technology

Chemical technology is mainly about recycled aggregates' treatment of immersing (soaking) and drying by using specific chemical grout which will cohere or fill the micro-cracks or micro-pores in recycled aggregates, this technology achieves the purpose of modification by changing the chemical composition of recycled aggregates' surface and makes them denser or improves their strength[5].

The available chemical grout can be listed as follows:

3.1. Polymer Emulsion

Polymer emulsion solution can be used to improve the properties of recycled aggregates, especially recycled fine aggregates. The tests of mortar blocks made of recycled fine aggregates after the modification of polymer emulsion solution showed that: the flexural strength improved obviously, while the compressive strength has little improvement[6].

Yang studied the strengthening of recycled aggregates by using cement grout with different kinds of high activated superfine mineral additives[7], the result is listed in Table 1. Compare the results of physical properties before and after strengthening, so were the mechanical results of recycled concrete made of modified recycled aggregates. Although the amounts of additives, mix proportions, and any other environmental conditions in these two experiments have some variations, they can still imply the strengthening degrees of the mixed grout.

Table 1. Experimental results of different polymer emulsion

Chemical grouts	Physical properties of RA				Mechanical properties of recycled concrete	
	Water content /%	Water absorption rates /%	Apparent density /(kg/m^3)	Crushing index value /%	28d compressive strength (MPa)	Growth rate of strength /%
untreated	2.58	6.77	2470	16.73	30.78	0
Neat cement grout	3.37	6.93	2580	13.24	31.10	1.04
Cement grout with additive slag	3.78	7.51	2570	13.12	33.08	7.47
Cement grout with additive diatomite	2.71	7.13	2523	12.11	36.39	18.23
Cement grout with additive silica fume	2.79	7.43	2534	12.80	35.72	16.05
Polymer emulsion solution	2.63	6.34	2500	11.80	37.58	22.09

3.2. Polymer emulsion and cementitious grouts

For modification of recycled aggregates, activators have similar function and mechanism to mixed cement grout. Immersing the recycled aggregates with inorganic composite alkaline activator and organic compound acid ester activator respectively, the test results are shown in Table 5[8].

Table 2. Experimental results of different activator

Aggregates	Water absorption rates /%		Crushing index value /%	Apparent density /(kg/m^3)
	10min	1h		
Untreated	3.80	6.25	24.1	2269
Inorganic impregnating solution	2.60	5.42	18.9	2290
Organic impregnating solution	3.50	5.73	22.5	2289

When considering the water absorption rate, crushing value, apparent density and other indicators, the properties of recycled aggregates with inorganic impregnating solution are slightly better than those with organic impregnating solution. The different performance indicators of recycled aggregates, when treated with organic impregnating solution, won't increase obviously.

4. Carbonation Technology

Carbonation will contribute to volume change, normally because the precipitation of CaCO3 mainly fill empty spaces in the capillary pores and cracks, thus leading to the reduction of porosity in the cement paste. Meanwhile, both the densification and strength will be improved. This is really a theoretically feasible technology for recycled aggregates' modification. The carbonation mechanism is shown in Figure 4.

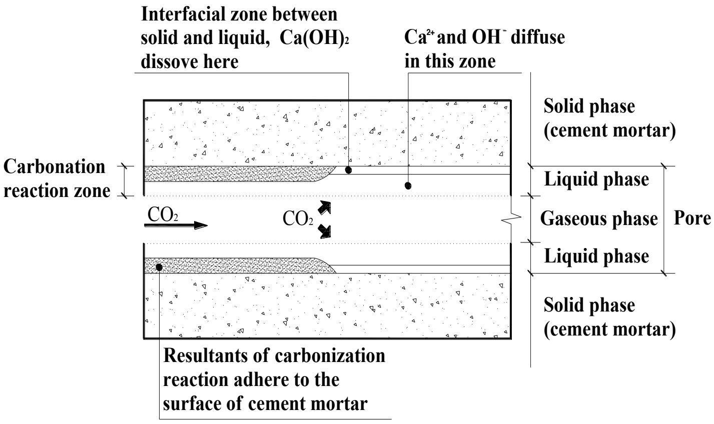

Figure 4. Schematic diagram of carbonation mechanism

Kou[9] chooses recycled mortar aggregates (RMA) to illustrate the relevant carbonation problems. RMA1 and RMA2, with sand to cement ratios of 3.0 and 2.5, and water to cement ratios of 0.55 and 0.45, respectively. And their carbonated counterparts are CI-RMA1 and CI-RMA2, respectively. Carbonation test is conducted in a steel airtight container with a CO2 concentration higher than 99%. The physical properties of aggregates are shown in Table 3 .After carbonation, each type of RMA was used to prepare recycled concrete, which will be tested for subsequent durability properties, such as compressive and tensile splitting strength, slump, drying shrinkage and chloride penetrability.

Table 3. Physical properties of aggregates

Property	Particle size (mm)	Aggregate type				
		Natural granite	RMA1	RMA2	CI-RMA1	CI-RMA2
Density (Kg/m^3)	20	2620	2326	2355	2345	2371
	10	2620	2326	2355	2351	2379
Water absorption (%)	20	0.89	11.82	9.30	7.32	4.84
	10	0.87	12.25	10.81	7.57	4.95
10% Fine value (KN)	14	156	96	116	108	134

The test results of the properties of different aggregates such as density, water absorption and 10% fine value are shown in Figure 5 , It was found that the properties of carbonated RMA improved compared with uncarbonated ones, but still lower than Natural granite's. And it also concluded that 24 h CO2 treatment was optimum.

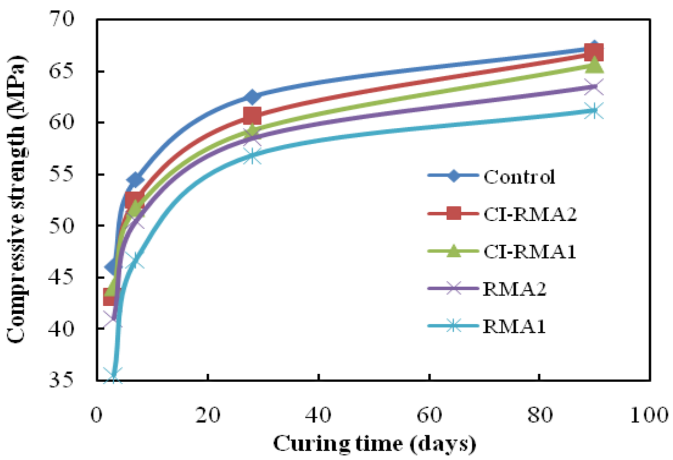

Figure 5. Development of compressive strength of concrete

The development of compressive strength of different concrete according to curing time is presented in Figure 5. Although the compressive strength of concrete prepared with RMA, carbonated or not, was still lower than that of control concrete at all tested ages, both the CI-RMA1 and CIRMA2 improved the compressive strength of the concrete significantly. At 90 days, the compressive strength of concrete made with CI-RMA2 was only 1% lower than that of control concrete. Besides, there is also an improvement in the resistance to chloride ion penetration for the concrete prepared with CI-RMA, and the drying shrinkage was decreased. Generally, carbonation is applicable for the modification of recycled aggregates.

5. Nano Technology

Just as improving the performance of concrete, nanomaterials are also being used to enhance the performance of RAC. Compared with other methods, nanomaterials have unique advantages to improve the performance of RAC.

Zhang et al.[10] apply surface treatment to recycled aggregate (RA) by two slurries containing nanomaterials. The new ITZs in RAC containing RAs surface treated by either of the two Nano slurries (the Nano-silica + nCa slurry or the Cement + Nano-silica slurry) were significantly enhanced. And the slump of fresh RAC, compressive strength and resistance to chloride diffusion was improved. The width and elastic modulus of the old ITZs in RAC did not develop as time passed, regardless of surface treatment on RA using nanomaterials, mainly because few unhydrated cement particles existed in the old ITZs and nanomaterials were not able to penetrate into the old ITZs. Maybe this phenomenon could be improved by increasing the processing time. Zhang et al.[11] discussed the modification effects of a Nano-silica slurry on microstructure, strength, and strain development of RAC applied in an enlarged structural test. Together with NAC, non-modified and modified RAC were applied in three beams in a real project. It is verified that beneficial effects of the employed nano-slurry on both the mechanical properties of MRAC material, and the deformability against shrinkage and loads of MRAC applied in reinforced beams in a real project. The nano-silica slurry employed in this study have improved the properties of MRAC's new ITZs between the old and new cement mortars, while the old ITZs between the virgin aggregate are not enhanced.

6. Conclusions

This paper has presented a critical review of existing and ongoing research on the modification of recycled aggregate. This review allows a number of significant conclusions to be drawn as follows:

1) Physical technology: with the help of the mechanical forces to remove the adhering cement pastes, then the ultimate recycled aggregates have high purity of gravels. However, this technology consumes more energy and resources, demands complicated equipments which tend to wear more serious, thus resulting in high cost. Therefore, physical technology is not suitable for long-term performance. Even so, the current recycled aggregates modification is mainly about physical technology.

2) Chemical technology: using chemical grout soaking to improve the performance of the adhering mortar in place of removing it. Although this technology has the advantage of convenient production process, considering the possible subsequent chemical reaction and the influence on the ultimate concrete strength or durability, this technology is still in the evaluation and discussion without been applied to engineering practice.

3) Carbonation technology: this technology has some commons with chemical technology based on the strengthening of cement pastes. Carbonization technology has the simple processes and environmental friendly advantages, but considering the cost of industrial carbon dioxide collection and carbonization room or conditions, there is a lot of subsequent research work to be done.

4) nano technology: nanomaterials can reduce the amount of cement content, improve the mechanical durable properties of recycled concrete especially at early age. These are based on the optimization of nanomaterials for microscopic structures and the promotion of hydration reactions. But at the same time, nanomaterials are prone to agglomerate that difficult to be stirred evenly, dispersion is not good and easy to reunite. the workability of RAC is affected largely.

For the modification of RA, we should not confine in physical and mechanical properties or any other short-term researches. When taking account of recycled concrete's long-term serviceability, it's indispensable for us to conduct deep researches on strength stability and durability. Compared with natural concrete, RAC is superior to environmental value in the reduction of CO2 emission in Life Cycle Assessment[12]. Besides, the available equipment, recycling utilization rates and costs of recycled aggregates' demolition and production should be evaluated. All these work also need to be incorporated with national conditions.

Abstract. A possible design strategy to improve the sustainability of building products is facilitating their future reuse. This strategy inspires some manufacturers to design innovative products, such as reusable façade products. Although these products might have a higher environmental impact for production, their reusability could lead to an environmental saving from a life cycle perspective. A possible method to evaluate their environmental performance is life cycle assessment (LCA). Nevertheless, LCA studies of reusable products are still rare. Furthermore, although the general LCA frameworks is fixed by ISO and CEN standards, some methodological choices must still be made by LCA practitioners. This paper first presents a method (as four methodological choices) for a parametric life cycle assessment of reusable building elements. Then, this method is applied to a comparative LCA of reusable and brick-and-mortar veneers. With proposed method, the reusable brick veneer is environmentally advantageous if it is reused at least once and if it is properly recycled at its end-of-life. The parametric method also indicates the relative influence of various parameters such as reuse rate, number of interventions, transport distances and waste treatment. The manufacturers can use this LCA study as a retrospective assessment to validate the relevance of design choices, but also as target-driven product management support to know hot-spots in the product' life cycle management. This study will hopefully inspire other designers and manufacturers and accelerate the transition towards a sustainable built environment.

1. Introduction

To achieve a sustainable built environment, circular economy principles advise designers to reuse construction products. However, using and reusing a product has also an environmental impact is henceforth no guarantee for environmental benefits [1,2]. These benefits can be quantified by performing a life cycle assessment (LCA). However, the link between LCA results and the design and use parameters is not always explicit, though important for designers. Therefore, governmental initiatives are developing tools, such as the Belgian TOTEM [3] or the French Elodie [4], to facilitate the use of LCA by the architectural practice. Nevertheless, these tools do not yet integrate the principles of circular economy. Further, the standards for LCA remain ambiguous when a product has more than one use cycle, for the reasons explained in Section 2. Some researchers even question whether LCA is at all suitable to evaluate so called 'circular' products [5,6]. To understand to what extend reusable products can be evaluated with LCA, we conducted a case study of a reusable brick veneer. In this paper, we present first four difficulties when evaluating reusable products with the LCA framework defined by the international (ISO) and European (CEN) standardization committees and propose a parametric LCA method to overpass them (Section 2). The proposed method uses parameters to understand the impact of decisions made at product design stage, production, or when the product is installed in a building. The method is then illustrated with the comparison of the environmental impact of reusable and conventional brick veneers (Section 3). We finally summarize our findings (Section 4) and conclusion (Section 5).

2. Parametric LCA of reusable products

When performing a life cycle assessment (LCA) of reusable or recyclable products, a recurrent difficulty is setting relevant system boundaries and allocating the environmental impact for production and waste treatment over the different products, as shown by the efforts invested in the search for an appropriate End-of-Life formula in the context of the Product Environmental Footprint calculation [7]. Often, an LCA assessor must choose to take the perspective of either the first use cycle (i.e. the 'new' reusable product), the second use cycle (i.e. the 'reused reusable' product), or the last use cycle before waste treatment (i.e. the 'reused non-reusable' product). To this difficulty is added the lack of (reliable) data about parameters influencing the life cycle inventory, such as products' lifespan, maximum amount of use cycles and necessary remanufacturing processes. The difficulties can be summarized into four methodological choices in the next paragraphs. These choices constitute the proposed parametric LCA method for reusable products and supports the case study in Section 3.

2.1. Should we take a product or building perspective?

Depending on the goal of the LCA, the assessment is performed either at building or product level. In the present case study, the goal of the LCA is to position the product on the market and the results are intended mainly as a marketing instruments. Therefore, SETAC recommends to take a product perspective, though the products must be brought into the building context in order to make a valid comparison [8]. Notably from the perspective of a reusable product, an LCA would then consider in module B, all use cycles, including the impact of relocating and reconditioning a product, until the end of its technical lifespan, which is usually longer than the building lifespan. A second reason for taking a product perspective is that approximating at once all the avoided products thanks to reuse is more abstract than defining scenarios including successive reuses. This second option implies a *system expansion*, which consequently solves the problem of allocating the impacts over multiple use cycles (i.e. multiple 'reused reusable' products). Nevertheless, the avoided products due to recycled content and product recyclability must still be accounted through an appropriate allocation procedure. Allocation procedures are not discussed in this paper.

2.2. How do we define the system boundaries in time?

Circularity means in theory endless use. If we take a product perspective, the period of analysis should not be limited to the lifespan of the assembly the product is part of, neither it can be endless. So, when to start and when to stop the inventory? We decide to define the period of analysis based on the technical lifespan of the reusable product. After all, no manufacturer guarantees that its product will last forever.

2.3. How to define use scenarios at building level that make sense for all compared products?

Use scenarios are conventionally defined at building level, by defining what creates the need for, and triggers, relocating/replacing the product. Then the product's 'response' to this need for change is evaluated. Nevertheless, the need for change at building level can be influenced by the feasibility of change at product level (i.e. rebound effect). This feasibility differs in both products. A conventional product can, in practice, be less often altered than a reusable product because of the burdens each intervention generates (which is the reason why we design reusable products). Here, because the reusable and conventional products must be comparable in terms of their 'resilience to change', we choose to test both products for identical use scenarios (i.e. the same need for change). Hence, they both have the same amount of use cycles (Figure 1).

2.4. How to (time-efficiently) evaluate many different use scenarios?

Because of the system expansion, the two products go through multiple cycles with multiple use scenarios to consider, and hence more uncertainty (e.g. different reuse rate, different transport distance, etc.). Even the amount of cycles can be unknown. To model these many scenarios efficiently modelled, parameters are introduced in the calculation of the total environmental impact (E), as in equation (1)

$$E = E_{prod} + E_{trans,c} + E_{cons} + N \times (E_N) + E_{dec} + E_{trans,w} + E_w \quad (1)$$

in which the potential environmental impact of the N[th] reuse cycle (E_N) is defined by equation (2).

$$E_N = E_{dec} + E_{cons} + E_{trans,N} \times R + \left(E_{prod} + E_{trans,c} + E_{trans,w} + E_w\right) \times (1 - R) \quad (2)$$

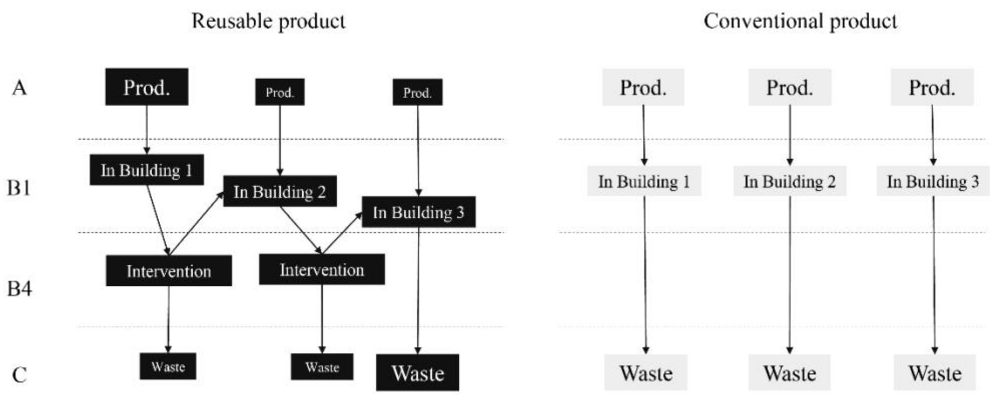

Figure 1. The reusable product is used over three cycles (with some losses), while the conventional product must be produced three times. ('Prod.' = production; 'Waste' = waste treatment)

in which,
E is the total environmental impact;
E_{prod} is the environmental impact of production;
$E_{trans,c}$ is the environmental impact of transport to construction site;
$E_{trans,w}$ is the environmental impact of transport to waste treatment;
$E_{trans,N}$ is the environmental impact of transport to next construction site;
E_{cons} is the environmental impact of assembly or construction;
E_{dec} is the environmental impact of deconstruction or demolition;
E_w is the environmental impact of waste treatment;
R is the reuse rate (i.e. the percentage in mass of the whole product that is reused in the next cycle);
N is the number of interventions, hence the number of use cycles occurring after the initial use, during the period of analysis.

The two main parameters are the reuse rate (R) and the number of interventions (N). R depends on the design but also on the use: it's not because a product is design for disassembly that it will be disassembled. By this parameter the level of 'circularity' of the system is represented. The higher the reuse rate, the more materials remain in use. A low R characterises a linear use of materials, while a high R characterises a circular use of materials. N depends on the need for functional changes (e.g. aesthetics, necessity to access and alter an internal layer, reconstruction of the whole system), and not on the need for technical changes. N is identical for both products, although in practice N might be higher for a reusable product than a non-reusable one due to rebound effect.

All the parameters and their interaction can be visualized in a process diagram (figure 2) which supports the case study presented in the next section.

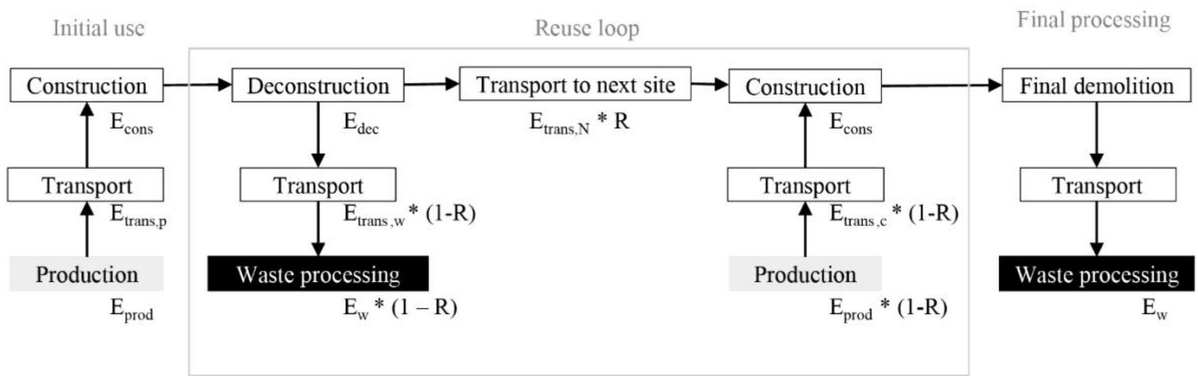

Figure 2. Process and flow model for the life cycle of product with multiple uses.

3. Case study

With the method for a parametric life cycle assessment (LCA) (Section 2), the potential environmental impact of two building products was compared. This section reports the LCA step 1 (goal and scope), step 2 (inventory) and step 3 and 4 (impact assessment and results of the attributional LCA).

3.1. Goal, functional unit and system boundary

The LCA is mandated by the manufacturer of a dry brick veneer available on the Belgian market, called '*Façadeclick*' (FC). The goal is to compare the environmental impact of FC, designed for a circular use of materials, with a '*brick-and-mortar'* (B&M) veneer, its most conventional alternative.

The functional unit (FU) is "a brick veneer, covering one square-meter of external wall with a self-bearing system, including anchors to the load-bearing structure, for 80 years". Both products have similar aesthetical, structural[1] and thermal performances[2], and both act as a rainscreen. Both products can reach a thermal transmittance (U) value of 0.24 W/m²K when combined with 0,14 m masonry wall and 0,11 m EPS insulation. The environmental consequences of a different of product's weight on the dimensioning of the foundations are not included in this illustrative case study.

As for the system boundary, the inventory of mass and energy flows is estimated from cradle to grave (from modules A1 to C4, as defined in the EN15804 norm). It includes the production of the different parts (E_{prod}), their transport between the different production and construction sites (E_{trans}), and the waste processing (E_w). Excluded from the analysis are packaging, storage, maintenance of the wall, assembly and disassembly of FC and construction and demolition of B&M.

[1] The compression resistance values are 11 N/mm² for the plastics inserts and 5 N/mm² the mortar, according to the product technical documentation.

[2] Thermal conductivity (λ) values are 0.69 W/mK for the reusable brick and 0.59 W/mK for the conventional brick, according to the product technical documentation.

3.2. Life cycle inventory

The life cycle inventory was carried on with LCA software SimaPro 8 [9], using the process data from the Ecoinvent 3.1 database [10], with default allocation[3]. The impacts of by-products are allocated following the recyclability approach (0:100) with credit for avoided virgin production, as defined by Allacker et. al. [7] who consider this approach valid for the criteria 'physical realism' at system level. Following this approach, no credit is given to recycled content (e.g. recycled plastic used in the plastic inserts), but the recyclability at End-of-Life is credited following Belgian conventional recycling rates [12]. The consumption data comes from the product manufacturers. Both FC and B&M products weight respectively 136 kg/m² and 176 kg/m². FC uses 130 kg of hollow bricks and plastic inserts to 'click' each brick on top of the other. B&M uses a similar quantity of bricks (128kg) and 48 kg of mortar. FC requires 8 steel anchors to attach to the load-bearing structure, while B&M only needs 5 anchors.

3.3. Modelling assumptions

The final environmental impact (E) score is calculated with the impact assessment method 'ReCiPe Endpoint (H) V1.12 / Europe ReCiPe H/A – single score'. The parameters value for the baseline scenario are estimated from discussion with the product manufacturers[4], with some modelling simplifications:

- The impact of production (E_{prod}) is calculated based on the inventory of materials and energy given by the product manufacturers.
- FC and B&M are both first installed in Wilsele, Belgium. During each reuse, FC is always relocated at 100 km from the previous site. B&M is installed at 80 km from the brick retailer. The mortar is transported over 5 km to the construction site. At end-of-life, both products are transported to the waste treatment plant over 30 km. All transport distances remain constant for each use cycle.
- Upon recommendation of SETAC [8], two waste treatment scenarios are compared: (1) an "average for Belgium" baseline waste treatment scenario, based on the BE-PCR[5] [12] and (2) an "improved plastic recycling" scenario, in which all HDPE is recycled. Both scenarios are defined as a mix of recycling, incineration, and landfilling per material category.
- In this model, B&M is not reused, therefore $R_{B\&M}$=0% by default. FC is reused with 5% losses over whole product (bricks, inserts and anchors), R_{FC}=95%.
- As for the number of use cycles (N), FC can be disassembled and reassembled up to five times. For the baseline scenario, N varies thus from 0 to 5.
- The service lifespan of all parts of the products is considered higher than the period of analysis (80 years). Consequently, replacements of sub-products are not considered.

3.4. Results

In this baseline waste scenario (FC1) and N=0 (i.e. no intervention), the *Facadeclick* (FC) product has a potential environmental (E_{FC}) impact of 6,0 points, that is 63% higher than the *bricks & mortar* (B&M) product ($E_{B\&M}$=3,7 points) (Figure 3). When one intervention occurs (N=1), both products have close E (6,6 and 7,4 points). From two interventions (N>1), FC is more environmentally efficient than B&M (7,2 and 11,1 points). In the "improved plastic recycling" scenario, in which the inserts are fully recycled at the end-of-life (FC2), FC has a lower E than B&M already after its first reuse (4,1 and 7,4 points).

As shown in both waste scenarios, when R_{FC} is high (95%), E_{FC} is almost no dependent on a variation of N, because each new cycle does not contribute much to E. Consequently, FC is more resilient to

[3] Default allocation in Ecoinvent 3.1 considers average supply market, unconstrained, and economic allocation of multiple outputs [11].

[4] The product manufacturers are 'Snel Bouwsysteem' and 'Nelissen'.

[5] In this BE-PCR waste scenario: Bricks: 5% landfilled; 0% incinerated; 0% reused; 95% recycled; Metals: 5% landfilled; 0% incinerated; 0% reused; 95% recycled; Polyolefins (PP, PE): 10% landfilled; 85% incinerated; 0% reused; 5% recycled.

changes than B&M. Therefore, the LCA of reusable products is more robust. A similar conclusion was drawn by Galle for the life cycle costing of reusable products [13].

With the environmental profiles of both products, we can discuss the choice of parameters' value for the baseline scenario. The demolition of B&M is probably generating environmental impact from the use of building machines and water spraying to control dust emission. If these flows were included in the inventory, it would not invert the interpretation of the results.

The FC's potential environmental impact for the baseline scenario ($E_{Baseline}$) depends on transport distance for the product relocation and the reuse rate during relocation (R), among other parameters. The sensitivity to those two parameters is assessed for two interventions (N=2). Comparing the impact of a 10% variation of transport distances and R for N=2, we see that $E_{Baseline}$ is especially sensitive for change of R (table 1). When R decreases 10% (R=85% instead of R=95%), $E_{Baseline}$ decreases 15%. E is much less sensitive to the transport distance: a 10% longer transport distance results to only 1% increase of $E_{Baseline}$. When the FC product is relocated twice (N=2), it must be reused at minimum 60**%** to equal the impact of the bricks-and-mortar, as shown by the variation of the E_{FC} to R (Figure 4). Consequently, losses during relocation FC should be limited to 40% (in mass) to perform environmentally better than the conventional system.

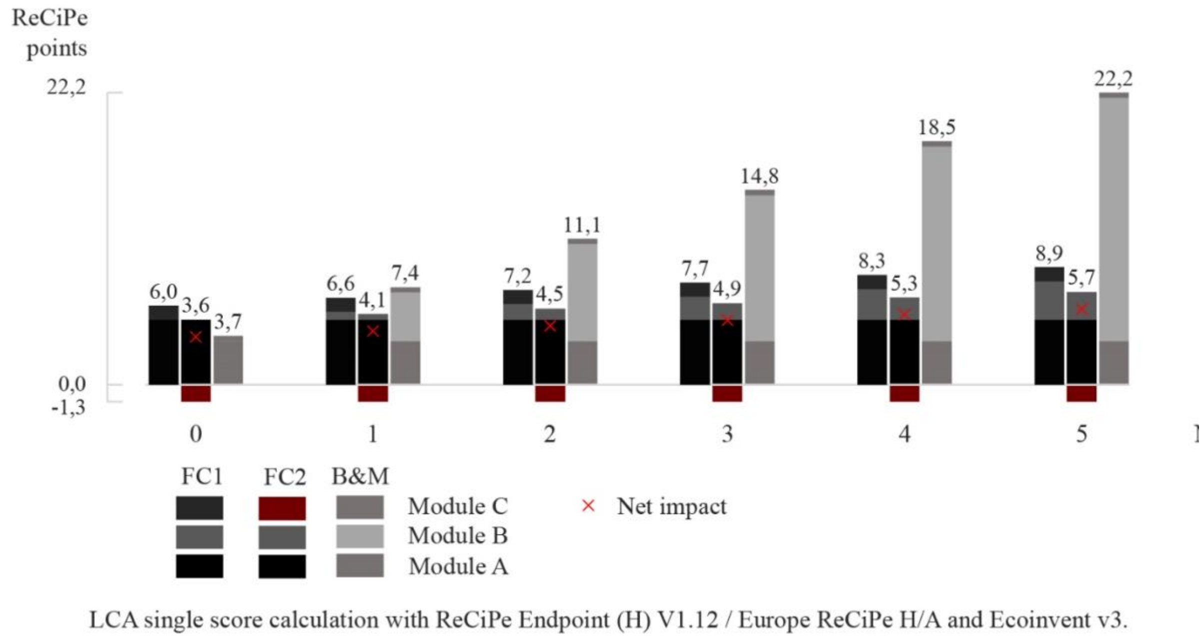

Figure 3. Environmental impact of FC and B&M brick veneers according to the amount (N) of interventions occurring during the period of analysis. In the 'average for Belgium' waste treatment scenario (FC1), the reusable product performs environmentally better than the B&M system from the second reuse (N=2). In the "improved plastic recycling" waste treatment scenario in which the plastic inserts are fully recycled at their end-of-use (FC2), the dry brick system performs environmentally better after the first reuse (N=1).

Table 1. Sensitivity analysis of the parameters influencing the LCA results of the dry brick wall, considering N=2 and $E_{Baseline}$ = 7,08 Points. The most sensitive parameter is the Reuse Rate (R).

Input parameters	Input parameters' value			Resulting E			
	Baseline	$\Delta_{10\%, min}$	$\Delta_{10\%, max}$	E_{min}	E_{max}	ΔE_{min} [relative]	ΔE_{max} [relative]

Transport distance [km]	100	90	110	7,03	7,13	0,56 [1%]	0,05 [1%]
R [%]	95	85,50	/	8,18	/	1,09 [15%]	/ [/]

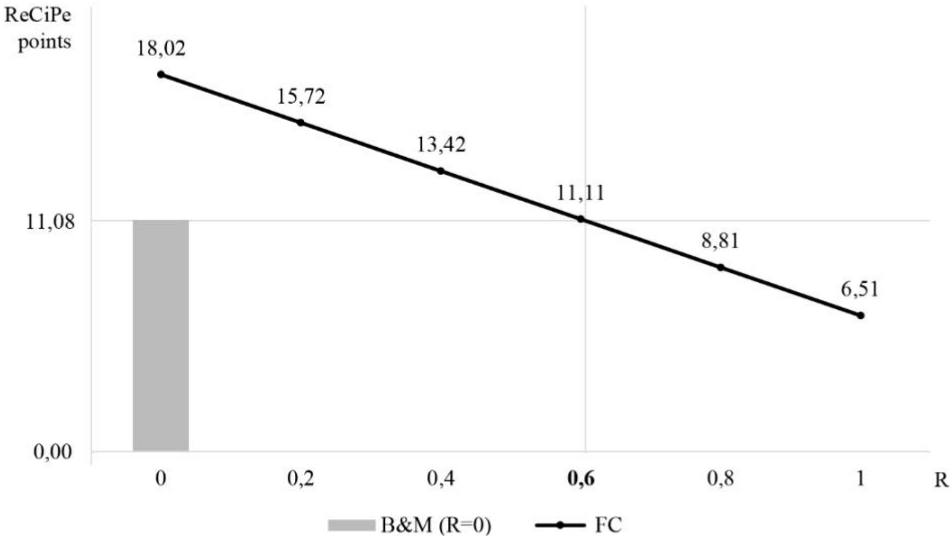

Figure 4. Sensitivity analysis of the Façadeclick's environmental impact to reuse rate (R) value. Considering two interventions (N=2), 60% FC must be reused to equal the impact of the bricks-and-mortar product (11,08 ReCiPe points).

An assumption which is worth discussing is the service lifespan of the sub-products. The service lifespan of all parts of the products is considered higher than the period of analysis (80 years), while the plastic inserts could age faster than the bricks and fail the technical requirement before 80 years. In the model, each time FC is relocated, 5% of the new FC is produced to compensate losses (flows occurring in stage B4 – Replacement of the product life cycle). The remaining service lifespan of these 5% is considered equal to the remaining service lifespan of the other 95%. As a result, the whole product is treated as waste after 5 interventions, although only 75% have effectively reached the end of their technical lifespan and 25% could still be reused.

4. Summary of findings

The case study yields both findings about the environmental impact of the brick veneers and about the parametric life cycle assessment (LCA) method.

4.1. Findings about the environmental profile of the reusable brick veneer

The potential environmental impact of the reusable (E_{FC}) product is 63% higher than the brick-and-mortar ($E_{B\&M}$) product when the veneer is never altered. It is almost similar to $E_{B\&M}$ when the veneer is altered once over the period of analysis and lower than $E_{B\&M}$ when the veneer is altered at least twice. When the plastic inserts are fully recycled, the initial additional environmental impact is always compensated, even without intervention, making both systems almost competitive from the start. These results depend on the simplifications and assumptions detailed in Section 3. E_{FC} is most sensitive for changes in reuse rate (R), while $E_{B\&M}$ is sensitive for changes in the number of interventions (N). When a product is efficiently reused (high R), the product environmental impact is almost not sensitive to N.

4.2. Findings about the parametric LCA method

As shown in the case study, the parametric LCA method proposed in Section 2 allows us to compare reusable and non-reusable products. To assess the LCA of the reusable product, we opt for a system expansion. Therefore, we avoid a complicated distinction of the ‘new reusable’, ‘reused reusable’ and ‘reused non-reusable’ products.

The analysis mixes product and building levels without any problem: the LCA is performed at product level (i.e. the brick veneer), considering use scenarios that are defined at building level. The LCA of the product is made at product level, upon recommendations of the SETAC report [8] and to draw possible use scenarios. For the sake of comparability, reusable and conventional products experience the same amount of use cycles, although this scenario is maybe unprobeable.

The proposed parametric LCA method clarifies how design and use parameters influence the environmental performance of (reusable) products. It shows the potential benefits of Design for Disassembly and Reuse. Thanks to the use of parameters, it also indicates the necessary conditions to realize these potential benefits (e.g. maximum losses, transport distance), which gives a target-based assessment. With the sensitivity analysis, the importance of the different parameters can be qualified and quantified. Common to other LCA studies, the bar chart shows which life cycle module contributes the most to the total environmental impact.

5. Conclusion

As designing a product for future reuse is no guarantee for environmental savings, a life cycle assessment (LCA) is necessary. However, the LCA standards remain ambiguous when the product has more than one use cycle. The main difficulties lie in the selection of the right perspective (building or product), the system boundary and the use scenarios. Additionally, considering many different use scenarios can be very time-consuming.

To overpass those difficulties, we proposed a parametric LCA at product level, with use scenarios defined at building level, combined with a system expansion approach to include the largest amount of use cycles as the product can technically withstand. This parametric LCA provides also good insight about the sensitivity of the model to different parameters (e.g. R, N). More than providing a binary ‘*yes or no*’ answer to the question ‘*Does product A perform environmentally better than product B?*’, this method shows how the environmental impact relates to both design and use parameters. Furthermore, the method can be used as target-driven LCA to support decision-making for the design and the use of building product.

The application of the parametric LCA method to the comparison of reusable and brick-and-mortar veneers shows the competitiveness of the reusable veneer. Considering a baseline waste treatment scenario, this product has a higher production environmental impact than a brick-and-mortar veneer but is competitive when the veneer is altered once. The more interventions, the more beneficial the reusable system becomes compared to the brick-and-mortar veneer. When the plastic inserts are fully recycled, the initial additional environmental impact is directly compensated by savings, from the first use cycle. When the reusable product is relocated and reused twice, the material losses should be limited to 40% (in mass) to compete with the brick-and-mortar veneer.

As illustrated by this case study, the proposed parametric LCA is an insightful yet simple method to evaluate the E of reusable construction products. It can provide product manufacturers with useful insight about the environmental profile of their product and the conditions to use it efficiently. However, the method has been developed according to this specific case study. Further research should verify the applicability of the method to other types of reusable products. Also, the service life modelling could be refined at sub-product level by specifying different R, N and technical lifespan per sub-products.

Outcomes of a Student Research Project on Circular Building Systems – Focus on the Educational Aspect

Janssens B, Knapen E, Winkels P, Verbeeck G

Faculty of Architecture and Arts, Hasselt University, Diepenbeek, Belgium

bart.janssens@uhasselt.be

Abstract. The growing need to shift from a linear to a circular economy has inspired producers of building materials and systems to innovate their products to match the requirements of a future circular economy. Others have been developing modular systems in the past to simplify the building process and are now reconsidering these products for their potential in a circular economy. However, at this early stage on the road towards a circular economy, claims of circularity are often made too easily and many producers as well as architects and builders are still struggling with the practice of circular building. In this context and within an assignment for master students in architecture, three cavity walls, each 9m² and composed with a different system for the inner and the outer wall, have been constructed and disassembled in order to test their potential for circularity. The extent of circularity has been critically analysed with an existing framework of evaluation criteria for design for change: three criteria on interface level (reversibility, simplicity, speed), three on component level (compatibility, durability, manageability) and three on composition level (independence, pace-layering, prefabrication). This analysis was complemented with an environmental assessment of the materials used and with interviews with contractors who have experience with these systems. In a final step, proposals for improvement of the products and systems have been made and tested on a mock-up scale, in order to better fit a possible future circular economy.

1. Introduction

The exploitation of resources and the linear way in which materials are harvested, consumed and discarded cannot be sustained anymore. The current economy must be transformed to a circular economy model in which a careful use of resources is part of managing a sustainable development. Strategies on an institutional level [1] (e.g. Flemish policy action 'Vlaanderen Circulair': https://www.vlaanderen.be/nl/vlaamse-regering/transitie-circulaire-economie), indicators and research projects have been initiated. Circularity in the building sector is high on public (nationally and internationally) and corporate agendas. As circular building will become key in the professional field, it is necessary that architecture students are being prepared.

Incorporation of circular principles has only begun recently. Producers of building materials and construction systems are rapidly taking the first steps and develop or redevelop products in view of the requirements for circular building. However, the risk is high that in the rush to quickly develop products, claims of circularity are made too easily.

Within this context, master students in architecture of the Faculty of Architecture and Arts of Hasselt University studied the potential for circular building of specific building systems. The objectives were threefold, in order of importance: educational, research methodological, niche development. The educational aspects included i.a.: trigger and train students to become architect-designers with a strong focus on circularity; and the competence to conduct research in a collaborative and critical way. The research methodological objectives consisted of exploring possibilities for actively involving architecture students in research on building-technical aspects (the nexus education – research*)*. The niche development objective fits the research field of the research line 'Sustainability' within the Research Group Arck of the faculty, framed within the 'civic university' model adopted by Hasselt University. Research is conducted on building-technical niches with a societal relevance, in this case building systems that enable circular building and enhance a circular economy model.

Primary aim of this paper is to present and discuss the concept of the student research. Secondary aim is to present tentative and illustrative outcomes of selected circular building systems.

After this first section, this paper consists of four more sections. The second section provides a description of the concept of the student assignment. The third section presents selected systems and composed cavity wall ensembles for the student research. In the fourth section, illustrative results are given and discussed on both the concept of the research as on selected systems and composed ensembles. Finally, a conclusion wraps up findings and perspectives.

2. Concept of the research

2.1. Description of the assignment

2.1.1. Positioning within the curriculum. The master programme of architecture at Hasselt University includes elective research seminars in which the nexus 'education – research' is operationalized. Each of the four defined seminars is linked to a research line of the research group Arck. The seminar 'Building concept' is substantiated by the research line 'Sustainability' of which the research is closely linked to the growing need to deal with the built environment in a more sustainable way. The objectives of 'Sustainability' are (1) to contribute to the scientific founding of sustainable architecture mainly at building level and with a focus on comfort, energy and material performance, and (2) to contribute to supporting the decision making process of both architects and building owners towards more sustainable designs, in line with the ambitions of the EU and Flanders for nearly zero energy buildings and more sustainable material use.

As from the academic year 2017 – 2018 onwards, the seminar 'Building concept' focuses on 'designing and building for/from circularity'. In a living-lab set-up, theory and experiment are used by students, as both designers and builders, to explore the concept of 'circularity' in the built environment. The focus alternates from year to year: one year theoretical models for circularity are studied by research by design on the building level; in the next year, specified circular building systems on the element level are tested. A constant throughout the two years is a critical analysis, a reflection and an optimization.

2.1.2. The assignment as such. Framed within the second part of the two-year cycle, academic year 2018 - 2019 focused on in-situ testing and improving circular building systems for cavity walls. Characteristic for cavity walls are a layered composition of an inside wall (mostly brick), thermal insulation, a narrow cavity, and a façade (mostly fancy brickwork) [2].

In three groups of each five students (mix of first and second master students), the aim was to test the potential of six preselected systems for circularity by the act of building, backed by an assessment with an existing framework of evaluation criteria for design for change and with an existing eco-design tool to evaluate and optimize the environmental impact of the materials used.

The assignment evolves from hands-on explorations, over analysis and assessment by desk-top research, to the formulation of improvements by design & build research. The research assignment consisted of six phases. In the first phase, manufacturers of selected systems presented their products to the students. In the second phase, cavity wall compositions were developed by using two circular building systems (one for the inner leaf; another for the outer leaf). During the third phase, students had to detail the building knots (scale 1:20 to 1:5) of a given in-situ building experiment. The act of building, build and disassemble, was operationalized in phase four. In overlap with phase four, phase five consisted of an assessment. In the sixth and final phase, possible improvements, material wise and/or building-technical wise, were explored and tested in mock ups.

2.1.3. Learning objectives. The set-up of the research seminar holds three learning objectives. A first, and most obvious, objective is to trigger and train students to become (better) circular-thinking architect-designers and builders. The two other objectives, explained in paragraphs below, have a more generic feature: learning and preparing to work in a collaborative way; and the development of critical thinking skills.

In recent years, focus is laid on an 'Integrated Design Process' (IDP). An IDP is a process that purposefully brings together the work of various design and engineering disciplines in order to achieve successful projects outcomes. Following Rovers [3], the IDP is characterized by the integration of several activities in a project team. During an entire project development process, several disciplines/stakeholders (the client, the architect-designer, the specialist-engineers), or the Integrated Design Team (IDT), are involved. The IDP implies a social process between the members of the IDT. "Projects participants work and make decisions not in isolation, but rather within a framework of social interaction". One of the key features of an IDP is working in a group. Due to the growing degree of specialisation of the aspect of designing and building this collaborative way is urged [3-4-5], and therefore seen as an important learning objective.

To prepare students for the complex and dynamic world of the 21st century, professionally, socially and personally, it is necessary to develop critical thinking skills. This is a core theme in contemporary education made explicit by the World Economic Forum [6]. Critical thinking helps to: make informed decisions without being biased; handle, deal with the abundance of information available; understand the learning material and to use it in different contexts; continue learning; deliver a respectful and rational contribution to society; support the transition from the study time to the professional life.

2.2. Framework of evaluation criteria for design for change

For the fifth phase of the assignment, the assessment, the design guidelines for 'design for change' on the element level developed by the Flemish agency for waste management (OVAM) based on Vandenbroucke [7] were used. Nine criteria are differentiated in three aspects: *interface*, which focuses on the interaction between components, holds the criteria 'reversibility', 'simplicity', and 'speed'; *components*, which focuses on the features of the parts, holds the criteria 'compatibility', 'durability', and 'manageability'; and *composition*, which focuses on the whole, holds the criteria 'independence', 'pace-layering', and 'prefabrication'.

2.3. Complementary assessment

In order to have a more complete and a non-univocable evaluation, the environmental impact of selected building systems was assessed with the Ecolizer tool (http://www.ecolizer.be/), an eco-design tool for product design made available by OVAM.

By initiation, complementary assessment was targeted with interviews with contractors who have experience with the systems. However, this was canceled due to time restrictions.

3. Selected systems, composed cavity wall ensembles and set-up building experiment

3.1. Systems

Six manufacturers were willing to collaborate in the research: system 1 – Construclick; system 2 – Facadeclick; system 3 – Systimber; system 4 – Clickbrick; system 5 – Steko; system 6 – Facatile.

Figure 1. The six building systems selected.

3.2. Compositions

Focused on the aspect of cavity walls and taking into account the availability of testing materials, two cavity wall compositions were retained by the tutors, and detailed by the students: composition 1 - Construclick/Facadeclick; composition 2 – Systimber/Clickbrick (see figure 2).

3.3. Set-up building experiment

The in-situ building experiment was conducted at the faculty. Framed within an existing floor, concrete columns and beams, two set-ups of cavity wall constructions of 9m² including a window (A, with a corner; B, without a corner) were designed, built and disassembled (see figure 2).

Figure 2. Left, the two compositions 1 & 2; right, the two set-up building experiments A & B.

4. Results and discussion

Following outlined objectives, this section provides and discusses results: first, regarding the educational and research set-up; second, regarding the studied systems and compositions. The objectives were three-fold, in order of importance: educational, research methodological, niche development.

4.1. Educational aspects

4.1.1. Students' perspective. After the research, students had to submit a self and peer assessment, including a personal reflection on the assignment. These submissions provided valuable insights in the students' perspective on the seminar.

The in-depth focus on materials and construction methods, and having the time and space to experiment with details of/for new ways of building, was believed to be an added value for the curriculum. The set-up of the seminar, with its structure and balance between theory and practice, enabled to gain good insights in circular building, regarding the challenges and opportunities, both for architects and product developers. In addition, the seminar enabled to develop critical thinking skills, inter alia by including an assessment tool. This assessment tool appeared to be both a blessing and a curse, as it was found to be time consuming.

Students appreciated the differing learning process than they are used to. Especially the practice-based approach with the hands-on experimenting was interesting and helpful to gain insights into circular design aspects. In fact, students state that, although it requires a lot of work, more hands-on learning activities in the curriculum would be welcomed. To strengthen their vision, suggestion was made to complement the assignment with a real-life full design/build project such as a small pavilion or a tiny house. This way, students could go beyond analysing materials/products/systems and use their creativity not only as builders but also as designers of spaces and places.

The peer assessment showed that the necessity of working in groups had both positive and negative aspects. Positive was the fact that students with other abilities and points of interest can work together, strengthen the quality of work and learn from each other. Negative part was that working in a team could be difficult, especially when students do not know each other well, when students only see their own opinion, or when students do not show interest or do not collaborate.

4.1.2. Tutors' perspective. Despite the labour intensive preparation, both the collaboration/interaction with system manufacturers and the hands-on approach were seen as promising for the research seminar and will be retained for and even elaborated in following editions. Three issues that must be addressed and need improvement are: (1) the aspect of working in group by students; (2) the aspect of (learning to) assess(ing) in an objective way; and (3) the aspect of encouraging/stimulating/feeding innovation during the development of improvements by the tutors.

4.2. Research methodological aspects in view of the nexus education – research. The nexus worked well mainly due to three aspects. First, the research topic is linked with the architecture and building practice, and has a strong societal relevance. Second, used research methods include tangible aspects (hands-on), and enable to expose outcomes (visibility). Both aspects enable to engage students more easily. Third, an assessment tool is included in the assignment, so outcomes can be validated and incorporated in scientific/academic research. Regarding the latter, a quantitative assessment method is preferred in order to avoid subjective assessments.

4.3. Niche development aspects

For each of the systems and compositions, students proposed and developed improvements based on issues identified by the assessment conducted. This subsection provides some illustrative proposed improvements.

4.3.1. Systems 1 & 2 – composition A. For systems 1 (Construclick) and 2 (Facadeclick) as a whole, three suggested improvements are discussed: a) a circular connection of the systems with the foundation; b) a circular fixation of the watertight slab in connection with the foundation; c) an alternative cavity anchor (see figure 3).

Within the 'reversible' criterion, the assessment showed that the connection with the foundation of both the inner and outer leaf of the composition, respectively system 1 – Construclick and system 2 –

Facadeclick, does not fit the idea of circularity. The application guidelines of both systems prescribe the use of a mortar layer. Students experimented with a mounting lath on a levelled basis (foundation).

The watertight connection between the foundation and the inner leaf is not 'reversible', at least not in the sense of reusing materials. Normally the watertight slab is glued on the outer side of the inner leaf. In order to eliminate this gluing, students thought of a connecting block which can be inserted in the gloves of the inner wall (to fix the cavity anchors). By means of rubber washers and metal screws the watertight barrier can be fixed to this connecting block.

Within the assessment criterion 'simplicity' and 'durability', the used cavity anchors demonstrated weaknesses. The form of the metal anchors needed some adjustments (bending) in order to be placed correctly in the spacers of the inner and outer leaf. This bending was also needed during disassembly so cavity anchors showed usage damage. To tackle this, students designed a compressible anchor which facilitates an easy placement and prevents usage damage.

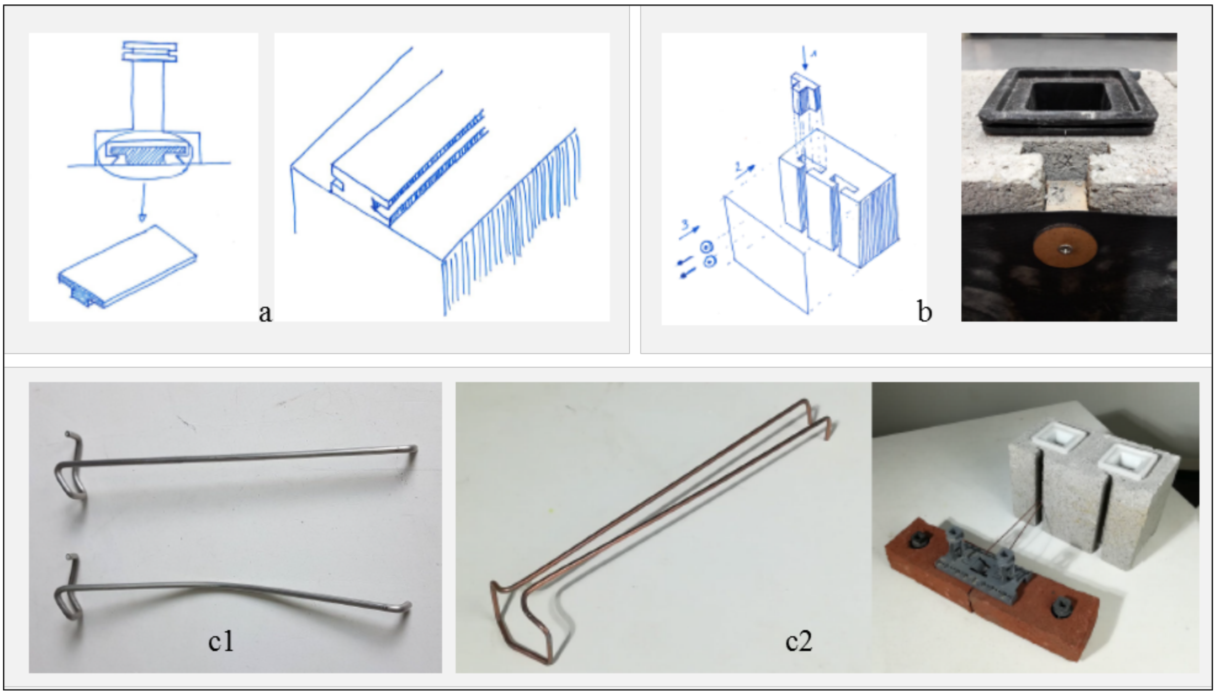

Figure 3. Three suggested improvements for systems 1 & 2 – composition A: a) a mounting lath for a circular connection with the foundation; b) a connecting block to fix the watertight slab between foundation and inner wall; c) with c1 the existing cavity anchor, and c2 an alternative cavity anchor.

4.3.2. Systems 3 & 4 – composition B. For both systems, Systimber (system 3) and Clickbrick (system 4), two suggested improvements are discussed (see figure 4).

During disassembly, it became clear that the metal spacers to connect the wooden beams of the Systimber system were not 'reversible'. Due to a limited grip of the screw machine cap on the head of the spacer, spacers showed such damage that reuse is impossible. Students experimented with wider grip surfaces of the head of the spacer.

Within a cavity-wall composition, Systimber is only limited circular as cavity anchors are drilled in and leave boreholes after disassembly. This may limit the potential for reuse. To prevent this, students designed two possibilities to anchor cavity anchors without leaving traces: first, a slidable two-part connector, in which one part is fixed permanently on the wood and where on the other part the cavity anchor is fixed; and second, the integration of a U-shaped profile in the wood with vertically slidable hooks on which cavity anchors are fixed.

Similar as in systems 1 & 2, the Clickbrick system lacks a circular connection with the foundation. Taking into account the specificities of the system, students designed a metal plate which must be screwed on a levelled basis (foundation).

Regarding the cavity anchors included in the Clickbrick system, a problem of 'reversibility' may appear as it is difficult to unscrew them. Students propose to provide the anchors with a screw head so they can always be screwed out easily.

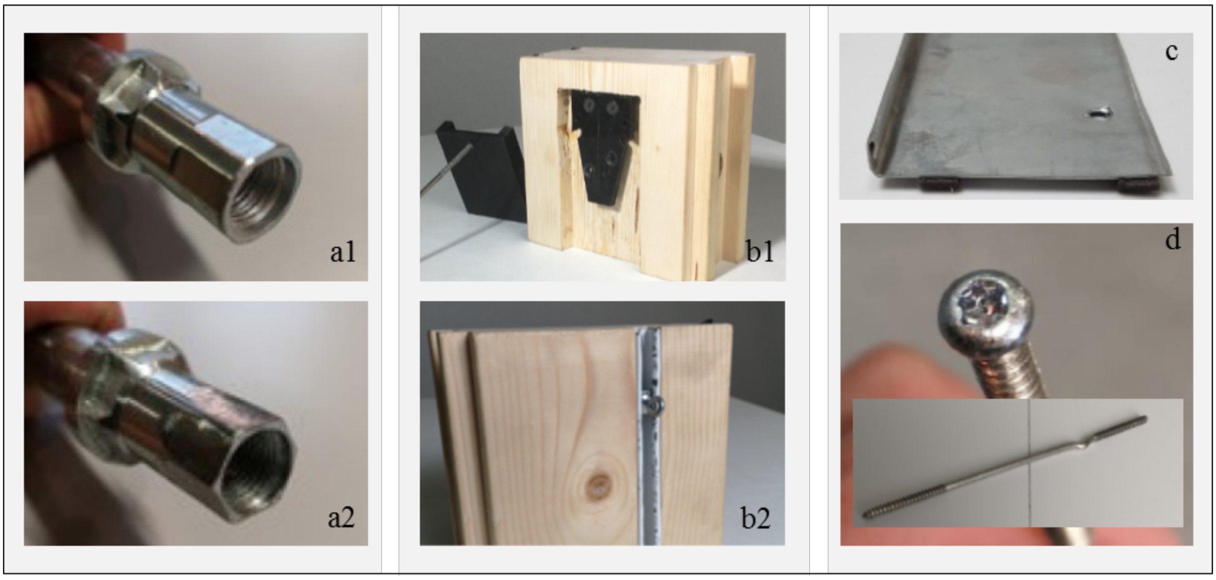

Figure 4. Three suggested improvements for systems 3 & 4 – composition B: a) wider grip surfaces of the spacer (with a1 the existing grip); b1 + b2) two anchoring solutions for cavity anchors; c) metal plate for a circular connection with the foundation; d) a screw head of the cavity anchors.

5. Conclusion

This paper presented and discussed the concept of the student research on in-situ testing and improving of circular building systems for cavity walls within the context of the research seminar 'Building concept' of the architecture programme of Hasselt University.

Based on reflections of both students and tutors, it can be concluded that the concept of the nexus education - research was successful and only needs minor revisions. Students appreciated the focus on new ways of building with a strong societal relevance, the balance between theory and practice and the hands-on experimenting. From the tutors' perspective, the collaboration/interaction with system manufacturers and the hands-on approach was evaluated positive.

Perspectives for future editions of similar student research are: regarding the topic, complementing the assignment with a real-life full design/build project; regarding the educational perspective, including a team building activity in order to improve the aspect of working in a group, and using tailored pedagogical methods to encourage/stimulate/feed innovation during the development of improvements by the students; from a research point of view, selecting a quantitative assessment method which avoids subjective assessments, and which is easy and quick to use by students.

Concerning the circular building systems, the research demonstrated that all systems as such work, are easy to use and fast to assemble and disassemble. Small-scale incremental improvements, as proposed by the students, on the individual system level are required. However, fundamental improvements and research regarding following aspects (non-exhaustive) are believed to be crucial for a full and successful application of the idea of circular building: circular connections between circular building systems and other building components (e.g. foundation, windows, roofs), compatibility (e.g. dimensions, connections) with other circular building systems, watertight and vapor tight sealing of both surfaces and joints, diversity of products within circular building systems (e.g. tailored lintels, corner solutions), broad building type (in view of needed performances) and project type application range (e.g. renovation); prefabrication potential, lowering the environmental impact (e.g. especially of connecting components) of existing circular building systems, and more broadly development of new circular building systems based on renewable and regenerative resources and considering open source knowledge and system development to maximize the development and implementation potential of circular systems.

Abstract. Earthen building materials offer an environmentally sustainable alternative to conventional materials because they are locally available, minimally processed, and waste-free. However, they have not been comprehensively implemented because their technical data is highly variable, and they are not fully represented in building codes. To address these hurdles, this paper presents an environmental assessment and a policy repair review, including an environmental embodied impact analysis, and a discussion of the regulatory development required for earthen construction. The results of the environmental assessment show that earthen wall assemblies significantly reduce environmental impacts by 62-99% when compared with conventional assemblies such as timber frame and concrete blocks. Additionally, the policy discussion provides recommendations to overcoming materials variability and regulatory organizational collaboration. Overall, this paper highlights the importance of environmental and policy measures that could be used by policy makers and earthen building advocates in their endeavours to catalyse the representation of earthen building materials and methods in mainstream construction.

1. A brief history of unsustainable architecture

Throughout history, human building practices followed the path of building shelters out of locally abundant materials, where the building components were always mined and curated from the nearby environment: earth, stone, trees and grasses. The evolution of these various shelters was developed in different cultures by improving materials, energy, water, and waste solutions, adjusting from generation to generation to meet new needs and opportunities [1,2].

It is only in the last few centuries that our relationship with buildings has changed. Cementitious materials started playing a vital role in the ancient world: the Egyptians obtained cementitious material by burning gypsum; the Greeks used lime by heating limestone; and the Romans developed hydraulic cement by adding crushed volcanic ash to the lime [3]. These techniques were re-developed and patented in western Europe as “Roman ––Cement” (in 1794) and “Portland Cement” (in 1824) [2,4].

These last developments, accompanied by the industrial revolution, changed the way building materials were produced and the techniques used for construction. Started as a wave in Western Europe, these highly-processed building materials and methods are still spreading into less-developed parts over the world. Thousands of new building products have been developed and replaced local traditional materials in ways that minimize labor and allow an increase in the pace and amount of construction. Nevertheless, these modern building practices require the extraction, transportation, and heavy processing of (often toxic) building products in ways that contribute to the consumption of large amounts of non-renewable resources, contributing to the deterioration of our global environmental [5].

In terms of building materials standardization, conventional modern construction materials, mostly made of steel reinforced concrete, wood, and synthetic insulation, are being implemented in the majority of modern buildings while meeting a wide variety of building codes and standards. Therefore, in light of the environmental impacts specified above, these building codes and standards (that were initially developed to ensure individual safety and public general welfare) are currently neglecting larger, ecologically-based risks to natural systems upon which everyone's safety and health ultimately depend [6]. Nonetheless, due to an increased interest in sustainable and green building practices, additional non-mandatory regulatory and rating systems have been developed that support materials and resources considerations in projects, as shown by the growing numbers of L.E.E.D^{TM} certified projects [7,8].

2. Why earth? The case for earthen building materials and methods

Parallel to the interest in sustainable and green building practices, there has been a growing interest in ecological and natural building materials and methods [8]. These are defined as minimally processed and locally available materials that enhance their local environment and economy, rather than only mitigating negative impacts [9]. Examples of natural building materials include natural fibers like straw and hemp, and earthen materials like sand and clay. Specifically, earthen materials exhibit various advantages; they provide high thermal inertia and offer better structural capacity in compression. As opposed to trees and crops, earth is usually abundant in and around the construction site. As opposed to cellulose-based materials, it has better resistance to fungi, insects and rodents. Furthermore, it allows a diversity of forms and styles, from sculptural monolithic assemblies to modular components [10].

Earthen architecture can be defined as building materials and methods in which clay is used as a binder [11]. It is also often referred to as a traditional and/or vernacular building material and method [12]. However, some earthen building techniques were developed in the past few decades (e.g., compressed earth blocks), while others were used traditionally and currently receive a new architectural interpretation (e.g., rammed earth) [13,14]. More specifically, in recent decades, material science has come to know much more about how clay works as a natural binder in building materials. Therefore, earthen building materials are recently suggested to provide a natural concrete alternative, namely a low-carbon, clay-based concrete [11].

Despite their benefits, earthen building materials and methods remain mostly unrealized in the mainstream construction industry from various reasons. First, the literature lacks aggregation of technical data that could quantify the performance of earthen materials for different climate and seismic conditions [15,16]. Second, there is a broad and often mistaken perception of these materials as being low-tech and having poor overall performance [8,17]. Lastly, one of the main barriers that is especially evident in the case of cob and earthbags is the lack of complete and user-friendly codes and regulations that could give rise to the conventional implementation of, for instance, affordable homes [6,18].

These concerns are broadly echoed in the literature. Woolley (2006) concludes that public policy incentives, particularly formal codes and regulations, should be developed for earthen materials, accompanied with financial incentives, in order to give rise to real-estate investments. Similarly, Swan, Rteil, and Lovegrove (2011) suggest that future research should a) aggregate the existing experimental engineering studies; b) provide analytical and numerical insights that could facilitate the design process and allow the inclusion of earthen materials in building codes; and c) provide a life cycle analysis of earthen construction assemblies.

3. Performance-based assessment of earthen building materials vs. conventional assemblies

The performance of a building material describes its functioning in terms of declared characteristic properties. Depicted though levels, classes or short descriptions, these performance parameters can portray the main features of earthen materials as opposed to conventional assemblies.

Table 1. Technical performance of earthen materials as opposed to conventional materials

	Performance Parameter	Earthen Building Materials			Timber Frame [19]	Concrete Masonry [20] uninsulated (insulated)
		Cob	Rammed Earth	Light Straw Clay		
Thermal	Thermal Resistance (m^2K/W per inch)	0.051 [21] to 0.106 [22]	0.025 [21,23] to 0.06 [24]	0.14 [25] to 0.26 [26]	0.5-0.7 (with fiberglass batt)	0.05 (0.15) [27]

Environmental (Sec. 4.	Air particulate pollution $PM_{2.5eq}/m^2$	0.00247	0.00145	0.00225	0.0574	0.130 - 0.143
Structural	Compression modulus (N/mm^2)	72 [32,33] to 650 [16]	550-960 [34]	Not load bearing	7,000-18,000 along grain [34]	15,000 - 60,000 [34]
Structural	Rupture modulus (N/mm^2)	0.17 [32] to 0.98 [33]		Not load bearing		
Others	Sound Transmission Class (STC)		57 [10]		33 [10]	55 [35]
Others	Fire resistance	Fire resistant [34,36]		Fire retardant [34,36]	Combustible requiring treatment or oversizing (ISO type 1).	Semi Fire Resistive (ISO type 5).

4. Environmental embodied impacts of earthen construction vs. conventional assemblies

Environmental LCA has become a common tool that is used to evaluate building products and processes. It is considered a powerful tool for the evaluation of and contribution to sustainable building development. [37]. However, LCA progress is slower in the building sector than other industries, especially due to buildings' complicated production process. Although the environmental LCA of earthen materials has not been comprehensively studied, it has been argued extensively that earthen materials and methods can potentially require less energy and emit less Green House Gasses (GHG), due to their self-sustaining, socially sustainable, cradle-to-cradle life cycle, as shown in Figure 1 [34].

Only a few studies have enumerated the environmental impacts of earthen building materials, including the LCA of adobe bricks [38,39], rammed earth [40,41], and earthen plasters [42,43]. Though significant, these studies are not comparable with conventional assemblies, due to the location and process-specific data used. To address this limitation, this study compares the environmental impacts of different earthen construction techniques to benchmark conventional techniques.

The presented LCA was implemented following the ISO Standard 14040 and 14044 format and methodology [44,45], using the SimaPro software [46], the US-LCI database [47] where possible, and EcoInvent [48] processes that are globally applicable otherwise (i.e., RoW processes). Six wall assemblies are compared: 3 earthen walls (cob, rammed earth, and light straw clay) and 3 conventional walls (timber frame, insulated and uninsulated concrete block). The functional unit used is 1 square meter of a single-family housing wall, located in warm-hot climates in the US, defined as IECC climate zones 1 through 4 [49]. The system boundaries consider embodied environmental impacts from cradle to construction site, including the extraction and processing of raw materials, manufacturing, storage, and transporting to the construction site.

Figure 1: Cradle to cradle life cycle diagram of earth as a building material (edited from Schroeder, 2016)

The Life Cycle Impact Assessment (LCIA) includes embodied energy demand, global climate change impacts, air acidification, and human health (HH) air particulate pollution. The impacts were assessed using CED (Cumulative Energy Demand) factors for fuels and sources of energy [50] and the TRACI (Tool for Reduction and Assessment of Chemicals and Other Environmental Impacts) for inventory emissions [51]. Weight distribution was calculated for each of the earthen wall components: straw, sand, clay-rich soil, and clay plaster. The cob and rammed earth walls were assumed to have an average 460 mm thickness [52,53], and the light straw clay wall a 300 mm thickness [54]. Clay-rich soil was assumed to contain 50% clay and the study accounts for a scenario in which this soil is not available on site and thus is processed and transported from a quarry. The LCA of the benchmark wall assemblies was assessed using existing LCI results. Specifically, the wood frame LCI incorporated lumber [55], plywood sheathing [56,57], gypsum board [58], and fiberglass batt. The concrete LCI incorporated concrete blocks [61], rigid polystyrene insulation [59], and Portland cement stucco [60]. These LCIs were selected according to their corresponding system boundaries of cradle to gate and geographical context of North America.

The impact assessment results, shown in

Figure 2, illustrate that all earthen wall systems have significantly lower environmental impacts as opposed to the benchmark wood and concrete block assemblies. Embodied energy demand of earthen walls is reduced 62-71% from that of conventional construction; embodied global climate change impacts are reduced 85-91%; embodied air acidification is reduced 79-95%; and embodied particulate pollution is virtually eliminated. These comparative results depict the environmental urgency of using earthen materials.

Specifically, transportation distances and amount of straw have the strongest effect on the environmental impacts of the different earthen walls. Among the earthen walls, light straw clay accounts for the least energy demand and global climate change impacts, due to its smaller thickness, as well as the absence of the sand and soil that require truck transportation. The rammed earth wall, with the same thickness as cob, results in fewer environmental impacts than cob for all impact categories due to its absence of straw that requires large amounts of chemicals for production. For the same reason, light straw clay has the highest impacts in terms of air acidification, following by cob, due to the straw production-stage emissions of methane (CH4), sulphur dioxide (SO2), and nitrogen oxides (NOx), associated with the use of pesticides and fertilizers.

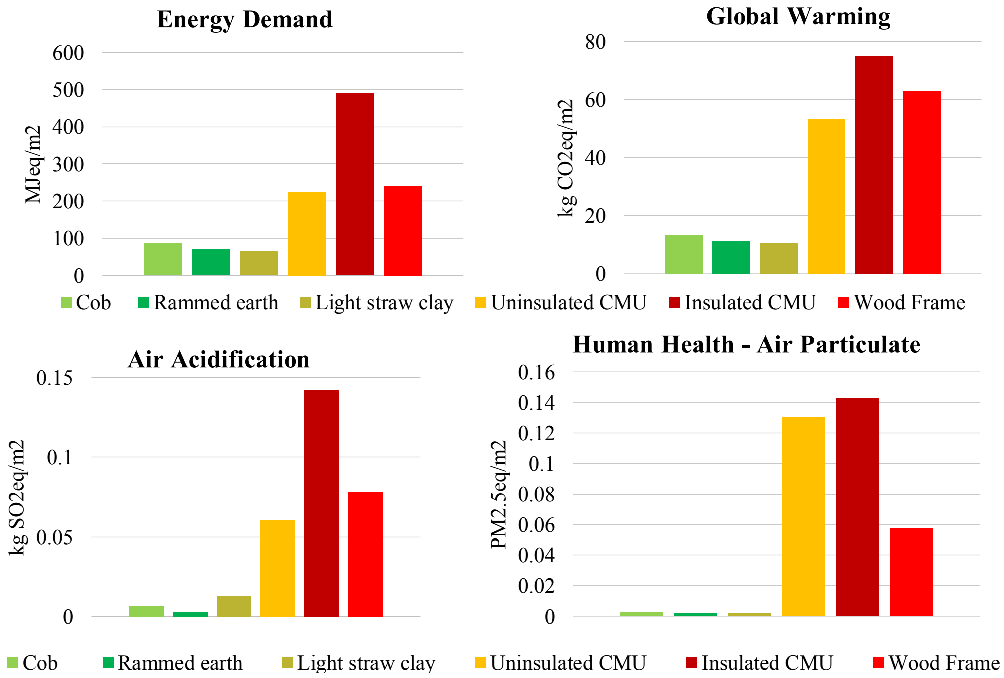

Figure 2: Environmental embodied impacts comparison among the different wall systems: cob, rammed earth, light strw clay, uninsulated Concrete Masonry Unit (CMU) blocks, insulated CMU, and wood frame (Source: authors)

5. Required Improvements to Earthen Building Policy

5.1. The Importance of Earthen Codes and Standards

The importance of earthen building materials standardization lies in both technical and sociocultural realms. In terms of their technical significance, standards for earthen materials gather accurate design values as well as provide a common frame of reference for the user community – a lingua franca of sorts. Technical performance tests could be compiled to obtain a more reliable understanding of the material's properties based on a statistical analysis which can lead to the refinement of, and confidence in, design values. This, in turn, could lead to a broader integration of the material in the construction community. Such integration, coupled with advocacy, can lead to broader social acceptance of what was previously considered a marginalized vernacular construction method [62]. While approximately a third of the world population lives in earthen structures, in both developing and developed countries, the existence of appropriate codes is of importance. However, current building codes are based on heavily processed materials such as concrete and steel products, earthen techniques that cannot fulfil heavy load bearing and high insulation requirements were excluded [63].

5.2. Challenges and Suggested Solutions to the Development of Earthen Codes and Standards

In order to embed earthen building materials in building standards and codes, their performance should be assessed through the work of universities, laboratories and professional organizations. To date, earthen building materials and methods are still considered nonconventional and their standardization is in its earliest stages; design, construction, testing protocols and technical terminology, even among experts, is fragmented and requires further evolution. However, in this context, even conventional construction materials such as steel, timber, and reinforced concrete were once unconventional and unproven materials and their acceptance was achieved through decades of testing, analysis, and experience. Codes and standards development has been described as "a long and onerous" process (Mottram 2017). Particularly for materials having few existing precedents, the task is daunting and meets resistance at many steps. The following lists many of the challenges and possible strategies to overcoming these.

5.2.1. Overcoming Materials Variability. One of the main challenges to the emergence of earthen materials standards is their high variability and reliance on local construction methods. Additionally, earthen materials are often locally sourced and processed or mixed on site. Such variation effects both the construction process (e.g., workability, drying time) and the performance of the building outcome (e.g., structural, thermal, durability). For instance, in an experimental study of cob technical performance, specimens were collected from local builders, resulting in a high coefficient of variation among the different mixtures [32]. In terms of building standards, this high variability could reduce characteristic strength values that could result in inefficient utilization of the material. This, in turn, could potentially lead to unrealistic required building element dimensions and higher environmental and monetary costs. Furthermore, due to their variability, and in order to verify their code compliance and desired performance, natural materials require frequent field tests.

The challenge of material variation could be addressed by various strategies. By using wood as an example for a natural building material with large variability, we can identify the ways in which we developed both prescriptive and performance standards for timber. While the number of wood species is great, the main strategy used in timber standardization is to group species according to their structural properties and appearances, prescribing uniform grade-use data for each group. Similar to timber codes and standards, a homogenization approach grouping different species or 'classes' of clay materials should be developed for earthen materials to ensure adherence with format and objectives of conventional standards.

Figure 3: Homogenized soil classification, assessed in accordance with Australian Standard [64]

5.2.2. Establishing Collaborative Standardisation Framework to Overcome Financial Challenges. Earthen building materials are non-commodified systems that have no 'industry association'. Often, they cannot be developed into products and cannot be patented. This leads to a lack of financial support and advocacy of nonconventional and vernacular materials at code and standards organizations and committees, whereas established conventional building materials representation is often compensated by their organization [65]. Additionally, national standard-writing organizations with limited resources and volunteer committees have little incentive to address technology that is often considered marginal.

One way to overcome this situation is to have existing experts organize in a way that can produce valuable exchange of experience and technical documents. For instance, in the case of the New Zealand earth building standards, the Earth Building Association of New Zealand (EBANZ), with the participation of local engineers and architects, first developed a set of guidelines in 1991. Thereafter, New Zealand Standards (NZS) took responsibility for the project and joined together with Standards Australia in 1993 to develop a joint standard with an enlarged committee [66]. The collaboration was discontinued in 1997 mainly due differences in seismic requirements, yet the exchange of information and expertise was valuable. One year later, NZS published the New Zealand earth building standards (NZS 4297, NZS 4298, NZS 4299), which comply with the local Building Code. Simultaneously, Standards Australia developed *The Australian Earth Building Handbook* (HB-195 2002) and the Earth Building Association of Australia (EBAA) developed the *Building with Earth Bricks and Rammed Earth in Australia* (EBAA 1997). The hybrid approach of Standards and non-standards bodies' development of construction guidance for earthen material is summarized in Figure 4.

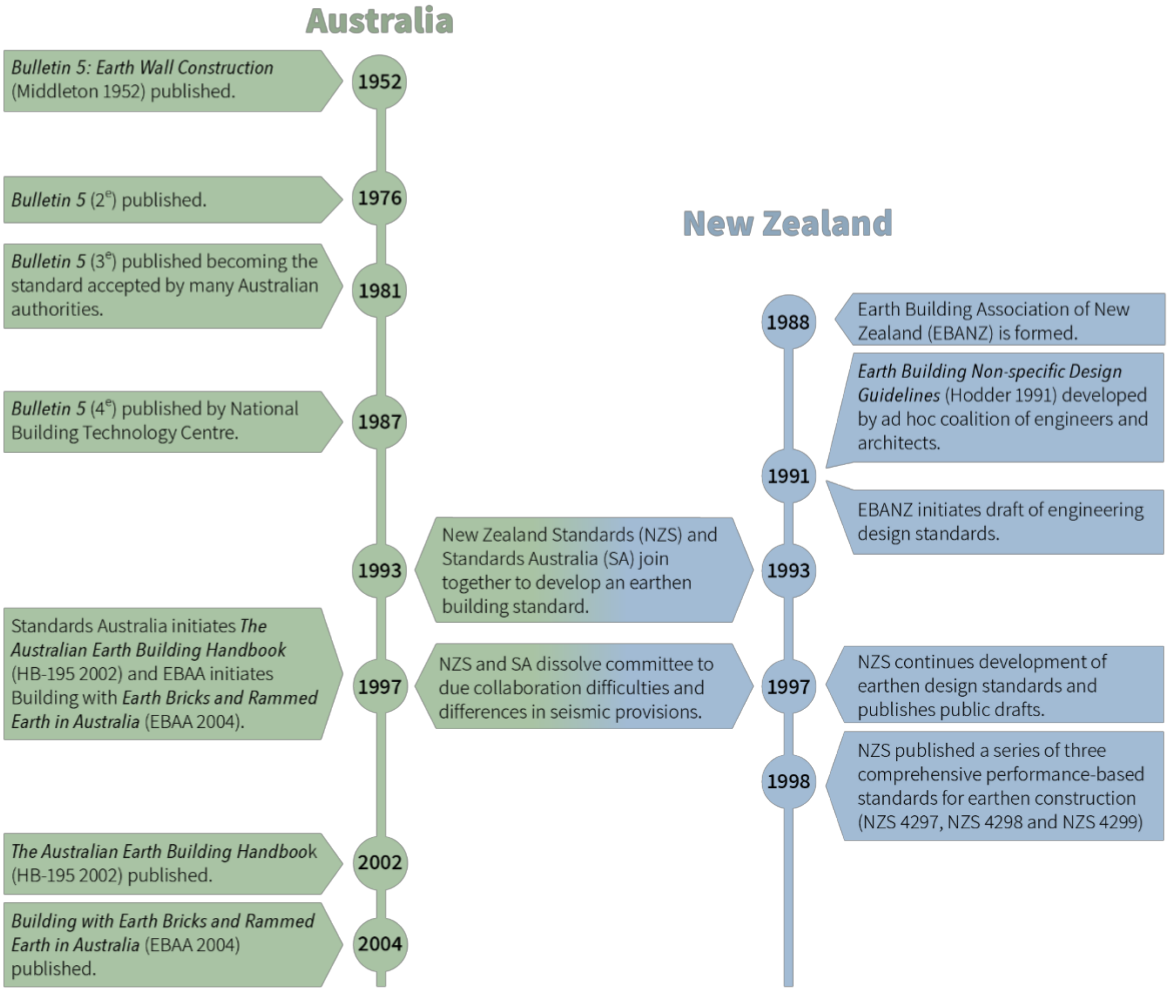

Figure 4: Timeline of New Zealand and Australia Earth Building Standards development process (Source: authors)

Additionally, using verb form is crucial to earthen building regulatory development. Similarly to NZS, Code-compliant mandatory language could allow reference from within building codes. Enacting documents or clauses – those that represent a legal obligation – are conventionally required to provide unequivocal and imperative requirements: "shall". Recommendations ("should") and permissive language ("may") are relegated to non-mandatory appendices or documents and are legally unenforceable, such as in the case of ASTM E2392.

5.2.3. Enriching traditional techniques with modern knowledge. Experience from previous generations that is well preserved in local tradition and dutifully transmitted to people living today can be the basis of an informal, non-codified "standard". For instance, bamboo standards consider the use of traditional practices as those constituting an "old and pure tradition" or treated as "general wisdom" within a community. The application of such traditional expertise is limited to similar scenarios and may not be extrapolated in terms of dimensional scale or locale [67].

Codes and standards reflect state-of-practice rather than the state-of-the-art. Therefore, the development of a sound 'engineering judgement' is an iterative process of continuous improvement and is reflected in the maintenance of standards worldwide. For this reason, standard development for earthen materials must begin with synthesis of the existing engineering data, as well as documentation and enhancement of local practices. Such synthesis requires using consistent test procedures in materials test studies, as well as proper documentation and analysis of results. To date, researchers studying earthen materials have adopted different established test methods – some for concrete materials, others for masonry units, and even others for masonry assemblies – and their attendant specimen geometries. These result in a considerable range of reported data that cannot be directly compared. In some cases, test method selection results in a bias in reported properties. For example, it has been shown that different studies report the compression modulus of cob material to vary by an order of magnitude depending on the test method used [68].

5.2.4. Establishing Clarity and User Friendliness in Earthen Building Codes. "Usability" of a standard, as the word implies, must be based on the needs and expectations of the user. An alternative to presenting design examples is to develop navigation flow charts for design standard provisions or typical design cases (for instance, as provided in [69]). These serve to improve ease of navigation but are also a tool the standard authors can use to ensure clarity and completeness. Development of a design work flow chart can identify provisions which are incomplete, lead to 'dead ends', or result in complex iterative procedures.

Additionally, the purpose of the code or standard should be clearly defined in order to reduce complexity and to refine its scope. For instance, a very specific scope statement is included in the New Zealand Earth Building Standards: *The objective of this Standard is to provide for the structural and durability design of earth buildings. The Standard is intended to be approved as a means of compliance with clauses B1 and B2 of the New Zealand Building Code* (NZS 4297). A more general suggested example may be an object *to codify existing knowledge in order to ensure structural safety, as well as to address common design situations while providing means of compliance with building codes and supporting innovative design*.

When considering earthen materials that are often nonconventional and vernacular, the user community might be further removed from the standards development process, increasing the risk of misinterpretation. This might lead to the standards simply not being applied at all. On one hand, the opportunity afforded by nonconventional materials for starting with a "blank page" when developing standards should be used to mitigate unnecessary complexity. On the other hand, existing codes and standards as well as committee constitutions that prove successful should be used as exemplars to avoid excessive complexity that results from "re-inventing the wheel".

6. Conclusions and Required Future Steps

Earthen building materials and methods offer a prominent solution to conventional highly processed materials. However, despite their advantages, earthen materials and methods have not been comprehensively implemented because their technical data is inconsistent, and they are not comprehensively represented in building codes. To address these hurdles, this paper begins with a comparative synthesis of the technical performance of earthen materials as opposed to conventional assemblies. Thereafter, the paper presents an environmental LCA that enumerate the environmental urgency of earthen materials, showing that the earthen walls save 62-71% of embodied energy demand, reduce 85-91% of embodied global climate change impacts, 79-95% of embodied air acidification and

98-99% embodied particulate pollution. Lastly, a discussion of the regulatory development required for earthen construction is presented, including main challenges and recommendations to overcoming these, including ways to overcome challenges of materials variability, collaborate between advocates and organizations, integrate traditional expertise with state-of-the-art knowledge, and establish language and scope clarity. Future studies on the environmental and policy measures should incorporate a full LCA that takes into account operational impacts, as well as develop inventories for a complete set of earthen and natural wall assemblies that could be used against inventories of benchmark wall assemblies.

Comparative analysis of an existing public building made from natural building materials and reference buildings designed from common building materials

Medgyasszay P

Department of Construction Materials and Technologies, Budapest University of Technology and Economics, Hungary

medgyasszay.peter@epito.bme.hu

Abstract. The paper examines a public building constructed of partially natural materials and two imagined buildings with the same geometry, using LCC and LCA methods, with self-developed software. The imagined buildings were designed using the building materials and building mechanical systems commonly used in Hungary which fulfil the relevant energetic requirements in 2010 and in 2019. As a sensitivity analysis the LCA performance of buildings was examined with residential building function. The paper introduces the environmental benefits that can be obtained with natural materials and with other tools in case of the examined building. Based on the results, design strategies can be phrase for environmentally conscious design of buildings with similar scale and function.

1. Introduction

The building industry, despite of the noteworthy increase of environment-conscious attitude, has a significant role and responsibility to handle the challenge of climate change, as one of the most important present problem of humanity. The buildings and construction are still responsible for the 36% of global final energy use and 39% of energy-related carbon dioxide emissions. According to the forecasts by 2060 230 billion m^2 new building floor areas will be constructed. This floor area is equivalent to the field area that in the next 40 years every single week the territory of city Paris would be inbuilt. [1]

To reduce the building industry-related energy consumption has several possibilities and strategies. Based on the publication of Global Alliance for Buildings and Constructions for 2050 the aims *"Achieving a large diffusion of net zero energy buildings"* and *"Reducing embodied energy and GHSG emissions"* have significant priority in the next 10 years. [2] The combination of these two aspects is also important because more and more building materials have to be produced in order to achieve better insulation. By using life-cycle approach analysis, like Life Cycle Assessment (LCA) with environmental focus or the Life Cycle Cost Analysis (LCC) with economic focus, we can find the optimum of the two, sometimes conflicting goals. Our previous research confirmed that natural building materials can achieve a low value in both embodied and operational energy need, because of their low primer energy content. [3] [4]

In the paper, a realized and two imaginary public buildings will be analysed with LCA and LCC methods. The imaginary buildings are the same as the realized building, but their material use and building service systems are representative for the age of the design and the present days. As a sensitivity analysis, beside the public building function the calculations were carried out also for a residential building function. The goal of this paper is to highlight the magnitude of environmental benefits that can be gained through natural materials and other measures.

2. Methodology

2.1. Case study building: realized building.

The constructed case study building was designed in 2010 by the Belső Udvar Architect and Expert Office by Péter Medgyasszay, Ágnes Novák and Péter Büki architects. [5] The whole project was introduced in details in previous publications. [6] [7] In the following, only the examined two-building complex Demonstration Centre will be described, where a small restaurant and kitchen on one side, the reception, auditorium and other functions on the other side are located. The two buildings form an inner yard, surround an artificial lake (figure 1). One end of each building is lower by 80 cm than the other. This arrangement of curved walls results in a sense of fake perspective in the enclosed space of the two buildings. Each building is in the scale of a Hungarian country-house (approx. 8,5x28 m), but because of the non-conventional wall shape and the large roofs, the two-building complex has a unique view (figure 2 and figure 3).

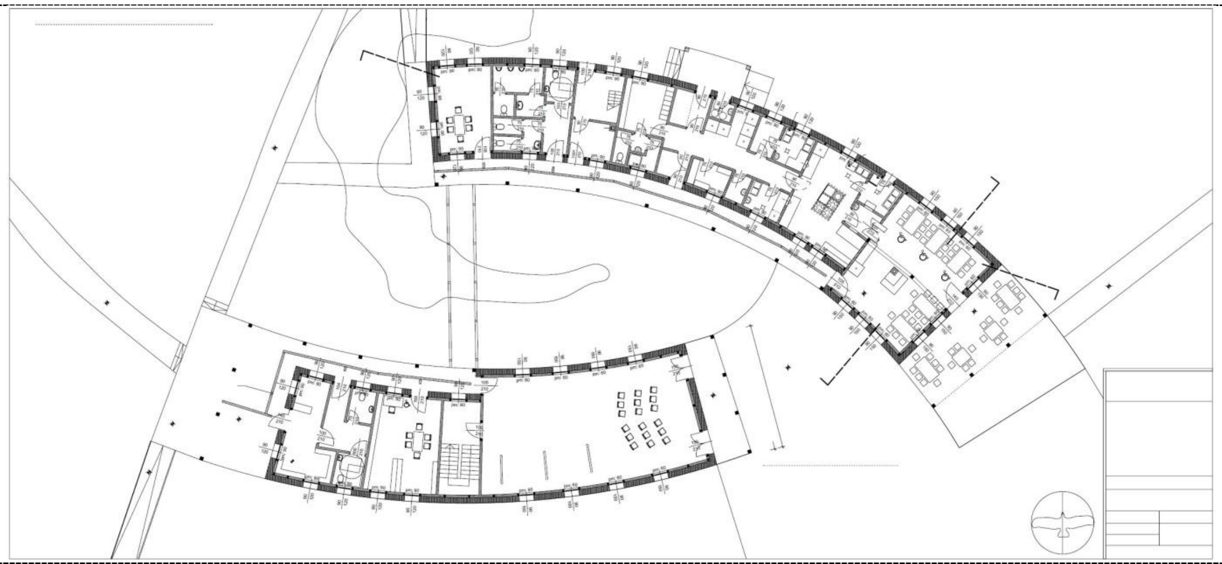

Figure 1. Ground floor layout of the Demonstration Building [5]

Figure 2. View of the Demonstration Centre from the parking. [Medgyasszay]

Figure 3. View from the terrace with the inner yard and the artificial lake [Medgyasszay]

The Demonstration Centre, also to demonstrate the environmental goals of the whole project, was built partially from natural building materials. Due to the deep loadbearing soil level and the considerable movement of the underground water, it was necessary to use pile foundation and beam grid under the walls. The beam grid structure was highly insulated due to low energy demand of the building. The external wall structure is constructed from a wooden post and beam structure. The wooden "ladder" frame consists of 10/15 cm pillars at the inner side and 5/10 cm pillars at the outer side at an average of 90 cm distance. The 15 cm thick adobe wall was positioned between the wooden loadbearing columns. The adobe hand-made bricks were produced in 20 km distance from the building site. The outer side of the walls are insulated with 35 cm thick straw bales harvested and collected from the nearby fields. The wall was plastered on both sides with adobe-plaster and painted with limewash. The roof was covered with tiles. The doors and the windows were made from wood with triple glazing. The floors were covered with ceramic floor tiles, brick and wood (figure 4).

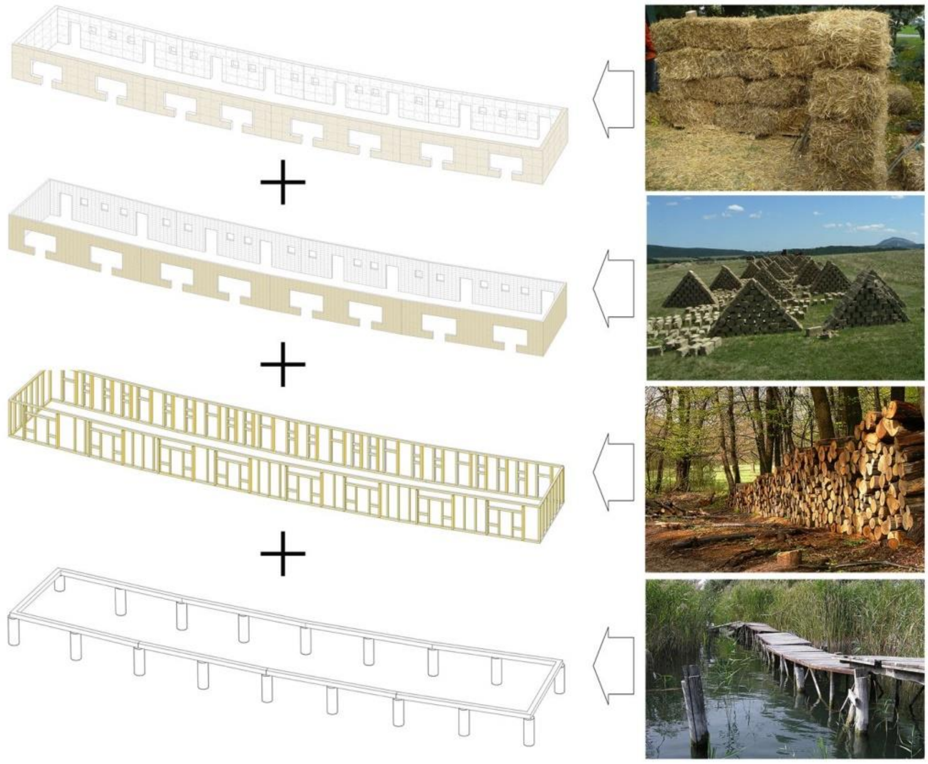

Figure 4. Structure and materials of the external wall, the foundation and the roof [6]

As heating system a wood chip boiler was installed with low temperature floor heating. A ventilation system was installed only in the kitchen area. Because of the good heat storage and heat insulation capacity of the constructions, no air-conditioning system was designed. The hot water need of the building was also covered by the wood chip boiler.

2.2. Case study building: imaginary building 2010

The design principle of the "imaginary case study building 2010" was to define an average Hungarian building from the year of the design what fulfil the actual energetic requirements with the same geometry as the constructed one. The external load-bearing wall was designed from brick (Porotherm 38 N+F), and in the slab on the ground construction 6 cm expanded polystyrene insulation (EPS) was planned. In the roof construction 15 cm rockwool was planned and the openings were assumed as wood construction with double glazing. The rest of the building was conceived with the same structures as the built building.

The heating system was imagined, as a common Hungarian system, with low temperature gas-boiler and radiator units. Like the realized building, the ventilation system was designed only for the kitchen, and no air-conditioning unit was applied. [8] [9]

2.3. Case study building: imaginary building 2019

The design principle of the "imaginary case study building 2019" was to define an average Hungarian building from the year 2019 what fulfils the present energetic requirements with the same geometry as the constructed one. The external load-bearing wall was designed from brick (Porotherm 30 N+F) with 10 cm EPS, and in the slab on the ground construction 12 cm EPS was planned. In the roof construction 25 cm rockwool was planned and the openings were imagined as wood construction with triple glazing. The rest of the building was conceived with the same structures as the realized building.

The heating system was imagined, as a common Hungarian system, with condensing gas boiler and radiator units. Like the realized building, the ventilation system was designed only for the kitchen, and no air-conditioning unit was planned. The following table introduces the differences of three building (table 1).

Table 1. Comparison of the structures, building services and energy demands of the realized and imagined buildings

	Realized building	**Imagined building 2010**	**Imagined building 2019**
Foundation	pile foundation	pile foundation	pile foundation
External wall	wood frame, adobe brick and straw bale insulation U=0,15 W/m^{2}K	brick wall U=0,45 W/m^{2}K	brick wall with 10 cm EPS U=0,22 W/m^{2}K
Roof and attic floor	wood frame, 25 cm rock wool insulation U=0,15 W/m^{2}K	wood frame, 15 cm rock wool insulation U=0,24 W/m^{2}K	wood frame, 25 cm rock wool insulation U=0,15 W/m^{2}K
Slab on the floor	flooring, concrete, 5 cm EPS, 5 cm XPS insulation U=0,33 W/m^{2}K	flooring, concrete, 6 cm EPS, insulation U=0,49 W/m^{2}K	flooring, concrete, 12 cm EPS, insulation U=0,3 W/m^{2}K
Openings	wood frame, triple glazing U=0,8 W/m^{2}K	wood frame, double glazing U=1,4 W/m^{2}K	wood frame, triple glazing U=0,8 W/m^{2}K
Heating, HWS	wood chip boiler	gas boiler	condensing gas boiler
Air conditioning	no	no	no
Ventilation	only in the kitchen	only in the kitchen	only in the kitchen
Primary energy demand of heating (kWh/m^{2}a)	9 as public building, 41 as residential building	25 as public building, 86 as residential building	12 as public building, 54 as residential building
Primary energy demand of hot water (kWh/m^{2}a)	5 as public building, 16 as residential building	15 as public building, 38 as residential building	15 as public building, 37 as residential building
Primary energy demand of ventilation (kWh/m^{2}a)	16 as public building, 0 as residential building	18 as public building, 0 as residential building	18 as public building, 0 as residential building
Primary energy demand of lighting (kWh/m^{2}a)	9 as public building, 0 as residential building	9 as public building, 0 as residential building	9 as public building, 0 as residential building

2.4. Calculation method: energy demand and vapour calculation

All calculations performed for the case study were made with the Belső Udvar E-P-LCC-LCA software. [10] The software development started in 2006 according to the methodology described in the Hungarian Government Decree on the Energy Performance of Buildings. [11] In addition to the initial, simplified energy calculation method, the software used a detailed method from 2010 onwards. The so called "detailed method" with the calculation of the solar gain depending on the orientation of the glazed surfaces and the length of the heating season enabled the software to calculate the energy demand of low-energy buildings with a good approximation. The building, as a specific public building, has different user behaviour profile from a common house. The spaces are not heated in the whole heating season, but in the kitchen area intensive ventilation (8 1/h) is necessary. As basic energy data the following parameters were taken into account:

- average air-change rate: 1,16 1/h,
- internal heat gain: 7 W/m^2,
- correction factor because of intermittent use: 0,4,
- net specific energy demand of lighting: 6 kWh/m^{2}yr,
- reducing factor of lighting: 0,6,
- nett specific energy demand of hot water supply: 7 kWh/m^{2}yr.

During the energy calculations the avoidance of interstitial condensation in external constructions was also checked. A vapour module was developed in 2008, which allows steady-state investigation of water vapour adsorption in structures according to the Hungarian calculation method [12].

2.5. Calculation method: Life Cycle Cost Analysis

The LCC module of the software was developed in 2011 in the framework of research financed by the JRC. [13] The global costs were calculated according to the European Directive 244/2012/EU and its guideline. [14] [15] To the investment costs were added the sum of annual costs for every year (energy costs, maintenance, replacements, etc.) and was reduced with the residual value, all expressed as Net Present Value referring to the starting year. It is important to emphasize that if the investment has shorter lifetime than the calculation period (e.g. mechanical equipment) additional investment (replacement cost) was calculated. [15] The lifetime of mechanical equipment was calculated according to the EN 15459. [16] The lifetime of each layer of building constructions was calculated according to the recommendation of Bundesministerium für Verkehr, Bau und Stadtentwicktung. [17] As economical basic data the following parameters were taken into account:

- calculation period: 30 years,
- discount rate, excluding inflation 4%,
- long-term energy price escalation: 2% for electricity and wood and 2.8% for natural gas.

The investment cost of building materials and mechanical systems materials, including the price of material and labour, were taken from cost databases [18], manufacturer data and quotes. The cost of heating and domestic hot water production was 50 HUF/kWh for electricity, 8,3 HUF/ kWh for wood chips and 16 HUF/kWh for natural gas.

2.6. Calculation method: Life Cycle Assessment

The LCA module of the Belső Udvar E-P-LCC-LCA software was developed in 2012 based on previous research. [19] [20] For the calculation of the environmental impacts, the method of life cycle assessment (LCA) was applied, following the norms ISO 14040 and ISO 14044. The functional unit was one building per one year. The environmental data of building materials and mechanical systems were divided by their life time, as the environmental data of operation was calculated according to the energy calculation. Environmental data from the Swiss ecoinvent 2.0 database were used, with certain modifications to account for the Hungarian circumstances where necessary. [19] Due to the typical environmental impact caused by the construction industry, only three impact categories were considered: [21]

- non-renewable cumulative energy demand (CED, n.r.) [MJ]
- global warming potential (GWP100a, CML 2001) [kg CO2-eq]
- acidification potential (AP, CML 2001) [kg SO2-eq]

2.7. Sensitivity analysis

In addition to the results calculated for the special public building, LCA tests were carried out for a more general function, examining the function-sensitivity of the findings. The building was also examined as a residential building according to the user behaviour profile described in TNM 7/2006. [11]

3. Results

During the LCC investigations, the problem appeared that due to the economic crisis of 2012 and the change of the Hungarian energy price support policy, the buildings from 2010 and 2019 are not comparable from economic point of view. Because of this reason, for the LCC result only the value of the Realized building and of Imagined building 2010 are introduced, both as public building and as residential building. (figure 5-6)

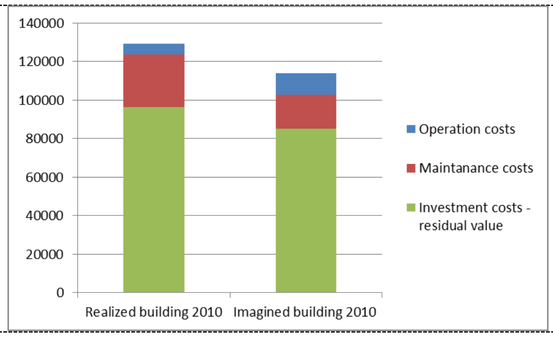

Figure 5. Global costs of the case study building from 2010 with public building function [1000 HUF]

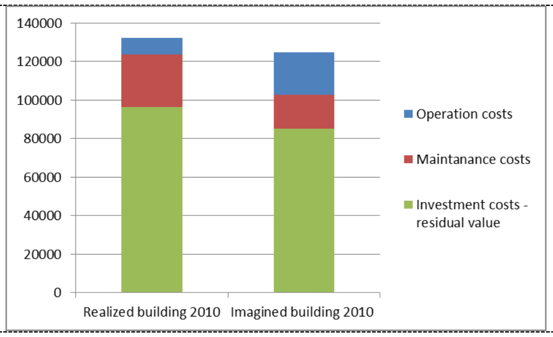

Figure 6. Global costs of the case study building from 2010 with dwelling function [1000 HUF]

The global cost of the Realized building, with higher energy quality and using natural materials, is higher than the global cost of the Imagined building. The higher global cost is caused by the higher cost of investment and maintenance, which was not compensated by the lower operating costs. It is important to emphasize that the higher installation costs (difference of 11,5 mFt) were only partly caused by the additional cost of the wall structure based on natural building materials (1 mFt). The other extra cost (10,5 mFt) was the difference in the cost of the higher energy-quality slabs, roofs and doors, as well as the higher cost of the mechanical equipment. If the building is used more intensively as a residential building, with the higher operating costs the global cost difference decreases (from 16.3 mFt to 7,3 mFt), but in the case study examined, the building with lower investment cost still has a lower global cost.

Figure 7-12 show the LCA results of three buildings as a public building and as a dwelling. In the realized building, the use of natural materials was primarily realized in the construction of the wall structure. Therefore, in the diagrams describing the results, the environmental loads associated with the construction of the wall structures are separately identified. It is also possible to identify separately the environmental load associated with the installation and the operation, the sum of which gives the whole lifetime value.

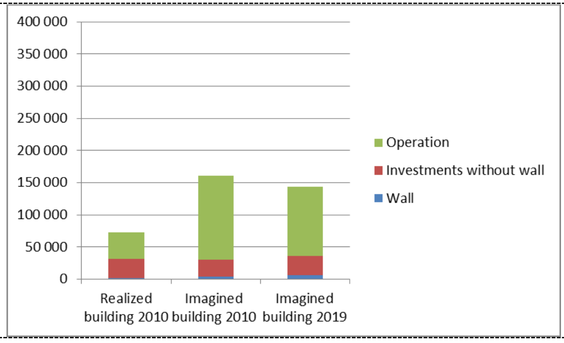

Figure 7. Cumulative energy demand of case study buildings with public building function [MJ/yr]

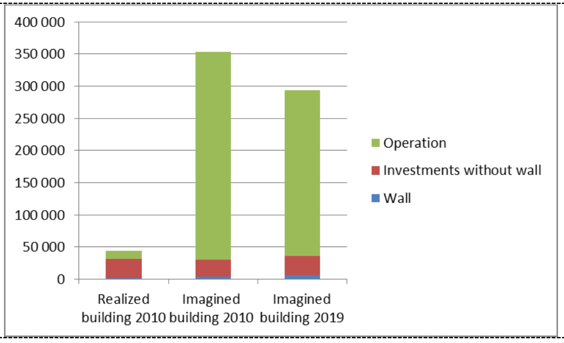

Figure 8. Cumulative energy demand of case study buildings with dwelling function [MJ/yr]

Figures 7-8 show that building structures made of natural materials are significantly more advantageous in terms of cumulative energy demand than conventional structures (1394: 4090: 5766 MJ/yr). However, the significant difference is due to the biomass-based heating system in the examined case studies. The greater is the importance of operation phase, the greater are the savings.

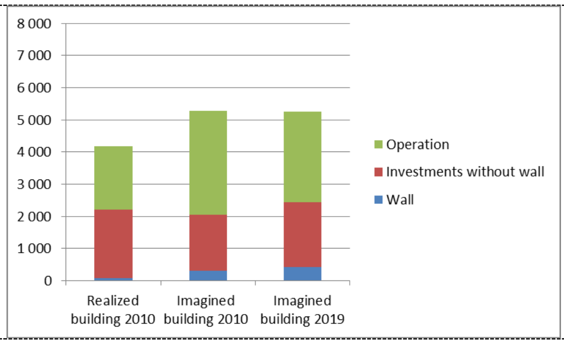

Figure 9. Global warming potential of case study buildings with public building function [kg CO_2-eq/yr]

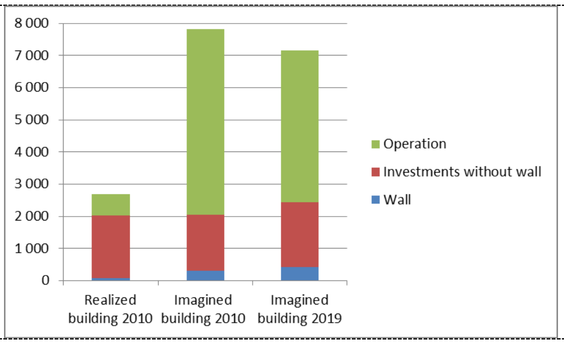

Figure 10. Global warming potential of case study buildings with dwelling function [kg CO_2-eq/yr]

Figures 8-9 show similar lessons to Figures 6-7, but the construction phase has a greater role than the operation phase. Savings in global warming potential by natural building materials are more significant than the savings in cumulative energy demand.

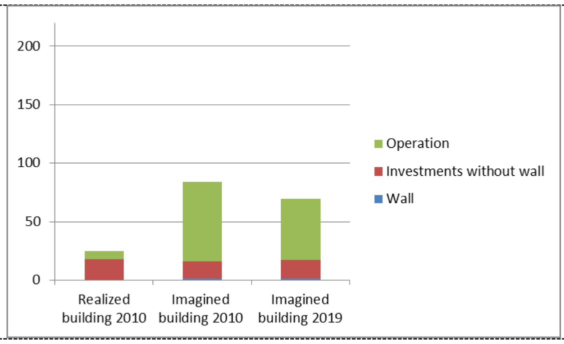

Figure 11. Acidification potential of case study buildings with public building function [kg SO_2-eq/yr]

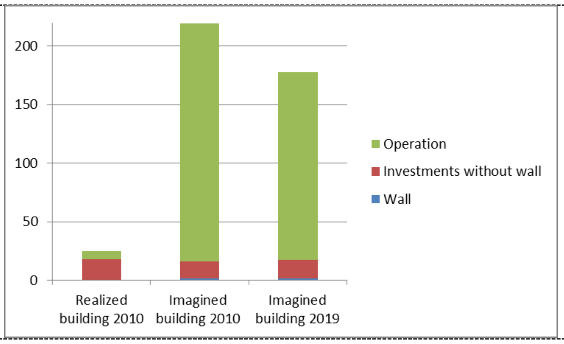

Figure 12. Acidification potential of case study buildings with dwelling function [kg SO_2-eq/yr]

4. Conclusions

The case study in this paper proved that natural materials can be used to achieve environmental savings. The wall structure made of natural materials is significantly more favourable in all calculated environmental parameters than commonly used wall structures (e. g. 66-76% saving in CED content). It is important to note that the wall structure of the "Imagined 2019" building results higher environmental impact than the "Imagined 2010" building due to higher energy requirements. It means that the environmental benefits of using natural materials will become more and more important in the construction of increasingly energy-intensive buildings.

However, the use of natural materials has in many cases technical limits, and in several constructions it is not appropriate to achieve the desired construction quality. In the examined case studies, the environmental savings associated with natural materials are not significant compared to the environmental impact of the whole building. In the case study, the greatest environmental benefit is not connected to the construction phase but to the operation phase. The mechanical system based on non-fossil energy has always resulted significant savings. These benefits are even more significant in the case of a function requiring higher operating energy (residential building) than in the case of the examined public building function.

The most important practical experience of this case study is that from the point of view of LCC analyses the phase of construction, while from the point of view of LCA analysis the operation phase is dominant. This caused a major contradiction in terms of investor and environmental goals. The investor side is interested in the construction of the cheap, energetically and environmentally weaker quality buildings. In contrast to achieve the environmental goals the most energy-efficient building is needed that uses the most natural materials, but in many cases with larger investment cost.

Environmental impact of timber frame walls

Steeman M[1], Himpe E[1], Vanroelen M[1], De Roeck M[1]

[1]Ghent University, Building physics research group

Marijke.Steeman@UGent.be

Abstract. Timber frame walls are increasingly applied nowadays due to the stringent energy performance requirements of buildings. The aim of this study was to investigate the environmental impact of this type of construction. Therefore, a cradle to gate analysis was used. The study consists of three consecutive steps. First the impact of the constituting materials was studied. The results show e.g. that the environmental impact of LVL studs is significantly larger than that of SLS studs or I-joists. Based on these results on material level, in the second stage three timber frame walls were designed and evaluated. All walls had the same thermal performance. When comparing the results, it was noted that the environmental impact of the wall with the highest impact is three times larger than that of the wall with the lowest impact. Finally, the study also looked at the additional impact of tapes for guaranteeing the air tightness of timber frame constructions and at the impact of fasteners. It could be concluded that the impact of tapes is negligible when looking at the total impact of the wall (less than 1%). The fasteners on the other hand, lead to an increase in environmental impact with almost 20%.

1. Introduction

Buildings have a large impact on our environment: 25% of the total primary energy use is related to the use of buildings while 40% of the CO_2-emissions are generated by fossil fuels used in buildings. On the other hand, a large amount of energy is embodied in the building materials. Studies show that in a typical Belgian dwelling 10 to 30% of the total environmental impact is caused by the building materials [1]. As the energy performance of buildings increases, the relative impact of the building materials will rise due to the lower operational energy use at the one hand and the larger amount of materials (i.e. insulation materials) on the other hand. Therefore it is important to gain insight in the environmental impact of construction elements.

As the energy regulations move the construction sector towards thicker insulation layers, timber frame construction elements become in favour. Figures show that in the past years timber frame is used more frequently. In 2011, in 5,9% of the new Belgian dwellings timber frame construction was used. In 2016 this figure was almost doubled (9,3%). It is expected that this number will further increase to 15 to 20% in 2020 [2].

Therefore the aim of this work is to gain insight in the environmental impact of timber frame walls. In a first step the environmental impact of the constituting building materials is studied. Based on these results on material level, in the second stage three timber frame walls were designed and evaluated. Finally, the influence of fasteners and air tight tapes on the total environmental impact is investigated.

2. Methodology

The analysis is carried out in Simapro version 8.4.0.0 with the Swiss Ecoinvent database v3.3 [3]. As many building materials that are used in Belgium are in whole or in part produced in Europe, the

European context is a good estimation for the Belgian context. Moreover, it is shown that the European electricity mix is a good assumption for the Belgian electricity mix [4].
Furthermore the allocation default model in Simapro is used. The building materials considered in this analysis are mainly primary materials. This means that materials do not consist of recycled or reused materials. In that way allocation is avoided.

The ReCiPe end point (h) method is used. The study includes a cradle to gate analysis, meaning the operational phase and the end-of-life phase are excluded from the analysis. Hence mining, production of materials and transport of materials to the building site are considered.

During forest growth CO_2 is captured in wood. This energy is released during wood incineration. When however, different life cycle phases are split up and the embodied energy in timber construction is analysed, the initial energy is of no interest because it is not related to production or transportation. When on the other hand, wood is used as a fuel (biomass), it is important to include the initial embodied energy [4]. Consequently, for this study the initial energy is not included in the analysis.

In the analysis replacements are only taken into account for finishing materials when looking at the environmental impact of the timber frame wall. It is expected that construction materials such as sheathing boards will not be replaced during the life span of the timber frame construction (60 years). The life span of the building materials that are used in timber frame construction is based on [4].

3. Impact analysis of constituting materials

The constituting materials are divided according to their functionality: structural elements, thermal insulation material, interior sheathing board, exterior sheathing board, interior finishing boards and exterior finishing materials.

3.1. Structural elements

Three types of structural materials are considered: I-joists, laminated veneer lumber (LVL) beams and massive spruce studs (SLS) The functional unit is the material that is needed for a structural part of 1 m^2 of timber frame wall of a typical single family dwelling with three floors. The wall has a heart to heart distance of 40 cm, which is typical for this type of construction. This results in three vertical studs per functional unit. Table 1 shows the material volumes that were taken into account. The life span of all structural elements is 60 years [4].

Table 1. Material data for timber frame structures

Category	Materials	Dimensions (mm)	Volume (m^3)
SLS	Sawnwood	45x184	0,025
LVL	Laminated timber	45x200	0,027
I-joist (45x200)	Sawnwood (web)	45x45	0,012
	Fibreboard (flanges)	6x126	0,002

Figure 1a shows the impact of the wood structure included in $1m^2$ of timber frame wall. As wood is used as a structural element, the impact on Land use is significant, which leads to a higher score on the Ecosystems category compared to Human Health (HH) or Resources. When comparing the three types of structural elements, it is noted that the impact of the LVL studs is larger than that of SLS or I-joists. Two explanations can be found: when applying LVL studs a larger material volume is used. On the other hand the material is used less efficient: to produce $0,027m^3$ laminated wood $0,053m^3$ softwood is necessary, while less is necessary to produce SLS studs. The I-joist clearly has the lowest impact in the Ecosystems category which is due to the lower amount of wood used. Furthermore the use of synthetic resin in LVL studs generates a high impact on HH and Resources. This is also the reason why I-joists have a slightly higher impact than SLS in these categories.

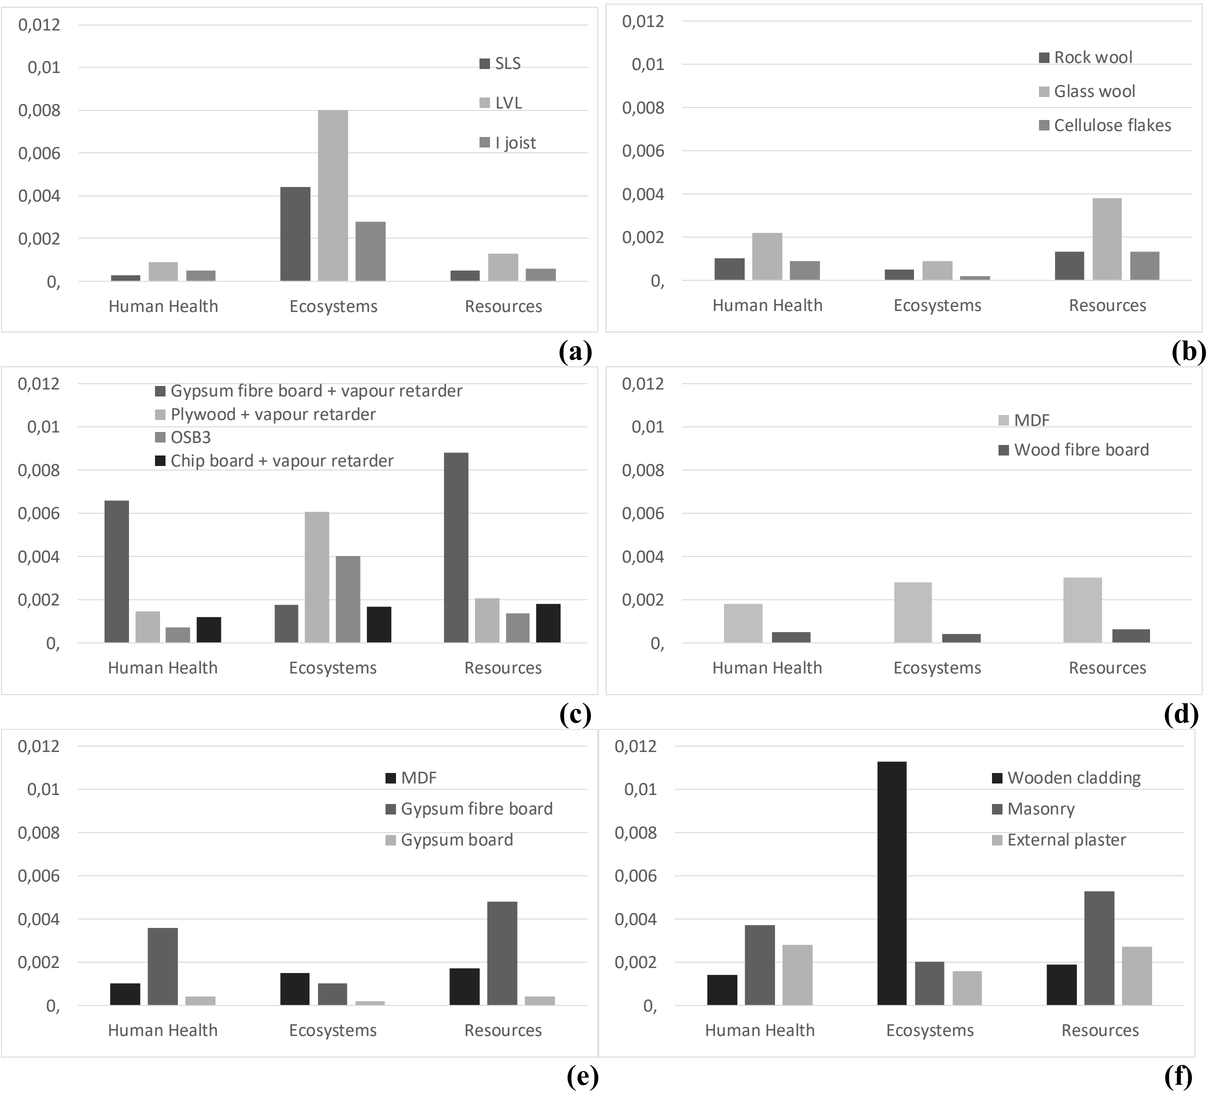

Figure 1. Normalized impact of wood frame structure (a) ; insulation material (b) ; interior sheathing board (c) ; exterior sheathing board (d); interior finishing boards (e) and exterior finishing materials (f)

3.2. Thermal insulation

Next, the environmental impact of three types of insulation material that are typically used in timber frame construction is evaluated: cellulose flakes, glass wool and rock wool. The functional unit is 1 m² of material with a heat resistance R_c of 4,17 m²K/W. This corresponds to a U-value of about 0,24 W/m²K which is a requirement for new walls in Belgium. Life span of insulation materials is 50 years [4].

Table 2. Material data for thermal insulation materials

Category	Thermal conductivity (W/mK)	Layer thickness corresponding with R_c = 4,17 m²K/W	Density (kg/m³)	Mass for 1m² wall (kg)
Cellulose flakes	0,040	0,167	50	8,33
Glass wool	0,039	0,163	40	6,50
Rock wool	0,035	0,146	45	6,56

Figure 1b shows that glass wool generates the highest impact, while cellulose flakes have the lowest impact. The production process of glass wool is energy-intensive, explaining the high impact on Resources. Furthermore polymerised synthetic resin based on urea is used during production, having an impact on HH. Cellulose flakes are produced from recycled newspaper. The impact on HH and Resources is due to the use of zinc during the production process where it is used for a better bond between the paper fibres and the boron salts.

3.3. Interior sheathing board

The impact of four types of interior sheathing board is compared: gypsum fibreboard, plywood, oriented strand board (OSB) and chipboard. All boards have a comparable thickness, representative for a typical thickness that is available on the market (Table 3). The functional unit is 1 m². In order to take exclude the risk of interstitial condensation in the timber frame elements, an additional vapour barrier is added for all sheathing boards except OSB. The life span of all sheathing boards is 50 years [4].

Table 3. Material data for interior sheathing boards and vapour retarder

Category	Thickness (m)	Density (kg/m³)	Mass (kg)	Volume (m³)
Gypsum fibreboard	0,018	1150 kg/m³	20,7 kg	-
Plywood	0,019	650 kg/m³	-	0,019
OSB3	0,018	600 kg/m³	-	0,018
Chipboard	0,019	680 kg/m³	-	0,019
Vapour retarder (PE film)	0,0002	-	0,188	-

Figure 1c shows the results. Gypsum fibre board has the highest impact on HH and Resources. This is explained by the use of zinc during production. The impact of the other sheathing boards is lower for these categories, and largely determined by the amount of binder that is used for compressing the wood into a plate material. The impact on Ecosystems varies for all sheathing boards and is the highest for plywood. This can be explained by the amount of wood used during production. E.g. in the production of chip boards a large amount wood residues are used, resulting in a relatively low impact on this category. Furthermore, the impact of the vapour retarder showed to be negligible [6].

3.4. Exterior sheathing board

The impact of wood fibre board (WFB) is compared with the impact of medium density fibre board (MDF). Both boards have a thickness of 0,018 m, which is a typical thickness available on the market. The functional unit is 1 m². The life span of the sheathing boards is 50 years [4].

Table 4. Material data for exterior sheathing boards

Category	Thickness (m)	Volume (m³)
WFB	0,018	0,018
MDF	0,018	0,018

Results can be found in Figure 1d. A large difference between MDF and WFB is observed. Though the impact of MDF is on average lower than the impact of other sheathing boards as shown in Figure 1c, it is clearly higher than the impact of WFB. The low impact of WFB is explained by the use of wood residues from saw mills (low impact on Ecosystems) and the use of lignin as a natural binder instead of synthetic resin glues during production (positive effect on HH and Resources).

3.5. Interior finishing boards

Gypsum fibre board, MDF and gypsum board (also known as plaster board) are commonly used as an interior finishing board. Once again, materials with a typical thickness available on the market are considered. The functional unit is 1 m², the life span of these materials is 50 years [4].

Table 5. Material data for interior finishing boards

Category	Thickness (m)	Density (kg/m³)	Mass (kg)

Gypsum board	0,0095	810,5	7,7
Gypsum fibre board	0,010	1150	11,5
MDF	0,010	760	7,6

Results can be found in Figure 1e. The impact of gypsum fibre bard and MDF was already discussed in Figures 1c and 1d. Note that the impact of MDF used as an interior finishing board is lower than when used as an exterior sheathing board due to its reduced thickness.

Figure 1e shows that the impact of gypsum board is the lowest for all categories. The gypsum used in the production of gypsum boards either is a natural product or it is originated from flue-gas desulfurization of brown coal power plants, explaining its low environmental impact. The production also requires zinc, which results in a higher impact on HH and Resources. Gypsum fibre board generates the highest impact of all three materials.

3.6. Exterior finishing materials

Three types of exterior finishing layers are considered: bricks, external plaster and wooden cladding. The material thicknesses that are considered in table 6 are based on a correct technical design. E.g. for the wooden cladding, vertical wooden battens (30 x 24 mm) are used, with a heart to heart distance of 60 cm. Hence, two vertical battens per functional unit of 1 m² of finishing layer are taken into account.

Note that the life span of the finishing materials differ: for masonry, external plaster and wooden cladding the life span is respectively 80, 15 and 30 years [4]. This means that for the external plaster and the wooden cladding replacement of materials has to be taken into account. During a life span of 60 years the plaster layer will be replaced 4 times, while the wooden cladding requires one replacement.

Table 6. Material data of exterior finishing materials

Category	Components	Density (kg/m³)	Thickness (m)	Mass (kg)	Volume (m³)
Masonry	Bricks	1900	0,075	116,15	-
	Mortar	1800	-	5,31	-
External (mineral) plaster	Fiberglass reinforcement	-	-	0,44	-
	Plaster	1700	0,015	99,20	-
Wooden cladding	Vertical wooden battens	450	0,030	-	0,0029
	Horizontal wooden boarding	600	0,018	-	2

Figure 1f shows the results of the impact analysis. The outlier in the Ecosystems category pops out immediately: the use of wood generates a large impact on Ecosystems. On the other hand, the impact of wooden cladding on the HH and Resources is relatively limited.

The impact of the brickwork is determined by the ceramic stones, the influence of the mortar in the joints is rather limited. The material mainly has an impact on Resources: on the one hand this is due to the high energy use in the burning of ceramic bricks requiring fossil fuels, on the other hand it can be explained by the exhaustion of mineral resources used for the production of ceramics.

The main resources needed for the production of mineral plaster are sand and cement. While sand is a natural product, the use of cement generates a high impact because of the high temperatures in the production process, causing a high energy demand. Because of the replacement during the total life span, the overall impact of plaster becomes larger. Due to this, the impact of plaster will be higher on HH and Resources than that of a wooden cladding.

When considering all three categories, from an environmental point of view the mineral plaster is favourable over the masonry façade and the wooden cladding.

4. Impact variation of timber frame walls

Based on the previous results on material level, in a second step the constituting materials are combined in three timber frame wall designs. Care is taken that the construction is correct from a hygrothermal point of view. All walls have a similar thermal transmittance U of 0,22 W/m²K.

Figure 2 shows the wall constructions: the first timber frame wall is constituted from materials with an overall low impact ("low impact wall"), while the constituting materials with an overall high impact are used in the "high impact wall". Finally the environmental impact of these wall types is compared with that of a typical timber frame wall design used in Belgium.

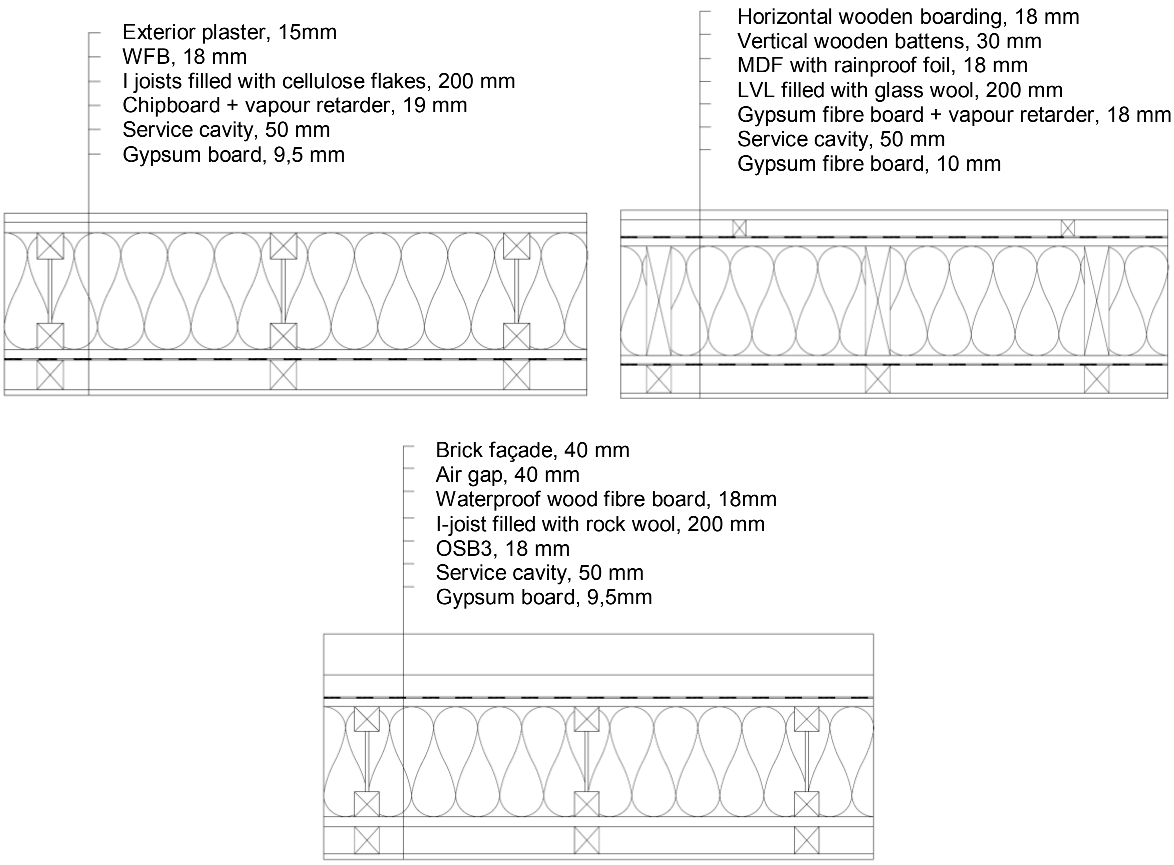

Figure 2. Low impact wall (upper left), high impact wall (upper right) and typical Belgian timber frame wall construction (below)

Figure 3 shows the environmental impact of the three wall types. It can be seen that the impact of the low impact wall is about three times lower than that of the high impact wall, for each of the impact categories. Furthermore it can be observed that the impact of the typical timber frame construction is more leaning towards the low impact wall: the impact on HH and Resources is comparable (slightly higher), while the impact on Ecosystems is about 25% higher.

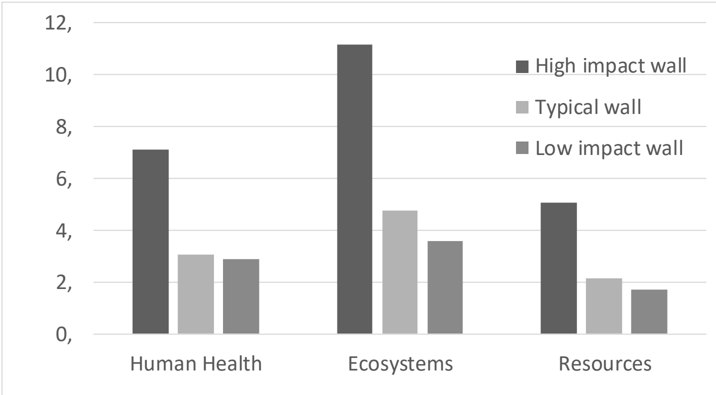

Figure 3. Impact variation between timber frame wall constructions

5. Impact of fasteners and tapes

In a last step the impact of fasteners and tapes that are necessary to guarantee the airtightness of a timber frame wall are included in the impact analysis. The impact analysis is based on the typical timber frame construction shown in figures 2 and 3. In order to evaluate the environmental impact a wall with and without fasteners and tapes is compared. A timber frame wall of 3 m length and 2,44 m height is considered (total area of 7,32m²). Taking into account a heart to heart distance of 40 cm, the timber frame wall consists of 8 vertical studs.

Following fasteners are included in the wall, based on typical practice:

- Cavity anchors: 4 per m² of brick façade
- Staples to fasten WFB (dimensions 600 mm width x 2500 mm height), spacing 100 mm
- Staples to fasten OSB3 (dimensions 600 mm width x 2440 mm height), spacing 100 mm
- Screws to fasten gypsum board (dimensions 1200 mm width x 2600 mm height), spacing 200 mm

The boards are cut to a height of 2,44 m and to the width between two vertical studs (40 cm). The amount of fasteners and their total mass can be found in Table 7. All fasteners are made of stainless steel (density 7930 kg/m³).

Table 7. Fasteners

Category	Number	Length (m)	Diameter (m)	Volume (m³)	Mass (kg)
Cavity anchors	30	0,160	4,00	-	0,44
Staples wood fibre board	196	0,042	1,48	0,000336	2,66
Staples OSB3	196	0,042	1,48	0,000336	2,66
Screws gypsum board	98	0,035	4,20	0,000047	0,38
Screws horizontal wooden beam	32	0,060	4,20	0,000027	0,21
Threaded rod	4	0,060	6,00	0,000007	0,05

Furthermore, airtight tape is considered:

- At all seams between the OSB3 boards (8 seams x 2,44 m height); and
- At the top and bottom of the timber frame wall (2 x 3 m)

Table 8 summarizes the total amount of tape used.

Table 8. Air tight tape

Running meter (m)	Width (m)	Mass (kg/m)	Mass (kg)
25,52	0,06	0,0277	0,71

The results show that the impact of a wall including fasteners and tapes is higher than that of the wall excluding fasteners and tapes. This finding is quite logical as an additional amount of material is added, i.e. 6,40 kg of stainless steel and 0,71 kg airtight tape. By taking into account these secondary materials, the impact increases with 17,75%. This means that one fifth of the total impact of a typical timber frame wall is due to the fasteners and tapes. When only air tight tapes are included in the impact analysis, the impact increases with only 0,81%. This shows that the impact of air tight tape is negligible, whereas 16,94% of the total environmental impact results from the fasteners.

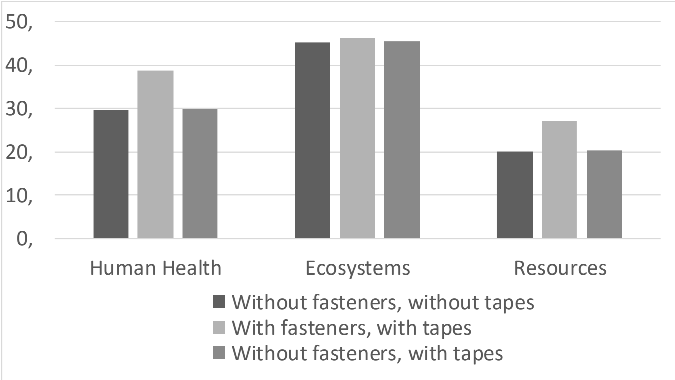

Figure 4. Impact of fasteners and air tight tapes

When analysing the impact categories, Figure 4 shows that the impact of fasteners and tapes on the Ecosystems category is negligible. The HH and Resources categories show the largest variation when including the fasteners.

Conclusions and future work

This paper discusses the environmental impact of timber frame walls. The results showed that the impact of timber frame walls can differ largely by the choice of constituting materials. For instance it was shown that choosing LVL studs results in a higher impact compared to I-joists. Naturally environmental impact is only one of the decision criteria in designing a sustainable construction. Furthermore, the analysis showed that external finishing materials can have a major environmental impact, especially when a brickwork façade is used. Also, it was demonstrated that fasteners have a significant contribution to the overall environmental impact.

In a next step the relative impact of fasteners should be assessed. Also the impact of alternative materials, such as plastic cavity anchors was not investigated in this study. Nevertheless, these fasteners could not only be favourable from a thermal point of view but also from an environmental point of view.

Abstract. Consequential life cycle assessment was applied to forestry systems to evaluate the environmental balance of expanding forestry onto marginal agricultural land to supply more timber for the built environment, accounting for land use effects and product substitution. Forestry expansion to supply timber buildings could mitigate UK greenhouse gas (GHG) emissions by 2.4 Gg CO_2 eq. per ha of forest over 100 years, though net mitigation could be halved if beef production were displaced to Brazil. Forest thinning increases wood yields and percentage conversion of harvested wood to construction sawnwood, resulting in 5% greater net GHG mitigation compared with unthinned systems. Optimising the environmental sustainability of construction timber value chains in a circular, bio-based economy will require holistic accounting of land use (change), forestry management and complex flows of wood.

1.. Introduction

Forests sequester and store carbon (C) from the air as they grow, and harvested wood products (HWPs) can continue to store carbon and/or displace fossil fuel (FF) combustion for energy generation or displace production of mineral construction materials, further mitigating GHG emissions. Life cycle assessment (LCA) studies have shown that timber use in buildings can reduce embodied GHG emissions due to displacement of mineral materials (Hafner and Schafer, 2017, Pajchrowski et. al., 2014) and the UK Committee on Climate Change (CCC) has recently recommended that by 2025 all new housing should be timber framed (CCC, 2019). The construction sector already accounts for 61% of UK timber consumption and there is no plan to address how an increased demand will be met. The UK imports 66% of consumed timber (98% of its sawn softwood) (TTF, 2017) and whilst UK (and global) timber consumption is rising (FAO, 2017), projected UK timber supply is in decline (FC, 2016). The UK is failing to achieve even half of its 20,000 ha/year planting target (CCC, 2018). Land for afforestation could be released through increased productivity of existing farmland and forests (CCC, 2018; Lamb et al., 2016) and reduced meat consumption. However, displacement of farming activities (e.g. beef production) could also lead to detrimental indirect land use change elsewhere (Searchinger et. al., 2018).

.... In commercial plantations, young trees may be thinned; i.e. a proportion of trees removed in order to create more growing space for the remaining trees, with the aim of increasing the yield of usable timber over the life of the crop (FC, 2015). Thinning can improve stand quality and reduce the time taken for trees to reach valuable sawlog size (Hibberd, 1991), but incurs additional costs. Decisions on thinning depend on current and anticipated timber markets, stand quality, risk of wind damage and costs (FC, 2015). Logs are sorted into different product quality categories during harvesting, with the best logs ultimately ending up as higher value sawn products with longer product lives. Therefore, thinning could increase the size of the harvested wood product (HWP) carbon pool and potentially improve the overall environmental benefit delivered per hectare of managed forest. However, to our knowledge there have been no LCA studies quantifying the environmental impact of shifts in HWP value chains as a result of thinning.

.... The main study objective is to evaluate the environmental balance of expanding forestry onto marginal agricultural land in the UK to provide more timber for the built environment, accounting for land use effects and product substitution throughout extended wood value chains. A secondary objective is to evaluate the impact of forest thinning on production of higher value timber products, and on the environmental balance.

2.. Materials and Methods

2.1Scope and boundary definition

Given the significant GHG mitigation potential of wood use as construction material and for bioenergy through substitution of mineral building materials and FFs, respectively, as well as the potential impact of direct and indirect land use change (LUC), we applied a consequential LCA approach (Weidema, Ekvall, & Heijungs, 2009) (Figure 1) to evaluate environmental impact. The functional unit is the total production from the reference flow of one hectare of land in the UK, converted from grassland used for low intensity beef production, to forest land, planted with 100% Sitka spruce and managed under a clear-fell system on a 50-year rotation. A 100-year study period was used to account for two forest rotations. Expanded boundaries encompassed: (i) LUC due to afforestation, and displacement of extensive beef production; (ii) forest establishment; (iii) forest growth; (iv) forestry operations; (v) debarking; (vi) sawmilling (including drying, planing and chemical treatment); (vii) wood panel production; (viii) paper and paperboard production; (ix) biomass energy generation; (x) credits for avoided use of FFs (energy generation and construction materials); (xi) carbon storage (and 'decay') in HWPs and (xiii) recycling and disposal of 'decayed' HWPs. The production and transport of all material and energy inputs were accounted for, as were the construction or manufacture of infrastructure and capital equipment.

2.2Life cycle inventory

This study assesses a simplified timber value chain in which production of construction-grade sawn timber is maximised. Forest growth, decay and harvesting volumes were calculated using CBM-CFS3 carbon model (Kull et. al., 2016), assuming 'average' soil type. We input to that model the best fit yield tables from Forest Yield (a PC-based yield model for forest management in Britain) (Matthews et. al., 2016), specifying 100% Sitka spruce and yield class 18. The thinned scenario assumes a single thinning in year 21 of each rotation, with 36% of the 'harvestable' material (i.e. logs only, not branches, leaves or stumps) being removed for HWPs). How CBM-CFS3 implements a thinning disturbance is to reduce the biomass components and transferring carbon out of the ecosystem or to the dead organic matter as appropriate. Then the next increments are assigned to the reduced biomass so in effect the same gross volume is eventually achieved. Clear-fell harvest is implemented in year 50 (a conservative average for this species in UK conditions), followed by immediate replanting, to enable a second clear-fell in year 100. Non-merchantable biomass was assumed to be left to decay on site. The carbon modelling results provide the quantity and year of harvested timber as well as the net ecosystem C change over the 100 year period.

The quantity of harvested material was converted into a product breakout (at the forest gate) using operational data from the forest management company Gresham House (GH) for 2,000 ha of commercial Sitka spruce plantations across the UK (47% unthinned, 54% thinned) (Table 1). The GH data show that thinned forest stands had 26% higher merchantable volume by the time of the final harvest (excluding thinning harvests) compared with unthinned stands (Table 1). The thinned stands also had greater conversion of harvested trees to higher value log products ('greens') (64% vs 57% of logs), with fewer logs going to chip/fuel/pulpwood (15% vs 21%) (see Table 1 for product definitions). Downstream product breakouts were calculated from data provided by the sawmills of James Jones & Sons Ltd (JJ) and from UK timber-use statistics (Forestry Commission, 2017). Detailed material flow tables were produced, along with Sankey diagrams (an example is provided in Figure 2). Around 40% of main crop harvests end up in construction materials (carcassing and wood panels) for both unthinned and thinned systems. However, a greater proportion of carcassing materials is produced from the thinned system (17.9% vs 15.9%). Conversion of harvested carbon from CBM-CFS3 to merchantable volume was

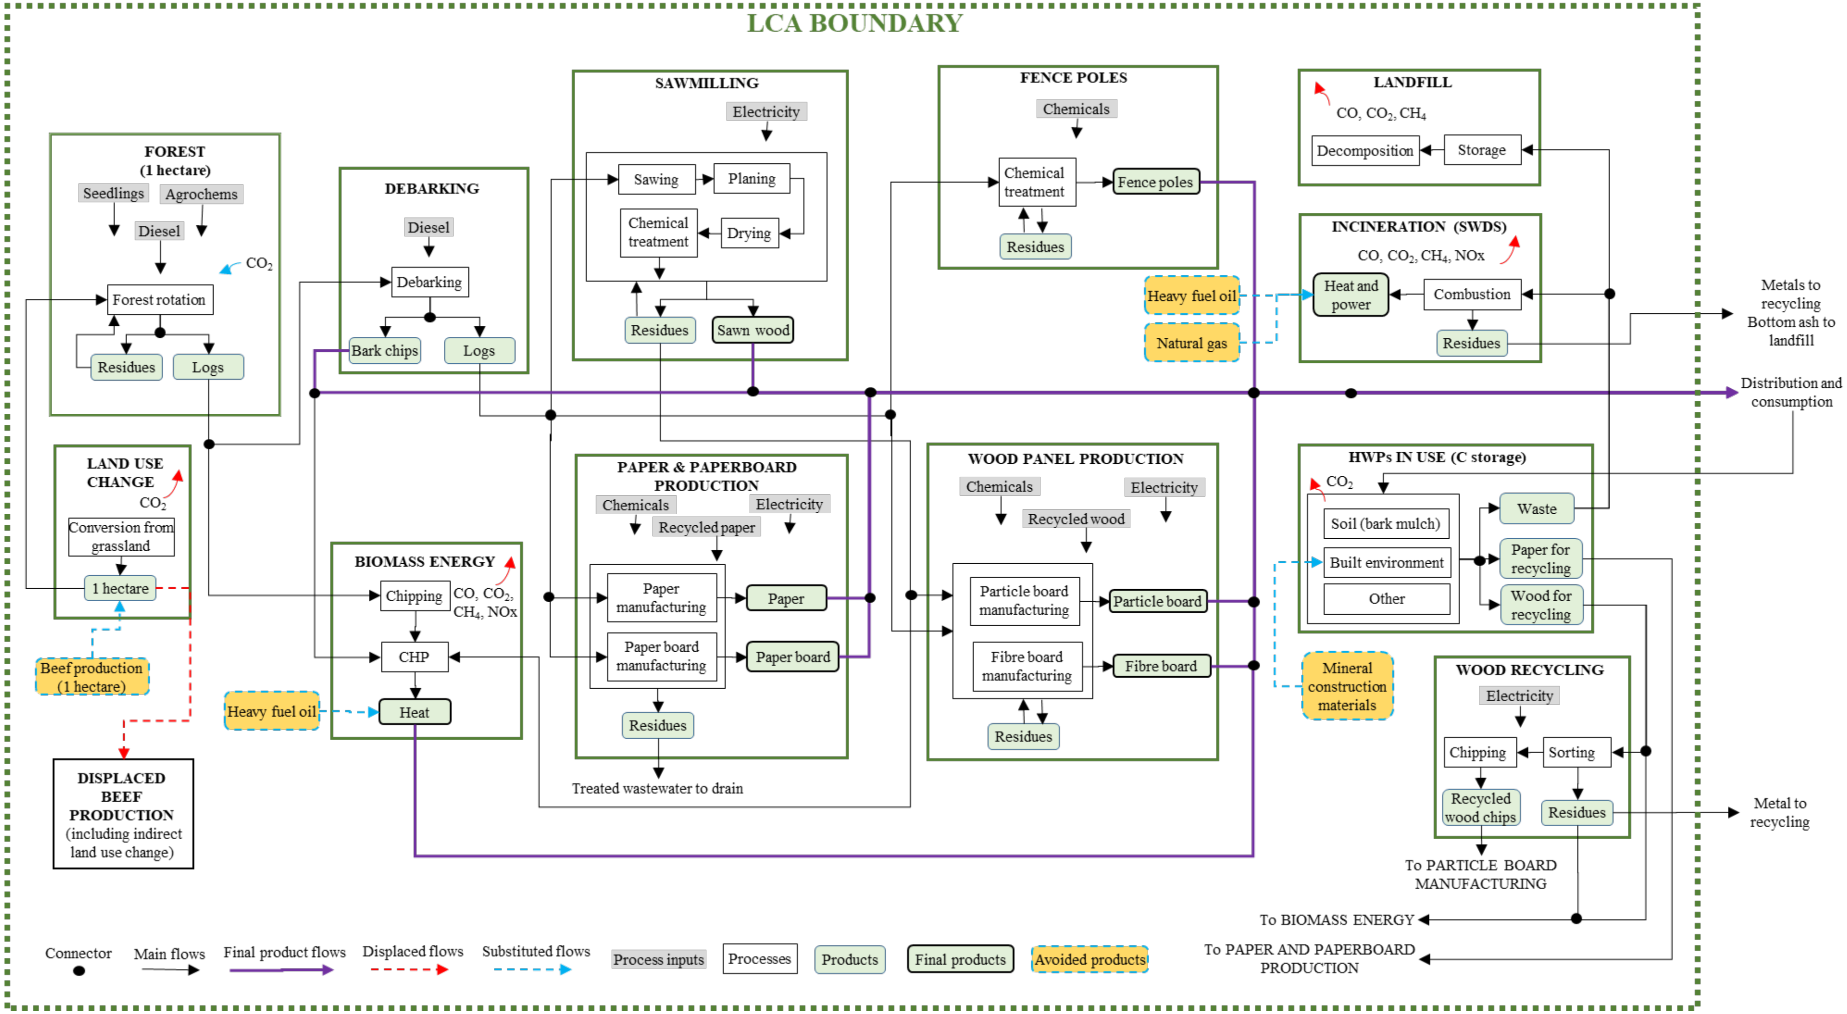

Figure 1. Main processes and inputs accounted for within expanded consequential life cycle assessment boundaries, including: storage of C in HWPs, recycling and disposal of HWPs; substitution of fossil fuels for energy production; substitution of mineral building materials.

calculated assuming 49.95% C content of dry wood, and the wood density factor 1.08 m3/tonne assuming 47% moisture content.

Table 1. Product break out from Sitka spruce stands (main crop harvest), listed in order of value. 'Red' and 'Green' refer to a threshold of acceptable straightness, taper and knots in a log, with 'Green' being the higher quality. Source: GH. Thinnings data are not collected by GH so an equal split between 'chip', 'fuel' and 'fence pole' logs is assumed. Merchantable volume is per clear fell harvest.

	Log quality categories (from low to high, left to right)					Merchantable volume
	Chip/Fuel/Pulp	Fence pole	Red	Bar/Pallet	Green	m^3/ha
Unthinned (main crop)	21%	5%	2%	15%	57%	499
Thinned (main crop)	15%	4%	2%	15%	64%	630
'Thinnings'	67%	33%	0%	0%	0%	unknown

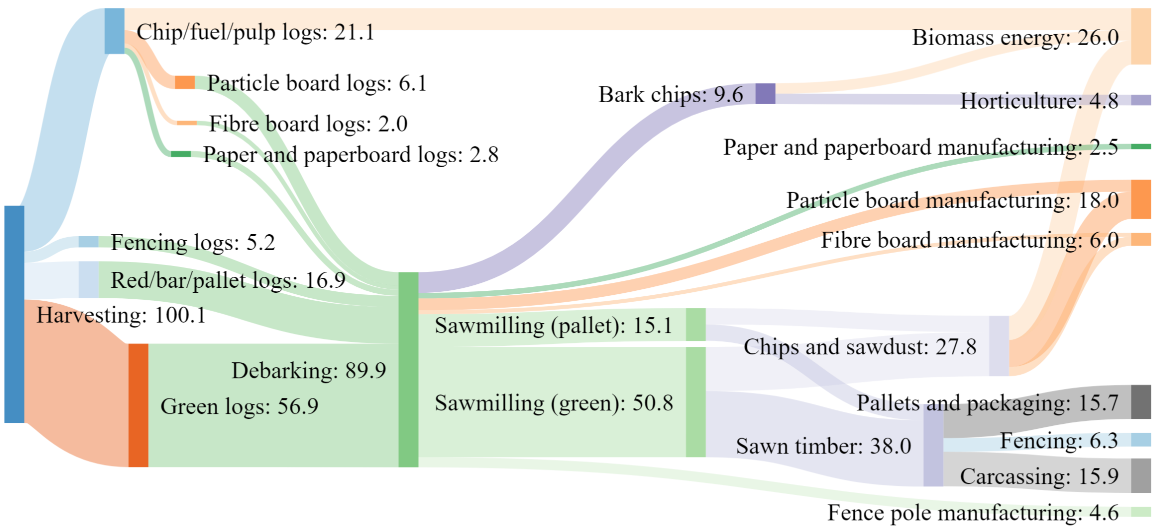

Figure 2. Biogenic carbon material flow of main crop wood harvest (from an unthinned forest). Units are percentages of original harvest. (A rounding error is present in the harvesting total.)

.... Table 2 summarises the main inputs and outputs along the value chain life cycle stages considered in the LCA. Input and output data were extracted from unit processes in Ecoinvent v.3.5, using OpenLCA v1.7.4 for all timber processing phases and scaled up in Microsoft Excel using the HWP material flow. Possible LUC consequences were modelled by accounting for displacement of beef previously produced on land areas converted to forest according to simple scenarios: intensification of existing UK beef production systems (Scenario 1), or expansion of beef production in Brazil, driving indirect deforestation (IPCC, 2006) (Scenario 2). Changes in direct emissions from beef rearing were also accounted for based on intensive UK and average Brazilian beef production footprints (Styles et al., 2018).

.... The rate of 'decay' of the HWPs is calculated according to IPCC methods (IPCC, 2006). As products 'decay' from the HWP C pool, they are recycled or disposed of (by incineration or landfill) in proportions calculated from Defra, (2018) (using 2016 data), respectively. Note that almost 100% of paper and paperboard is recovered and 80% of wood products are recovered (16% to biomass energy). All 'decay' of tertiary products is assumed to be disposed of. Horticultural mulch is assumed to decay at a rate similar to composted municipal solid waste (Bruun et. al., 2006) since no data could be found on the decay rate of tree bark. Wood fuel is not included in the HWP C pools owing to rapid oxidation.

All biogenic C emissions from oxidation of wood at ‘end of life’ is assumed to be zero (since the sequestration of this C is not accounted for in the net forest C sequestration).
.... All burdens associated with production and transport of inputs, as well as for all timber processing phases, were extracted from Ecoinvent v.3.5 (Wernet et al., 2016) using OpenLCA v1.7.4. Emissions from landfill disposal were calculated according to the IPCC First Order Decay (FOD) method (IPCC, 2006). Fuel-to-energy conversions factors (for natural gas and wood chips) from Ecoinvent unit processes were used to calculate fossil fuel substitution by biomass energy and wood waste incineration. Substituted FF is assumed to be natural gas, given a trend towards greener energy production and given the substitution occurs 21 to 100 years in the future.

In the absence of high quality data on direct product substitution ratios, preliminary estimates of the burdens avoided through substitution of mineral construction materials were made by first translating the final mass of construction timber per ha (129 and 150 tonnes per ha (20% moisture), for unthinned and thinned forests, respectively) into an equivalent area of timber-framed wall using industry standard design (0.0175 m^3 of timber per 1 m^2 wall). 1 m^2 of timber frame wall was assumed to replace 1 m^2 of single skin, 140 mm concrete block and mortar wall (typical of a UK house). This enabled avoided burdens to be calculated, using emissions factors from Ecoinvent for the manufacture of concrete blocks, sand and cement, scaled to the quantity of materials used per 1 m^2 of concrete block and mortar wall. To estimate the area of forest required to supply a prescribed number of houses, data on the volume of timber contained in a typical timber framed house was used (6 m^3 in the timber frame) (Suttie et. al., 2009).

Table 2. Inventory of key inputs and outputs for processes considered along the life cycle of forestry value chains derived from unthinned and thinned forest systems over 100 years. Emissions factors (EF) and their sources are indicated. FRDP is fossil resource depletion potential and GWP is global warming potential.

2.3Impact assessment and interpretation

Two environmental impact categories were considered in this study: global warming potential (GWP), expressed as kg CO_2 eq; fossil resource depletion potential (FRDP), expressed in MJ. Summary results are presented in the main body of the paper.

3.. Results and discussion

Afforestation of 1 ha of grass land to produce timber for construction offers significant CO_2 mitigation potential, for both unthinned and thinned forest management scenarios, with FF displacement of 4.3 TJ and 4.9 TJ, and GWP mitigation of 2.3 and 2.4 Gg CO_2 eq, respectively (Table 3) over 100 years. Thinning increases GWP mitigation by 5% and FRDP mitigation by 14% over 100 years (for scenario 1). Although unthinned forests achieve higher net forest C sequestration over this timescale, this is more than offset by the higher quantity of harvested timber produced in thinned systems, and improved conversion to sawnwood – which results in higher accumulation of C in HWP and greater emission avoidance via fossil fuel and mineral construction material substitution (Figure 3). When comparing scenarios 1 and 2, the burdens associated with displacement of beef production vary significantly (Table 3). The displacement of beef to intensive UK systems achieves further GWP savings via reduced emissions intensity of production, whereas displacement to average intensity production in Brazil increases GWP, mainly due to indirect land use change (deforestation) (Table 3 and Figure 3).

Table 3. Mitigation of fossil resource depletion potential and global warming potential achieved by converting 1 ha of beef production land to timber production forest, over 100 yrs. Displacing beef production to intensified UK production (Sc1) and Brazil on land converted from rainforest (Sc2).

	Scenario 1		Scenario 2	
Impact category	Unthinned	Thinned	Unthinned	Thinned
FRDP (TJ eq.)	-4.28	-4.88	-4.28	-4.88
GWP (Gg CO_2 eq.)	-2.30	-2.41	-1.12	-1.22

3.1Abatement potential - Construction use

Timber use in construction has significant abatement potential through both long-term storage of C in the HWP C pool and also displacement of mineral construction materials (Table 4). Thinning produces 16% more wood product for carcassing use (e.g. timber-frame walls) than unthinned systems per ha of forest. If used as external-wall timber framing, this additional 16% increases GHG mitigation by 110,176 kg CO_2 eq (over 100 years) due to displacement of mineral construction materials.

Table 4. Avoided CO_2 eq. emissions and FF depletion from displacement of mineral construction materials by sawn timber (used in external timber frame wall, replacing concrete block and mortar wall) from 1 ha of afforested land over 100 years.

GWP (kg CO_2 eq)		FF depletion (MJ eq)	
unthinned	thinned	unthinned	thinned
681,807	791,983	4,365,022	5,070,383

.... To build 100,000 new houses in the next 20 years (as projected for Wales: Welsh Government, 2018) using timber-frame construction would require 10,424 (unthinned) to 8,974 (thinned) ha of forest to supply the timber frames (not including supply of sawn timber required for roof and floor structures, and assuming forests are already established and ready to be harvested to meet demand). This would achieve 1.4 Tg CO_2 eq avoided emissions for mineral building material substitution. In addition, the forest supplying these houses (and their extended value chains) over a 20-year period could provide GWP benefits of -4.3 Tg CO_2 eq, and FRDP benefits of -8,753 TJ (for thinned systems).

3.2Conclusions

Expanding forestry onto marginal agricultural land with the aim of providing more timber for the built environment will provide significant environmental benefits, in particular mitigation of GHG emissions and fossil resource depletion. Mitigation is primarily driven by C sequestration in growing trees, storage of C in the HWP C pool and the substitution of FF and mineral construction materials. However, this mitigation could be significantly reduced at the global level if agricultural production is displaced internationally, causing “carbon leakage”. In particular, displacement of beef production to Brazil could drive indirect deforestation, which could offset 50% of the UK GHG mitigation effect. However, there is significant scope for forestry expansion to be accommodated by, or even to drive, “sustainable intensification” of existing land-use systems within the UK, further enhancing net mitigation potential.

.... This study highlighted the considerable potential to increase the resource efficiency of UK forestry, and to reduce the 98% import dependency for sawn-timber construction products. Currently, only around 40% of harvested timber ends up in buildings under best-case assumptions (16% carcassing plus 24% wood panels for unthinned systems; and 18% carcassing plus 23% wood panels for thinned systems). Thinning of forest systems improves resource-use efficiency by increasing productivity and timber quality, which reduces the area of land required to supply a given volume of sawn timber to the construction sector by 16%. This could be increased further by improvement of forestry management and processing efficiency, e.g. by greater use of thinning, which is currently carried out in only approximately half of commercial forests in UK. Resource efficiency could also be enhanced through increased recycling of wood products, with 80% (not including paper and paperboard) currently recovered (16% for biomass energy generation; 64% for non-energy uses) (Defra, 2018).

.... Further work will be carried out to elaborate impacts of: (i) alternative land-use change scenarios; (ii) alternative forest management systems; (iii) UK-specific substitution factors for displacing mineral construction materials; (iv) alternative FF substitution scenarios in a future energy mix; and (v) alternative study periods.

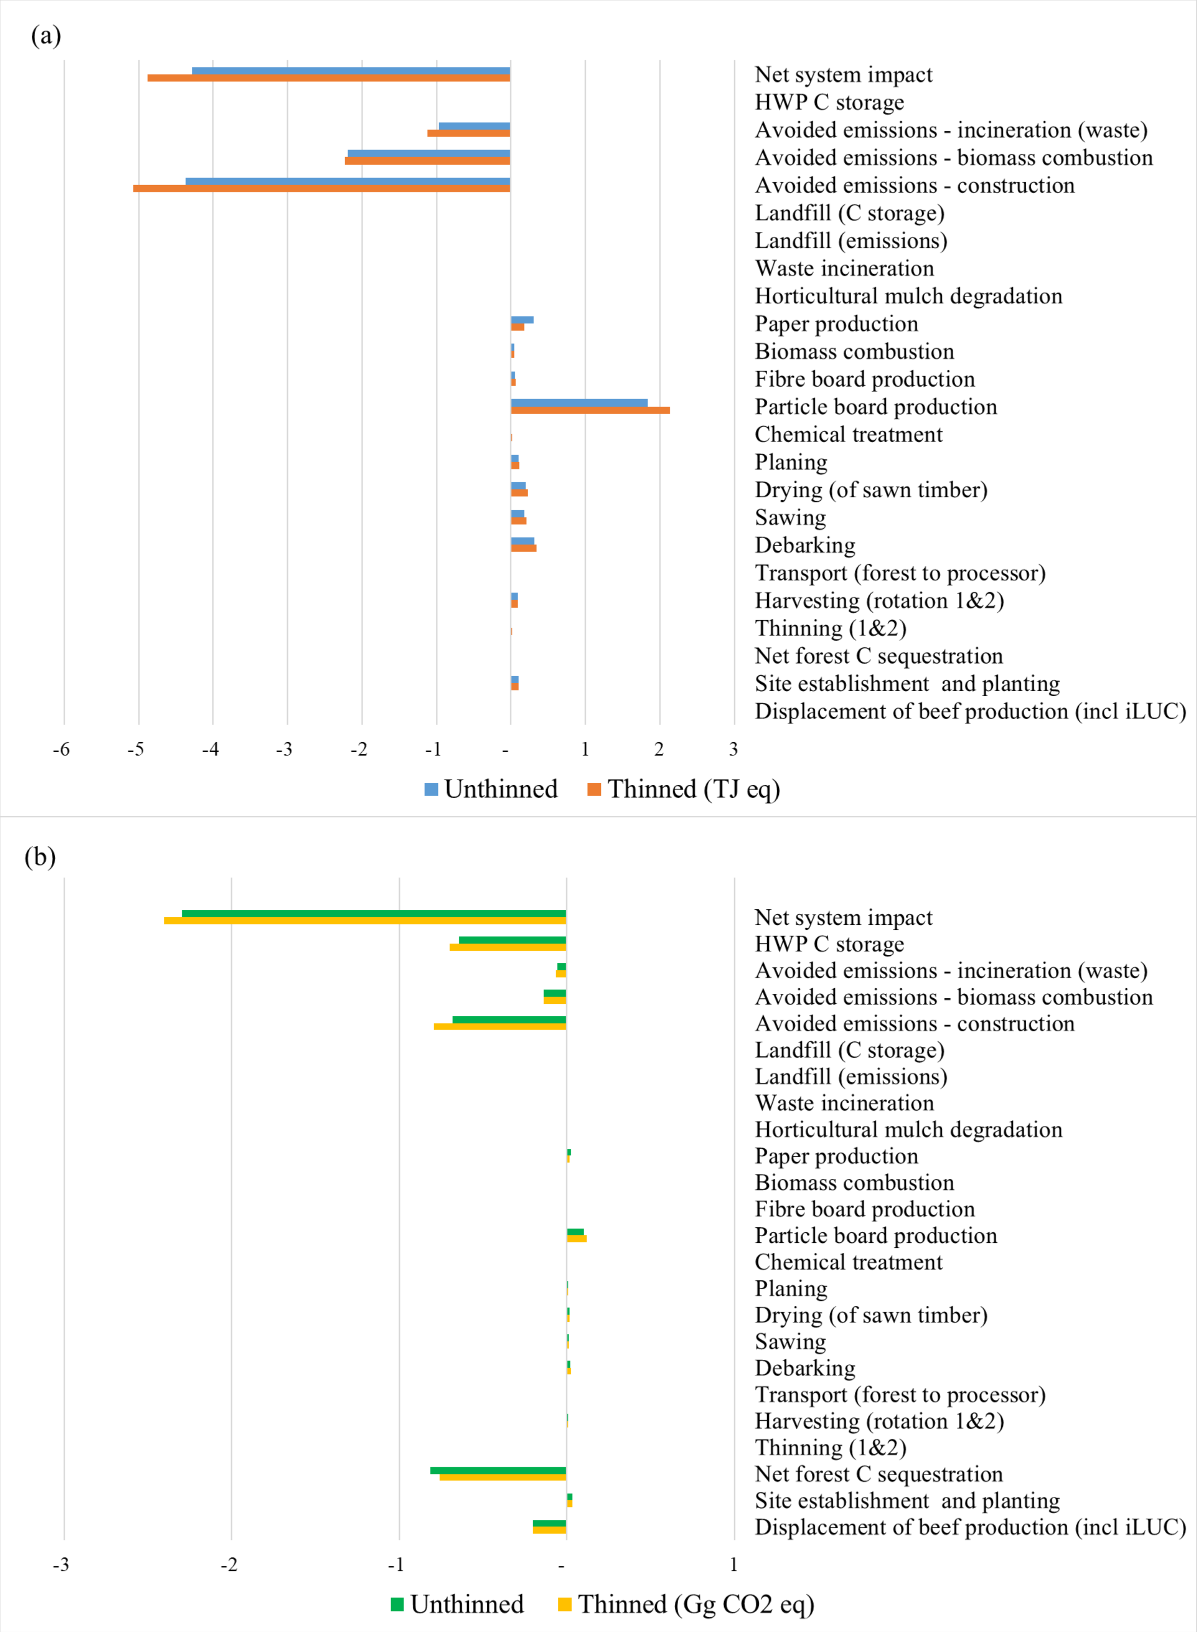

Figure 3. Life cycle assessment results for unthinned and thinned forest management systems (for scenario 1, displacement of beef to high intensity production, UK). Results expressed for (a) fossil resource depletion potential (TJ eq) and (b) global warming potential (Gg CO_2 eq).

Abstract. Given increasing environmental concerns, lower energy building materials are being developed to reduce greenhouse gas emissions. The ancient technique rammed earth has been combined with modern industrial waste products to both reduce greenhouse gas emissions and reduce waste. The new rammed earth mixes have been developed using alkaline activation (sodium hydroxide) of industrial by-products: fly ash, ground granulated blast furnace slag and silica fume. This paper explores the 'cradle-to-gate' life cycle assessment, assessing global warming potential of these rammed earth materials, considering acquisition of raw or recycled materials and processing to final product of residential building envelope. These are compared with commonly used building envelope materials, brick veneer and cavity brickwork, and the more common rammed earth variety, cement-stabilised rammed earth. Results show that greenhouse gas emission savings can be made using these rammed earth mixes compared to the control building materials while achieving comparable or better material properties. Greenhouse gas emissions associated with the building envelope materials are reduced by more than half or one third when compared to cavity brickwork or brick veneer respectively. Following testing of the waste products in surplus in a given area, the same process could be followed for any geographic location.

1. Introduction

Globally, buildings account for a significant portion of total energy use throughout the full life cycle, from raw material acquisition and processing, through the operation stage and finally, at end of life. Although in Australia per capita building sector energy use has been declining, population increases will result in absolute growth over time [1]. As such, buildings are an important area where greenhouse gas emissions (GHGE) reductions could be made. Average house sizes have been increasing and, as improvement are made in the operational energy stage, energy spent on the structure (known as embodied energy) becomes a higher portion of total emissions [2].

Further to GHGE, the building industry uses around 30-50% of raw materials and is responsible for approximately 40% of landfill waste in OECD member countries [3,4]. These statistics highlight the importance of repurposing waste both to reduce virgin material use and to reduce landfill waste.

Rammed earth (RE) is an environmentally friendly building material when made using traditional methods; natural inclusions such as clay and straw were used as binders [5,6]. However, the more modern versions of RE are 'stabilised,' incorporating more energy intensive materials; in the last century it has become more common to add stabilisers such as lime, bitumen and cement, with 5-10 wt.% cement becoming the most common [7,8]. While improving material properties, cement addition significantly reduces environmental benefits. The cement industry is responsible for 6% of annual GHGE with around one tonne of CO_2 emitted per tonne of clinker produced, an intermediate product in cement production [9,10]. New RE mixes have been developed by the authors replacing cement with industrial by-products to lower GHGE associated with embodied energy of buildings and reuse waste.

Life cycle assessment (LCA) is being increasingly used to determine environmental impacts of any product or process. In the context of embodied energy in the building industry, LCA aids better material selection or can be used to identify problem areas and improve processes to reduce GHGE. In this study, LCA is used to determine GHGE associated with embodied energy of the newly developed RE mixes as well as the more common version cement-stabilised RE. The aim of the study is to determine potential benefits from a global warming perspective of using the RE mixes made with industrial by-products compared to more common building envelope materials.

2. Materials and methodology

2.1. Rammed earth materials

RE mixes being assessed are listed in Table 1. The mix most commonly used in Western Australia (WA), crushed limestone (CL) stabilised with cement, is used as a control mix. The second mix, CL_AA, replaces the cement with alkaline activated aluminosilicate materials, mostly industrial by-products. The third mix replaces the CL with recycled brick and concrete (RBC). The industrial by-products used are fly ash, ground granulated blast furnace slag (GGBFS) and silica fume. A by-product of coal combustion, it is estimated there are 225 million tonnes of fly ash currently stockpiled in Australia [11]. GGBFS is a by-product of iron and steel production. It is popular as a supplementary cementitious material (SCM) used by the concrete industry. The GGBFS produced in Australia is fully or largely used by the concrete industry with more imported [12]. Silica fume is produced as a by-product during silicon metal and alloys production and is supplied to the market by primary manufacturers based in Bunbury, WA. It is also used as a SCM by the concrete industry. Kaolin clay is available commercially. NaOH was prepared as a 12M solution. Additional water was then added to each mix to reach the optimum moisture content, determined according to AS 1289.5.2.1—2003 [13].

Table 1. RE mix designs.

Mix	UCS (MPa)	Mix components (%)								
		CL	RBC	Kaolin	Fly ash	GGBFS	Silica fume	Cement	NaOH pellets	Water
CL_C	11.1	81.5	-	-	-	-	-	8.2	-	10.3
CL_AA	19.8	73.0	-	3.7	7.3	3.7	2.9	-	1.65	7.8
RBC_AA	24.1	-	73.0	3.7	7.3	3.7	2.9	-	1.65	7.8

2.2. Sustainability analysis goal and scope

This LCA is completed in accordance with ISO 14044:2006(E) [14] and EN 15804:2012+A1:2013 [15] specifically for coproduction methodology. Results could be used by government in development of sustainable building policies, designers and builders, and to assist the general public when making material choices while building their own homes. The LCA has been completed as a 'cradle-to-gate' approach, incorporating material acquisition through to production of the final product, an external wall of a residential structure. Two common residential building envelopes were selected as controls to compare with the RE wall designs: brick veneer (BV) and cavity brick (CB). Brick veneer is the most common residential construction type around Australia while cavity brick is still commonly used in WA.

The functional unit (FU) considered is one vertical square meter of an external load-bearing wall. Envelope walls have been designed to meet requirements of Australia's climate zones 4-6, in which around 70% of the population resides [16]. To meet Australia's National Construction Code 2016 (NCC) 'Deemed-to-Satisfy' Provisions, two options are available: a house may meet the required Energy Rating for a particular climate zone using house energy rating software or Elemental Provisions may be satisfied [17]. Building envelope construction types assessed in this study have been designed to meet Energy Efficiency Elemental Provisions. In climate zones 4-6, high mass materials (>220 kg/m^2) such as cavity brick and RE can be used without additional insulation so long as certain other requisites are met, e.g. glazing and shading requirements. If not high density, external walls must meet minimum R2.4 in climate zones 4 (hot dry summer, warm winter) and 5 (warm temperate) and R2.8 in climate zone 6 (mild temperate). For the purposes of this study, this is achieved using various thicknesses of glasswool insulation (GWI) with a density of 40 kg/m^3. Details of each envelope design are shown in Figure 1. Bricks were modelled as 110 mm commons, average of Midland Brick cored commons and Austral Bricks Standard 76.

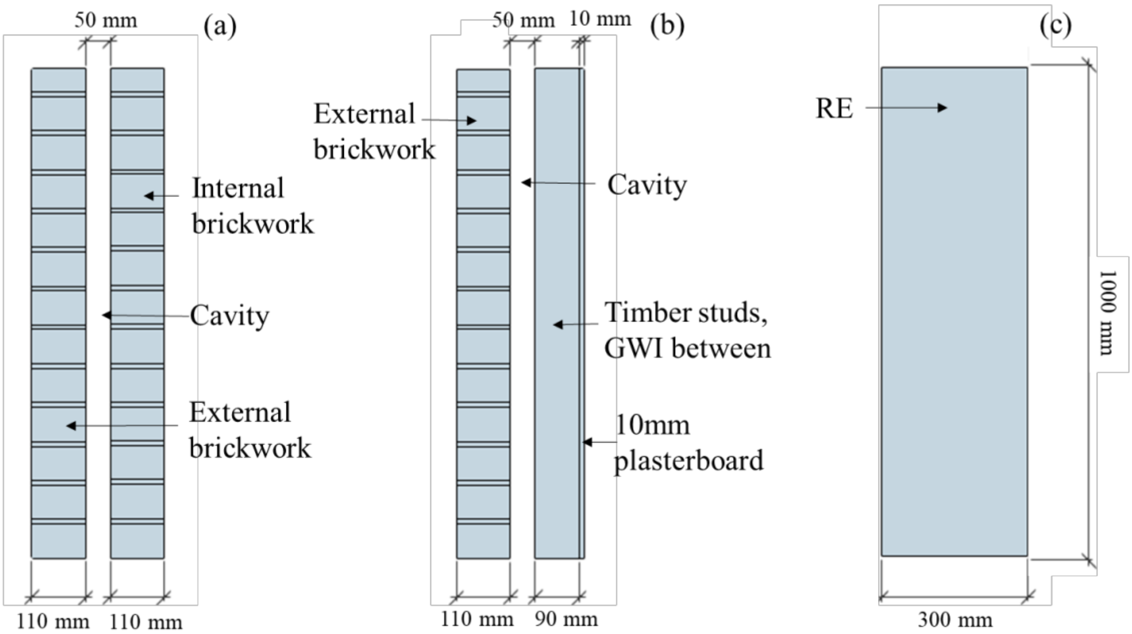

Figure 1: Cross-section of building envelope construction types; (a) cavity brick, (b) brick veneer, (c) rammed earth.

The boundary of the system studied is shown in Figure 2. Transport from plant to site has been excluded in the initial results as it is reasonably consistent regardless of material. A sensitivity study is conducted comparing different site locations. Construction energy has been excluded as it was found to negligible for RE in a previous study [18]. For consistency, brick veneer and cavity brick construction energies were also excluded. Operation stage was excluded in this assessment as thermal testing of the materials in question has not yet been completed.

The inventory is modelled based on EN 15804:2012+A1:2013 [15] which is predominantly an attributional approach. A cut-off system model is used meaning by-products were available burden-free at the primary production location. Transport and any processing required to prepare the by-product for the secondary material market is included. At end-of-life, the materials may be able to be recycled as aggregate however this stage has been excluded due to the uncertainty associated with long lifespan of a residential house, as the material properties at end of life are not known. Recycled content of materials has been included in the inputs to the model.

OpenLCA v1.7.2 software [19] using the AusLCI database v2.8 where possible [20] and Ecoinvent v3.4 where AusLCI data was unavailable [21] were used. Recycled brick and concrete were conservatively both included as recycled concrete aggregate. Brick's lower density would demand lower crushing energy. The environmental indicator category considered was global warming potential over 100 years (GWP100), developed by the Intergovernmental Panel for Climate Change [22]. This category measures emissions over a 100-year time period of any greenhouse gas, using CO_2 as an equivalence measure.

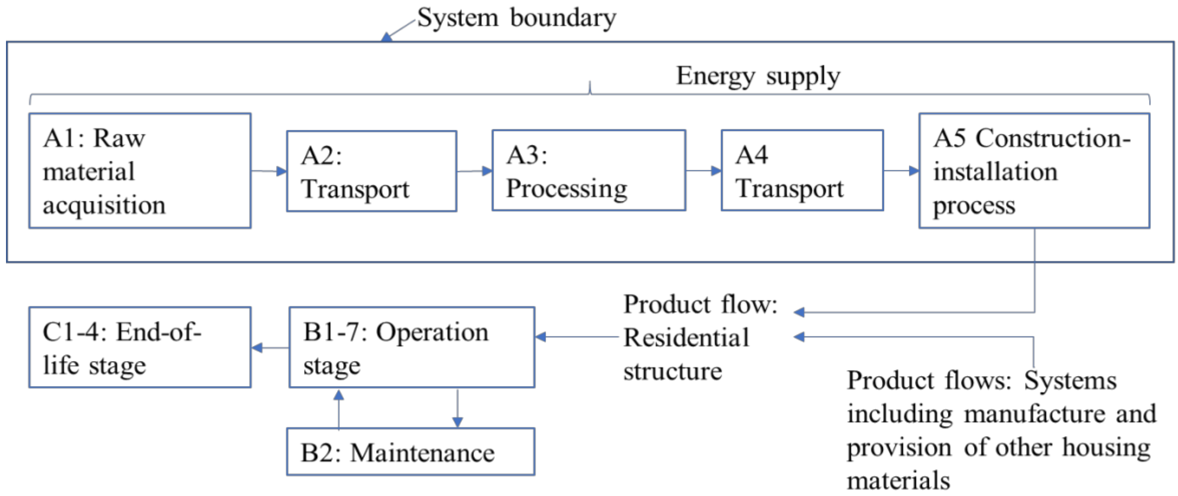

Figure 2: System boundary of RE LCA study, modules A1-5

3. Results and discussion

Figure 3 shows GWP100 (kg CO_{2eq}) for each material as a percentage of cavity brick emissions. These are a baseline measurement for each material/construction type: only required elements are included, e.g. bricks are unrendered/painted. Additional GWI required for brick veneer to meet R2.8 in climate zone 6 is shown separately to the GWI included to meet R2.4 in climate zones 4 and 5: the impact of additional insulation is minor compared to the total. For the three control materials, brick veneer, cavity brick and CL_C, the calcination process causes the vast majority of GHGE. For brick veneer and cavity brick, it is heating the kiln to fire the bricks that is responsible for GHGE whereas for cement production it is heating the kiln but also the inherent CO_2 released during clinker production, an intermediate product in production of cement:

$$CaCO_3 + \text{heat} \rightarrow CaO + CO_2 \text{ [23].} \qquad (1)$$

As calcination is not required for any of the components of RE mixes that include industrial by-products, this significant emission step is avoided. Inclusions for by-products were any processing required to render the by-product useable for its purpose as the secondary material, e.g. grinding of blast furnace slag, plus transport from the primary producer to a metropolitan storage location.

Just over 50% of CL_AA and RBC_AA emissions are directly related to NaOH production. Bricks used for residential construction are typically specified to have a characteristic compressive strength of 12 MPa. CL_C has been designed to match this strength requirement. However, the newly developed mixes currently have varied 28-day UCS strengths, as marked on the Figure 3 secondary axis: CL_AA and RBC_AA are both significantly stronger than required, averaging 19.8 MPa and 24.1 MPa respectively. While it is known that strengths achieved by CSRE are directly related to cement content [24], future work by the authors will determine if this same relationship applies to these mixes. Given the contribution of NaOH to overall GWP, it is nevertheless reasonable to assume that materials with a smaller proportion NaOH, will have lower environmental impacts.

Based on the current mix, CL_AA, replacing cement with NaOH and industrial by-products, GWP is 60% lower than cavity brick and 40% lower than brick veneer. For the control RE mix, CL_C, GWP is 37% lower than cavity brick but only 8% lower than brick veneer due to the high emissions associated with cement production. This highlights that RE does not necessarily have significantly lower environmental impacts than 'business-as-usual' construction types but that this is highly dependent on stabiliser selection.

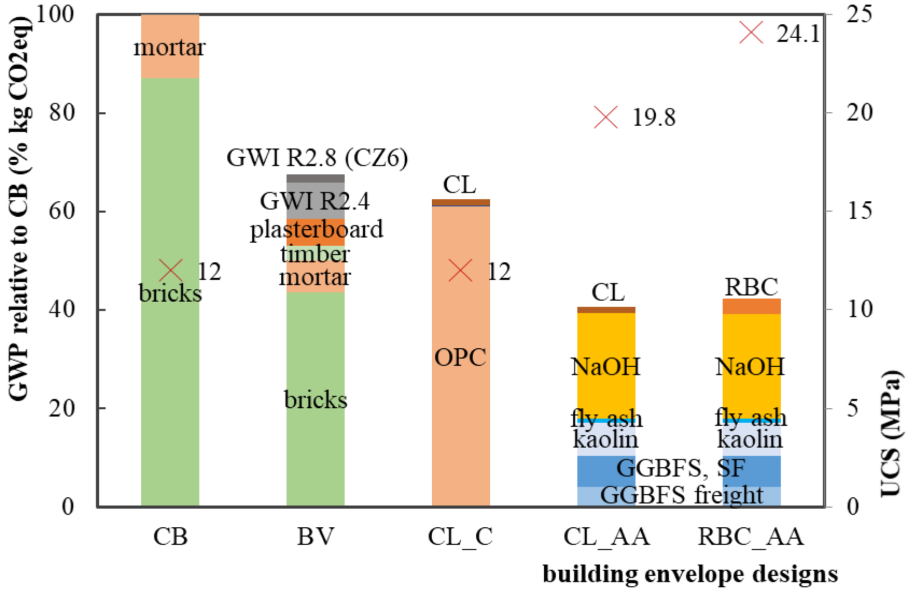

Figure 3: LCA results for environmental indicator category IPCC GWP for 1 m² of vertical external wall meeting insulation requirements for Australia's Climate Zones 4-6, system environment modules A1-3 only

Further to stabiliser selection, the base 'earth' component of a mix can also vary GWP of the final material. When comparing the two mixes CL_AA and RBC_AA, all components and proportions are identical other than base earth component. CL has low GWP as it is abundant around Perth, meaning transport distances are minimal, and it is a low density material so processing energy required is low. RBC, on the other hand, requires additional transport from demolition sites to processing locations, more varied sorting compared to the virgin CL, and additional processing energy as it is a higher density material. These factors result in a higher GWP for the fully recycled base earth compared to the virgin material for the same material mass. However, it should be noted that for the same mix proportions, RBC_AA has higher strength than CL_AA. Therefore, to achieve a given strength, less stabiliser should be required. As stabiliser contributes a much greater portion of the material's total GWP than earth, this will result in lower overall GWP. An additional benefit of using RBC over CL is its support of reusing waste materials to reduce use of virgin materials and reduce landfill, an OECD priority [3].

Another factor to consider in conducting LCA of RE is site location and transport requirements. Results of a sensitivity analysis addressing different transport requirements are shown in Figure 4. Two site locations are considered, 1) Perth metropolitan and 2) Kalgoorlie, a regional city 600km east of Perth. Two transport options are considered for Site 2:

i) all stabiliser materials transported from Perth, local material used as 'earth' component,
ii) all stabiliser and base earth materials transported from Perth.

It should be noted that, separate to these transport calculations, relevant freight to Perth metropolitan has already been included, e.g. fly ash includes 200 km transport in a 40T truck from coal plant location and GGBFS includes a portion of ship freight to account for imported material. GWP associated with material acquisition and production through to intermediate location in Perth metropolitan of RBC_AA materials are shown in Figure 4 to highlight impact of transport relative to total material impact.

Site 1 conservatively assumes a delivery location of 50 km in metropolitan Perth for all materials, based on location of material storage and processing locations around Perth. When stabiliser materials (NaOH and aluminosilicates) are transported from Perth to the site in Kalgoorlie, this adds 3.6 kg CO_{2eq} or 10% in the case of this mix for the FU of 1 m^2 vertical wall. If all materials, including base earth material, are transported from Perth, transport impacts increase significantly due to the mass of the earth component. In the case of RBC_AA, transport adds a further 60% on top of the material impacts considering a site within Perth. Local earth material in a regional location such as Kalgoorlie could include a local virgin material or local recycled materials so long as the location has the capacity to process the materials e.g. to crush recycled brick. Any local soil would require testing to establish whether it was appropriate to be used as a RE base. This potential to use local materials for the bulk of wall mass increases the benefit of these RE mixes relative to more standard building materials if components of these require transport to regional locations.

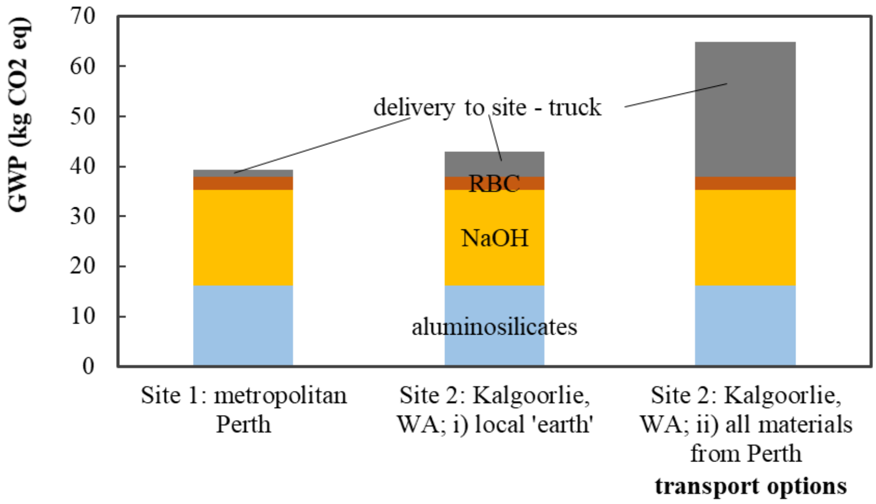

Figure 4: Varying site location and/or delivery requirements, mix: RBC_AA

4. Conclusions

The aim of this paper was to assess GWP of RE materials using LCA and determine whether use of these materials may provide a benefit over use of more common building materials. Results show that use of RE mixes stabilised with aluminosilicate by-products and NaOH would reduce GWP by 60% compared to cavity brick for the same unit of external wall and by 40% compared to brick veneer.

The newly developed alkaline activated RE mixes have a GWP 30-40% lower than the current most common RE variety in WA, CL_C, highlighting the benefits of using alternatives to cement in RE construction. Nevertheless, given the most prevalent construction type in Perth, WA is cavity brick, RE stabilised with cement is still a significantly better alternative in terms of reducing GHGE.

If the construction site is in a regional location, maintaining the benefit of using any RE mix is contingent on ability to use local materials, virgin or recycled, as the base 'earth' component. The high mass of base material required means GHGE emissions associated with long transport distances are high. Where possible, use of recycled materials as the base material has the benefit of supporting waste reuse, a current government and OECD priority.

Valuable further work would include thermal analyses of the mixes studied here as well as others to determine variability according to mix design, i.e. to what degree thermal properties are controlled by variables such as wall thickness and density rather than exact components and proportions. Thermal testing, i.e. determination of resistance to heat flow (R-value), would allow for comparison of GWP based on FU having identical R-values as well as wall designs meeting the current NCC requirements. Air quality tests of indoor environments created by these materials would also be beneficial. Lastly, analysis of materials at end-of-life would better enable understanding of capacity for reuse and/or recycling. This data could then be used for a more complete LCA of the full life cycle.

Acknowledgements
The authors thank Tim Grant of Lifecycles for having provided advice and assistance that was invaluable in completing the LCA. The authors wish to acknowledge Josh Galvin, Max Hoy, Joel Bonsel, Paul Shaw, Matt Noack and Jing Bong for their contributions to the laboratory work. Abstract. An efficient butt-joint bonding technology allows to build new types of timber structures. Under the name Timber Structures 3.0 a connection has been developed which connects timber elements with an end-grain to end-grain butt joint bonding. Therefore, it is now possible to build continuous, point supported flat slabs in cross laminated timber (CLT). Multiple CLT slabs are connected rigidly together and are only supported by columns. Some major challenges had to be solved in terms of bending strength of the glued connection and shear resistance of the part of the slab above the column. The research in both topics is successful and more projects were built in the last two years using this technology. Starting point was a real scale structure at ETH Zurich, followed by a working platform for a timber construction company and finally four three storey residential buildings. The research team is continuing to optimize the different elements of this innovative technology and will soon provide engineers with guidelines to design their own biaxial, point supported timber flat slabs.
